complete and is found immediately following the injury when often the nerve is sectioned or a portion of the nerve is destroyed. Injury may occur during the reduction of the fracture by faulty manipulation or unnecessary roughness, or in an attempt to control a struggling patient during incomplete anesthesia. Later during the repair of the bone, the nerve is sometimes involved in the callus, either by inclusion in it with secondary contraction, or by external pressure on the nerve trunk. Hyperesthesia or partial paralysis of motor or sensory function denotes pressure on the nerve trunk. At all times during the process of repair one must constantly be on the alert for these signs of involvement of the nerve and examinations of the arm to test its function should be carried out weekly. During the treatment of these cases prior to reduction, it is imperative to note whether there is or there is not a nerve involvement, and again if present or not, the fact should be determined immediately after the reduction. Prompt and proper recording of these findings will save one some of the tribulations that might follow, if the case goes to litigation.

If the musculospiral nerve is injured early, exploration within a period of 10 days to 3 weeks with suture or other treatment as indicated should be carried out. If the involvement is late, then exploration after the union is solid should be done.

Treatment The principles of reduction are the same as for any other bone, namely, to effect as early as possible an anatomical reposition of the parts. Here, because of non-weight bearing, shortening of an inch or so does not, as a rule, give rise to loss of function, but we feel that the nearer the perfect reduction, the earlier the union and the more perfect the function. This is often best accomplished by traction and countertraction, manipulation, and molding of the parts with the hand. The direction of traction on the distal fragment is made in the direction of the long axis of the proximal fragment with the distal fragment rotated to the same degree as the proximal one.

As has been stated, save for generalities, there is no set position for the upper fragment to assume. Many deformities and displacements are made worse by improper fixation and manipulation immediately after the accident, and during the period of transportation and hospital waiting prior to the taking of x-ray films. During this period in all suspected cases of these fractures, a Murray-Thomas (hinged Thomas) arm splint should be applied with fixation and traction through adhesive plaster and Spanish windlass, as outlined by the Committee on Fractures of the American College of Surgeons. With this fixa-

tion, patients can be readily transported with ease and comfort and certain assurance of not permitting greater displacement or deformity. Often by this primary method, a spontaneous reduction will take place. When properly applied, this splint also permits the examination for blood vessel and nerve complications and allows, within reason, the taking of x-ray films in two planes for diagnosis. If by these films or views one cannot satisfy himself as to the position of the fragments, then a second set of films (stereoscopic type) should be made. Many cases of fracture will show little or no displacement and in these cases we feel that fixation by the application of molded plaster, as will be described later, will suffice.

In the transverse or slightly oblique types of fracture with notching of the ends, manipulation under anesthesia often permits of a ready reduction. This is carried out on a fracture table with the fixed or portable fluoroscope. Certain deformities in certain individuals can be reduced without anesthesia, however, here failure is met with more often than success. The anesthesia is one of choice—novocain locally has its marked limitations; nerve blocking is difficult and not without danger; but we prefer general anesthesia. Ether was our choice until the past year when we have employed the intravenous solution of the barbiturate group with such satisfaction that it is now our preference.

With the study of the x-ray films, the various maneuvers necessary for reduction can be anticipated. This is carried out by flexing the elbow to a right angle, with a firm grasp of the forearm with one hand and the lower third of the arm with the other, while an assistant steadies the upper arm. This maneuver should be carried out in as gentle a manner as possible, so as to prevent further damage. It is our custom and belief that once the fracture is reduced it can best be maintained by the application of molded plaster splints. These should extend, one posteriorly from the level of the knuckles over the wrist, forearm, elbow, arm, and over the shoulder to the level of the scapular border, another anteriorly from the apex of the axillary fold forward to the midpalmar region. After setting of the plaster within 3 to 5 minutes, the entire splint can be supported by a sling. During this procedure the forearm is placed in the position of midpronation and supination, and often at times it is necessary to include or support this splint by the application of a shoulder spica with the plaster extending below the level of the costal margin, thus permitting the placing of the lower fragment and forearm in a necessary or desired position.

FRACTURES OF THE SHAFT OF THE HUMERUS

J HUBER WAGNER M D F A C S , Pittsburgh Pennsylvania

FRACTURES of the shaft of the humerus include all those fractures below the so called surgical neck, marked by the upper level of the insertion of the tendons of the pectoralis major and latissimus dorsi muscles, downward to the level of the supracondylar region or say 1 or 2 inches above the lower articular surface. All varieties of fractures may be found here, varying from the simple transverse, with or without displacement, to the oblique, longitudinal and comminuted types the fracture line extending from a short distance to the entire length of the shaft, with all degrees of displacement of one or more fragments including rotation, angulation and shortening from 1 to 6 inches.

All types of displacement common to fractures of the long bones are found here and no particular type is noted with any degree of frequency. However, in simple transverse fractures at certain levels muscular action at times determines the type of deformity and tends to certain displacements, for instance fractures of the upper third of the shaft above the insertion of the deltoid often present the upper fragment in an adducted position due to the action of the latissimus dorsi and pectoralis major muscles with the lower fragment abducted and overriding the upper because of some traction of the deltoid whereas below the level of the deltoid tendon insertion the upper fragment is abducted by this muscle and the lower fragment is adducted and overrides the upper, due to the action of the biceps triceps and other muscles. In certain types of fracture of the lower third of the shaft, the tendency is toward anterior angulation or displacement of the lower fragment, due to the action of the extensor group of muscles the brachialis brachioradialis and extensor carpi radialis longior.

The force causing the fracture is, we feel the primary and principle agent in determining the type of deformity. Especially is this true in the oblique and comminuted types with secondary displacements caused by improper handling improper splinting of the fragments with the action of the force of gravity on the distal fragment and finally by muscular action.

Causes External violence is the most usual

cause, however these fractures may be caused by direct muscular action. To this end in passing we cannot help but mention the spiral fracture that one occasionally sees resulting from athletic feats—wrestling or trials of strength. These are rare causes when compared with those of direct trauma.

Symptoms The symptoms of the fracture are classical. In this we may include the history of direct injury or accident followed by pain, loss of function, deformity, abnormal mobility and crepitus, and these lead to the final and modern aid in diagnosis, the making of an x ray film of the part. Often these fractures of the humerus are but part of the picture and are complicated or associated with fracture of the clavicle scapula, shoulder, elbow, ulna and radius. It is at these times in the treating of these cases, that the surgeon's skill and dexterity are taxed to capacity.

Complications Directly associated with the fracture are injuries to contiguous blood vessels and nerves. Any injury to the larger blood vessels is rare, especially the brachial artery, but if this vessel is severed or contused with secondary clotting, the pulse is absent. On the other hand if there is pressure of a fractured bone end against the vessel the pulse may be weak. Here one must constantly be on the watch, for generally speaking the greater the degree or severity of the fracture with associated soft part trauma the more apt is the liability of blood vessel involvement.

Nerve injury Because of location, the musculospiral (radial) nerve lends itself to injury. For at least one third of its course in the arm it is found lying in the groove which bears its name and is almost in immediate contact with the shaft of the humerus. It is in this particular location that the majority of the fractures of the shaft occur hence its apparent ready involvement in the trauma. However comparatively it is a rare complication and is variously estimated as occurring in from 4 to 8 per cent of cases. The symptoms of radial nerve injury vary from paresthesia over the sensory distribution in the forearm and dorsum of the hand and thumb to loss of supination, wrist drop and the loss of power of extension of the fingers and thumb. The involvement of this nerve whether immediate or late depends upon whether the paralysis of motion and sensation is

fixation by tap screws. This latter method has been the one of our choice and has been previously presented. Although this method shortens the bone an inch or so, we have never seen any actual loss of function from its use and union takes place in a shorter time than with grafting. In these cases, after proper preparation of the bone, we feel that the principles are the same as the treating of a new fracture and the main point after reduction is fixation. As in simple fractures, we do not count on the internal fixation alone, hence the molded splints are again applied and maintained for 8 to 12 weeks until union is firm.

Motion With the use of the arm splints, the patient is able to be up and about, but with the immobilization of so many joints, muscular atrophy takes place rapidly with the attendant fixation around the joints (peri-articular ad-

hesions). If this inactivity of the muscles persists the circulation diminishes while that of the bone increases. We feel that exercise of the muscles within the splints should be continued. To this end, we have the patient contract the muscles of the forearm by flexing and extending the fingers without force, and by contracting the muscles of the arm without motion. In this way a physiological balance of circulation is maintained and prevents atrophy of muscles and at the same time helps in forming bony union. Active mobilization of the part should not be attempted until union is firm.

There is little if any originality claimed in our methods as presented in this paper. The principles are those used in everyday practice, gleaned from the study of the work of our predecessors and by observation of our confrères.

In certain spiral and comminuted fractures by using the same procedure with prolonged traction or measured primary traction with mechanical aids, such as the Sutter traction apparatus and then manual traction, excellent reductions can be effected and the molded plaster splints applied.

Following the war we attempted the treatment in these cases of keeping the patient prone, with the use of the suspension and continuous traction and countertraction (both skin and skeletal), after the method of Blake and others. However, we found this not only distasteful to the patients, because of the necessary long hospitalization and concurrent expense but unsatisfactory because of the excessive care required in the necessary adjustments, non union occurring quite frequently due to the motion at the site of fracture. To give the impression that this method is now completely excluded, is wrong, as there are the exceptional cases with the attendant shock and other complications which not only permit but require this type of treatment.

In a sense, contradictory to what has been said before, i.e., that many fractures of the shaft despite position, if union is secured lead to good function we believe we should secure as nearly a normal position and alignment as possible. Often because of the interposition of soft parts and other factors—muscle contractions—closed reduction cannot be effected. In these cases we do not hesitate to reduce the fracture via the open method with internal fixation by the use of Sherman plates and screws. The technique is the same as has been advocated for fracture of the femur i.e. the non hand contact technique as advocated by Lane and improved by Sherman and others the details of which I shall omit.

The approach for the open reduction method is by the anterolateral or so called 'Henry' incision. The skin incision is made on a line with the longitudinal axis of the humerus lateral to the cephalic vein. The skin is blocked in the usual manner with towels by the use of the Michel clips and an incision is made through the deep fascia. The biceps is then reflected medially and an incision in the same plane is made through the brachialis anticus down through the periosteum reflecting the periosteum and muscles from the bone giving a neat exposure of the fragments. In this way there is no danger of injuring the radial nerve and as one approaches the lower third the nerve will be found in a groove between the brachialis and the brachial radial muscles. Again one might expose the bone by a posterior incision with reflection of the triceps after method used at the Massachusetts General Hospital.

During the operation, the elbow should be flexed to a right angle to remove the normal muscle tension. In the spiral short or long oblique types after reduction is accomplished fixation can be maintained by one or more transfixation Sherman tap screws. As a rule the longer the fracture line, the less the amount of transfixation necessary, or the fracture can often be held by a single screw properly placed, whereas with the short oblique lines and transverse fractures that are not notched and do not fix readily, bone plates with two or three screws to fix the plate above and below the line of fracture are used. These screws with plates when placed through the proximal cortex give enough fixation. It is unwise to count on internal fixation alone hence following the closure the molded plaster splints are applied and the patient is permitted to be up and about in 2 or 3 days.

Compound fractures are essentially the same as simple fractures save that the force is more severe and the soft part destruction is present to a greater degree. The treatment naturally entails more thought for the soft parts but as for the bone, it is the same as in a simple fracture. In the markedly comminuted fractures extension is carried out with fixation by the use of a plaster cast, whereas in those cases that permit fixation, such as a transverse and oblique fracture, the use of internal fixation is used. This is done at the same sitting as the debridement, and Carrel-Dakin technique is used in the treatment of the wound. Occasionally one has to treat these patients by the use of skeletal traction. Kirschner steel wire or ice tongs are applied with the patient recumbent. We have and prefer to use the body spica with fixation of the lower fragment in the molded plaster splint after transfixation by a Kirschner wire and proper traction. In this way windows can be left or later made in the plaster for treatment of the wound.

Ununited fractures of the shaft of the humerus are seen about as frequently as any other bone. The causes are many by theory such as the interposition of soft parts fracture through a nutrient artery lues, etc. but we feel the most important is the one of improper fixation and again we emphasize the necessity of proper splinting—internal and external—over a period of 8 to 10 weeks. When pseudo-arthritis or non union does occur, two methods of treatment are available. One—bone grafting using an autogenous inlay or onlay graft, transplanted from the tibia or the sliding onlay from the upper or lower fragment and fixation of the graft with tap screws and the other the so called 'step-cut' with

Specialism is a necessary outcome of the complexity of medicine. It is inevitable, and when it arises spontaneously as it should, it is advantageous. Each new specialism is the outcome of some particular need of the time; the existence of a field of work that has hitherto been neglected, the discovery of some new disease or theory of disease demanding intensive study, the need of an unusual technique or the use of delicate instruments, or the rarity of the condition to be studied, so that only by single minded application can a man hope to see enough cases to be familiar with its manifestations. Each is started by the vision and energy of a pioneer or group of pioneers and each will continue to live and grow so long as the need for it is a real one, and so long as the men who practice it are enthusiasts.

Some subjects return to the main body of surgery when the wave of discovery that lifted them from the common level is spent, others remain apart because they seem to be marked out by some convenient boundary of topography, age, or sex, or even by mere force of tradition. These last have advantages brought by all specialization, of intensive study and extensive experience, but they have their own dangers, particularly in the type of man they attract, and the amount of general surgical education which they demand as a preliminary. To found a new specialism requires ability, vision, courage, and a dogged tenacity, for these schisms are always bitterly opposed. It is the founding of a new land and it needs the spirit of a pilgrim father. But to enter one already explored, delimited, and settled, is indicative of the reverse qualities, the wish for a quiet life, freedom from competition, and a steady competence.

Is fracture work a specialty? The orthopedic surgeon will say that it is not a specialty in itself but a part of his own great specialism. I would hesitate to admit his claim without further examination and without at least a struggle. If orthopedics is the treatment of deformities, we say a fracture is not a deformity and never will be if properly treated. If orthopedics includes potential as well as declared deformities, it must eventually treat empyema and gonorrhea as potential causes of scoliosis and ankylosed joints. If it claims the whole locomotor apparatus as its province, it is demanding everything except the serous cavities and has become so vast a subject that specialists must arise within a specialism. Let us reiterate those conditions that demand specialization. Does the treatment of fractures demand a high degree of technical skill? Not skill but rather patience, conscience, and a determina-

tion to treat each case as an individual problem and to persevere with it until the result is as good as it can be. Does it deal with a pathology as yet imperfectly understood? It does not. Does it involve the use of delicate and complex instruments, of a meticulous technique which can be acquired only with difficulty and maintained at the adequate standard by constant practice? Again no. Are fractures so rare that it is necessary to group them in order that any man should see a sufficient number in a lifetime? Would that it were so. Is fracture treatment work that is at present badly done? With shame we must admit that this is the case, and in this admission lies the whole justification for the present demand that fractures should be segregated.

Are there any features that distinguish fracture work and indicate the form this segregation should take? There appear to be three.

First, fracture treatment is the most important branch of surgery, more important than that of the abdomen, far more so than neural or thoracic surgery, for it deals, not with disease, but with the disablement by trauma of a piece of mechanism hitherto perfect, and it should be possible to restore that perfection. In most surgery we have to drain, to modify, to excise, we can accept the nearly right as pretty good, and can share the blame with morbid processes. In fractures all the bits are there and if we put them together they will work again. We cannot in most cases view any loss of function with complacency, anything less than one hundred per cent is not good enough, but when we ask how this is to be done we can say only by hard work and ceaseless self criticism. There is no guaranteed road to success and the most diverse methods will produce good results in the hands of an enthusiast.

Second, fractures are urgent and they occur everywhere. The patient must be treated at once and he must as a rule be treated at or near the place where he fell. He cannot be saved up for the next visit of a traveling expert or transported to a central collecting station serving a large district. For this reason we need a large body of men throughout the country trained to handle fractures competently.

Third, fractures, resulting as they do from trauma, do not necessarily occur as isolated lesions. They often accompany some graver injury such as a cerebral laceration, a ruptured spleen, or a tear of the bladder, conditions demanding knowledge or technique foreign to that of the bone specialist. The training of the man who has to deal with traumatic surgery, to which fractures belong rather than to orthopedics, cannot be too

THE PLACE OF THE FRACTURE SERVICE IN A GENERAL HOSPITAL

W H OGILVIE M A, M Ch, M D (Ox) F R C S (Eng) London England

I AM deeply appreciative of the honor you have conferred upon me in allowing me to speak at the Fracture Symposium of your College. Coming to this conference as an outsider, a visitor to your country for the first time, a surgeon with a lifelong interest in fractures who is yet outside the ranks of orthopedists I feel bound to consider the more general aspects of the problem, particularly that which is concerning us very much at the present time in Britain, the organization of new fracture services.

I had the good fortune to be one of two representatives of general surgery on a committee of the British Medical Association which was appointed in 1935 to consider every aspect of the fracture question as it concerned Britain, and which presented a report to our Government that some of you may have read. The facts which that report brought to light have stirred both medical and lay opinion in our country and have led to a profound discontent with the existing state of things, and a determination to improve it. We may look upon discontent as the mother of progress, but we must remember that she begets change alone and that change is progress not because it brings something new but only when it brings something better.

The facts which were placed before this committee emphasized in a most remarkable manner the difference that lies between good and bad treatment of fractures. We all knew of course that correct treatment will produce better results than incorrect. We were familiar with some excellent series in particular fractures. But I am certain that very few of us were aware till we saw it in the cold logic of figures running into many hundreds and observations spread over many years, of the immense difference that lay between the series representing patients treated in regularly organized services under the control of experts, and those collected from scattered sources and treated by haphazard methods. These analyses did not merely show the contrast between perfect and imperfect anatomical reconstruction between complete and partial restoration

of function: they pointed to a great difference in the two series in the average time elapsed before the patient returns to any kind of work, and a marked divergence in the proportion of those permanently disabled after fractures at any particular site. They provided an estimate of the enormous financial loss that is sustained yearly by insurance companies and by industry as a whole, as a result of partial or permanent disablement that might have been avoided. They emphasized the tragic personal factor of the psychological wreck of fine workmen.

Medical and lay opinion in England is determined largely as the result of the interest awakened by this report, that the treatment of fractures must be put on a satisfactory basis throughout the country and not alone in certain areas. But there is a perfectly definite cleavage between those who advocate the very large clinic under purely orthopedic management designed to deal with all the fractures of a town or district, and those who would organize fracture treatment on the basis of the small unit incorporated in the emergency service of the hospital and employing both general and orthopedic surgeons. We already have representatives of each type and have studied the two systems at work in other countries. The best results we encountered, those given in our report to suggest a standard for emulation were almost necessarily derived from the big clinics, dealing as they do with large numbers carefully recorded and analyzed. The smaller fracture teams which are attached to the accident services in many of our teaching hospitals have no such figures but enquiry suggests that their results are equal to the best. The bad cases quoted for comparison were provided by surgeons or companies dealing with the legal aspects of compensation, and represent a collection picked from many sources for their very badness: the outcome of ignorant treatment or no treatment at all.

This question of the relative value of large or small clinics in fracture work that we are trying to settle is one of some importance. It is not only a matter of the place of specialism in surgery but of the particular demands of the fracture problem and the way they should be met to bring the greatest benefit to our injured fellow countrymen.

FUNCTIONAL DISABILITIES AFTER SIMPLE FRACTURE

With Special Reference to the Importance of Bone Atrophy in the Prolongation of Disability

FRASER B. GURD, M.D., F.R.C.S. (Can.), F.A.C.S., Montreal, Canada

WHEN the Committee of the College asked me to take part in the fracture symposium, and to present a contribution upon "Functional Disabilities after Simple Fracture," it soon became evident that it was not quite clear just what the title might be considered to indicate. That disabilities persist following simple fractures, and that such disabilities may last for a longer or shorter time, is, of course, axiomatic, that they occur in consequence of anatomic abnormalities, such as shortening, angulation, and rotation deformities and, also, that they follow in consequence of non-union, and of fixation of tendons in the neighborhood of the healing bone, is generally recognized. That in other cases patients remain disabled for a longer or shorter time, although objectively the reason for such prolongation of disability is not easily seen, is less generally appreciated. In consequence, I believe, on the one hand, innocent persons are accused of malingering and, on the other hand, suitable treatment is withheld.

The problem which I propose to consider is why, in a certain proportion of cases, patients whose original injury was not complicated by serious damage to structures other than bone, in which adequate reposition of bone fragments has been obtained, and in which bony union has occurred, nevertheless suffer for a longer or shorter period disabilities which may interfere with their return to their usual vocations. Although it is true that in a small proportion of patients functional disabilities in the sense of hysterical manifestations are exhibited, and although in a somewhat larger percentage of cases a type of disability for which the French (Brouardel) have introduced the term *sinistrose* occurs, it is not my intention to do more than refer to these problems.

The most frequent cause for the persistence or prolongation of disability in the type of case which I have indicated is, I believe, intimately associated with decalcification, osteoporosis, or

atrophy of the bones distal to the injured part, that is to say, the bones of the foot or hand in the case of injuries to the leg and forearm, respectively.

Since the publication in 1926 of a small book by Leriche and Policard in which these authors state their experiments upon and their conclusions regarding the physiology of bone, a number of authors have made contributions to the subject. I refer especially to the contributions of Watson Jones and Roberts, Key, and, more particularly, Greig of Edinburgh. King of Australia disagrees with reference to the relationship of hyperemia to decalcification but, in my opinion, somewhat weakens his case by agreeing that the two phenomena are concomitant.

The normal course of events following bone injury is that on the one hand new blood vessels are formed and an increased blood circulation through the part is exhibited and, on the other hand, decalcification of the bone ends in the neighborhood of the fracture takes place. It would appear evident that the latter phenomenon is exhibited in order to make available at the site of the injury calcium in a form which can be readily utilized in the development of new bone so that repair may be accomplished. As a rule, with the gradual and somewhat rapid maturation of the new connective tissue elements, obliteration of many, or most, of the new blood vessels takes place so that, at first, further decalcification is arrested and, second, the deposition of calcium in the new bone matrix is accelerated.

It does not come within the purview of this contribution to enter into a discussion of the physiochemical problem operative in the deposition of calcium in mesenchymatous tissues in the production of bone. The importance of hydrogen ion tension of the tissue fluids and of the phosphatase concentration in the tissues generally and locally, presents problems which are not, I believe, imperative to the discussion of the question at present under our consideration, nor is the writer competent to express views upon these subjects. It is, however, of importance that we consider the effects of normal, inadequate, and

wide or too extensive. In some favored centers such work may be undertaken by a team of experts in collaboration. Such a course implies a sharing of responsibility that is not always in the best interests of the patient, and it sets a standard clearly impossible of attainment in country districts.

It appears then that the treatment of fractures demands segregation more because of its importance than because of its difficulty. It should be kept entirely in the hands of those who have the time to devote to it, the energy to study it, the enthusiasm to make themselves personally responsible for its every detail. These requirements fulfilled, the more surgeons who take part in the work, the better. Segregation is certainly necessary but segregation need not imply undue specialization. It demands the grouping of fractures in one department, the unification of all those parts of a fracture service that will gain by centralization but it can allow a very wide distribution of personal responsibility.

In any hospital, possibly in many towns of moderate size, it will tend to increased efficiency to have all the executive services together, that is the roentgenographic and splint departments, the operating and plaster rooms, the secretarial and recording offices and it is equally important that the cases should all be in one group of specially constructed fracture wards and under the care of a common resident staff, nurses, sisters, and junior medical officers. But with such unification of executive control and grouping of material resources, I would plead for individual services of moderate size working side by side.

The upper limit of size in a clinic, in my opinion is that number for which the chief can be personally responsible without delegation. I have not in mind the assistance given by juniors attached for short periods for purposes of instruction, but the work of more experienced men who are permanent parts of the service. Once a size is reached where part of the work must be delegated either the assistant is given so much liberty that his unit is a separate one in all but name, or, more probably, he works under rules of procedure laid down by his chief, and treatment becomes a matter of routine rather than of individual initiative. It is very doubtful whether this apostolic relationship is good either for master or disciple. The one

acquires a stultifying sense of superiority free from comparison criticized by none and eventually unable even to criticize himself. The other learns a monastic acquiescence. The world knows no bigot like the yes man whose chief is on vacation, no orthodoxy so impenetrable as that of the pupil who steps into the shoes of the Great Master after years of subservience. It is indeed a remarkable fact that in those countries where a surgeon may succeed to a chair only where he has grown grey and cerebroclerotic in apprenticeship, the technique of the fathers is visited on the children to the third and fourth generations.

The subject of fractures is too important for us to neglect any step that will secure advance to forbid its training to any to whom it might be open and that is what the really large clinic does. It discourages advance by abolishing competition. It limits the number of men who receive the training of responsibility for excess to one means starvation to others.

Fracture clinics must arise in every large center, with sufficient out patient department, secretarial staff and grouped bed accommodation to deal with all the needs of fractures in that area. Unity will be assured by continuity in the senior nursing and resident staff. In such a unit the surgeon specially trained for fracture treatment, whether he be a general surgeon or orthopedist, will have the most important part, for he will be the pace maker, the touchstone by which the work of the rest is judged, but other surgeons interested or expert in the practice of traumatic surgery should also take their share, even those who profess an interest may be allowed to do so at the beginning for under such conditions of healthy rivalry the half hearted and half interested will soon drop out. No man is so thick skinned that he can see his own work compared unfavorably with that of his colleagues on the undisputable evidence of roentgenograms and function without either striving to do it better or giving it up. And the competition among those whose interest is genuine will tend to mutual stimulation to the comparison of results obtained by contrasting means to the exchange of views gained in travel and to a gradual rise in the level of fracture treatment in that center and in the country as a whole.

FUNCTIONAL DISABILITIES AFTER SIMPLE FRACTURE

With Special Reference to the Importance of Bone Atrophy in the Prolongation of Disability

FRASER B. GURD, M D, F R C S. (Can), F.A C S, Montreal, Canada

WHEN the Committee of the College asked me to take part in the fracture symposium, and to present a contribution upon "Functional Disabilities after Simple Fracture," it soon became evident that it was not quite clear just what the title might be considered to indicate. That disabilities persist following simple fractures, and that such disabilities may last for a longer or shorter time, is, of course, axiomatic, that they occur in consequence of anatomic abnormalities, such as shortening, angulation, and rotation deformities and, also, that they follow in consequence of non-union, and of fixation of tendons in the neighborhood of the healing bone, is generally recognized. That in other cases patients remain disabled for a longer or shorter time, although objectively the reason for such prolongation of disability is not easily seen, is less generally appreciated. In consequence, I believe, on the one hand, innocent persons are accused of malingering and, on the other hand, suitable treatment is withheld.

The problem which I propose to consider is why, in a certain proportion of cases, patients whose original injury was not complicated by serious damage to structures other than bone, in which adequate reposition of bone fragments has been obtained, and in which bony union has occurred, nevertheless suffer for a longer or shorter period disabilities which may interfere with their return to their usual vocations. Although it is true that in a small proportion of patients functional disabilities in the sense of hysteric manifestations are exhibited, and although in a somewhat larger percentage of cases a type of disability for which the French (Brouardel) have introduced the term *smistrose* occurs, it is not my intention to do more than refer to these problems.

The most frequent cause for the persistence or prolongation of disability in the type of case which I have indicated is, I believe, intimately associated with decalcification, osteoporosis, or

atrophy of the bones distal to the injured part; that is to say, the bones of the foot or hand in the case of injuries to the leg and forearm, respectively.

Since the publication in 1926 of a small book by Lenche and Policard in which these authors state their experiments upon and their conclusions regarding the physiology of bone, a number of authors have made contributions to the subject. I refer especially to the contributions of Watson Jones and Roberts, Key, and, more particularly, Greig of Edinburgh. King of Australia disagrees with reference to the relationship of hyperemia to decalcification but, in my opinion, somewhat weakens his case by agreeing that the two phenomena are concomitant.

The normal course of events following bone injury is that on the one hand new blood vessels are formed and an increased blood circulation through the part is exhibited and, on the other hand, decalcification of the bone ends in the neighborhood of the fracture takes place. It would appear evident that the latter phenomenon is exhibited in order to make available at the site of the injury calcium in a form which can be readily utilized in the development of new bone so that repair may be accomplished. As a rule, with the gradual and somewhat rapid maturation of the new connective tissue elements, obliteration of many, or most, of the new blood vessels takes place so that, at first, further decalcification is arrested and, second, the deposition of calcium in the new bone matrix is accelerated.

It does not come within the purview of this contribution to enter into a discussion of the physiochemical problem operative in the deposition of calcium in mesenchymatous tissues in the production of bone. The importance of hydrogen tension of the tissue fluids and of the phosphatase concentration in the tissues generally and locally, presents problems which are not, I believe, imperative to the discussion of the question at present under our consideration, nor is the writer competent to express views upon these subjects. It is, however, of importance that we consider the effects of normal, inadequate, and

From the Montreal General Hospital—McGill University.
Presented in the Symposium on Fractures, before the Clinical Congress of the American College of Surgeons, Chicago October 25-29, 1937.

excessive blood supply upon the maintenance, excessive deposit, and absorption of calcium in tissues, such as bone, of which calcium is a normal constituent. Sufficient evidence has been forth coming during the past few years to prove that bone, if subjected to an inadequate blood supply, will become more dense in consequence of an increase in the deposit of calcium. Even more definitely proved is it, I believe, that hyperemia or excessive blood supply is followed by osteoporosis or bone calcium absorption or resorption.

The pathological and biochemical observations which have been discussed, and which are of clinical importance, have been summarized by Watson Jones and Roberts. They state their conclusions the following way:

There is normally a balance between the calcium content and the vascularity of mesenchymatous tissues (which is probably associated with phosphatase activity)

In the case of bone —

Normal circulation	—Normal calcification
Increased blood supply	—Decalcification
Decreased blood supply	—Increased calcification
Blood supply cut off	—Unchanged calcification

If, in consequence of repeated attempts at reduction or of inadequate fixation stimulation of hyperemia is prolonged, the process of halisteresis is not arrested and gradually, although in some cases comparatively rapidly, as in acute bone atrophy such as has been previously described by the author (3, 5), and by others (1, 10) continued decalcification of bones distal to the site of the fracture occurs.

Although in the unusual case of acute bone atrophy it is perhaps comparatively easy to explain why and how hyperemia and consequent rarefaction develops, it is a fact that in a comparatively large proportion of fractures more or less atrophy of the bones distal to the site of the fracture occurs. It is to this phenomenon that the expression disuse atrophy has been applied. I wish to suggest as an explanation for such cases that if a limb receives a normal blood supply and at the same time does not function, there exists for all practical purposes a nimity of circulation.

Normal function with normal blood supply	Less than normal function with normal blood supply
—adequate circulation	—relative hyperemia

It will be noted that the foregoing equations attempt a simple explanation for what has been commonly described as the atrophy of disuse, since it would appear that when a bone receives more than an adequate blood supply, decalcification is inevitable.

In the present contribution I wish to urge that whereas in acute bone atrophy of the Sudeck type the clinical signs are clear and the disability in so far as the limb involved is concerned is absolute, there nevertheless is frequently exhibited a degree of atrophy which, although not characterized by the same impressive clinical appearance, is important in prolonging disability.

At a meeting of the Orthopedic Section of the American and Canadian Medical Associations at Atlantic City in June, 1935, I made the following statements: 'Although in consequence of the ease with which the condition is demonstrated by means of roentgenographic examination, the osteoporotic lesion in the bone is most easily identified it should, I believe, be borne in mind that the bony change is but one proof of acute atrophy of other structures. Particularly, I believe, the atrophic changes in the ligaments and their attachments about the joints and in the cartilage covering the ends of the bones in the articulations deserve special attention in an effort to elucidate the problems of cause, prevention and cure of acute bone atrophy.' I wish to extend this thesis so that it may apply to the less marked and clinically less impressive type of bone atrophy such as commonly occurs, and to which the phrase disuse atrophy has been hitherto applied.

The explanation for disability in the presence of decalcification of the bones of the foot and hand respectively is due, I believe, to the fact that when the bones become softened, the attachment of ligamentous and tendinous structures becomes insecure. The result of such insecurity is that when strain in consequence of either weight bearing as in the case of the ligaments and tendons of the foot, or of tendon pull and, to a lesser extent, ligamentous strain in the case of the wrist and hand, is exerted, a tendency toward, or actual detachment of either ligament or tendon as the case may be, from the bone to which it should be securely fixed, takes place.

In our laboratory at The Montreal General Hospital the observations of Dr. Joseph Pritchard, who has for a number of years carried on an investigation into the nature and origin of bone, cartilage, and tendon tumors, have been successful in proving I believe that the usual conception with regard to tendons and ligamentous structures, that they have their origin in and consequently as it were, they belong to the muscles is wrong. Dr. Pritchard's observations prove I believe that ligaments and tendons do, in fact, arise from the osteoblastema and consequently throughout the lifetime of the individual are a part of the bone (Fig. 1).

Fig 1 Photomicrographs, low and high magnification, from Dr J E Pritchard's collection showing osteoblastema forming bone on the one side and tendon on the other

These photographs support, we believe, Dr Pritchard's hypothesis that tendons and ligaments having the same origin as bone take part in the same regressive changes

When, as the result of trauma, these structures are injured, they exhibit a tendency to revert to the primitive osteoblastematous form, even to the extent of becoming myxomatous. It may, therefore, be assumed that when roentgenographic examination proves bone atrophy to have taken place, not only have the attachments of the tendons and ligaments become insecure but that, in addition, the latter structures have themselves become less stable.

The clinical diagnosis of acute bone atrophy can be made on a basis of typical signs and symptoms. Comparatively soon after an injury which is usually trivial and is commonly in the neighborhood of the hand or foot, the extremity rather suddenly becomes swollen and painful, particularly upon movement. The skin loses its normal markings and becomes glazed in appearance and discoloration of a dusky red is seen. The joints become stiff and movements are exquisitely painful.

With absolute rest, particularly if dispersion of the interstitial edema is at the same time obtained, relief from pain follows.

Roentgenographic examination made within a few days of the onset of the clinical phenomena just described shows characteristic patchy areas of almost complete decalcification of the bones. This is most marked in the small bones of the wrist or tarsus and in the extremities of the metatarsal or metacarpal bones and the phalanges. As the lesion progresses, the rarefaction becomes more complete in so far as the small bones and the cancellous tissues of the long bones are con-

cerned, so that the patchy appearance is lost, and marked rarefaction in the shafts of the long bones also becomes evident. This is the chronic, second stage.

The view which I wish to support at the present time is that, although in numerous cases in which the hyperemia stimulated is less marked and the objective clinical manifestations are not impressive, nevertheless, in so far as the ultimate bone changes are concerned, the rarefactive process may progress sufficiently to render the attachments of ligaments and tendons insecure. In other words, I am of the opinion that it is possible for the condition, which has been previously referred to as the chronic stage of bone atrophy, to be reached without the acute stage having been noted.

The change in the bone which is brought about by hyperemia, and which is recognized most easily by radiological examination, is, I believe, characterized by a reversion of the osseous structures to a more primitive form (osteoblastema).

Since the cartilage covering the bone ends, the ligamentous structures, and the tendons attached to the bones, has, in fact, the same embryologic origin, it is to be expected that similar reversion changes should occur in these structures.

Owing to the fact that operative interference even for the purposes of obtaining tissue for biopsy is not justified or indicated in the great majority of cases in which localized post-traumatic osteoporosis is present, no one has hitherto been in a position to make positive statements with regard to the actual changes which are commonly present

Fig 2 H H Sprained ankle in December 1936 Foot was placed in dangling padded plaster for 5 months a Normal foot for comparison b marked hallux valgus July 1937 c recalcification August 18 1937 following active movements and weight bearing with crutches

In consequence of a diagnosis of tuberculous arthritis having been made in connection with a recent case, it was deemed advisable by Dr James Shannon, under whose care the patient was being treated, to remove a small portion of the anterior border of the tibia at the ankle joint together with a small amount of attached capsule. Histological examination of the tissues so obtained proved useful, in the first place because it proved the absence of tuberculosis and in the second place is of especial interest to us in that evidence of reversion of both bone and ligamentous tissue to an embryonal type is shown by the sections

H H No 280637 Age 12 years Injury was a twisted ankle while skating in December 1936 Patient walked on painful ankle for 1 month Doctor diagnosed tuberculosis of ankle. Limb was placed in padded plaster dangling for 5 months

First seen by us July 1937 The foot was somewhat swollen and tender X ray examination was made and marked diffuse osteoporosis was noted Patient was discharged from hospital to return in 1 month In the meantime walked on ankle using crutches Examination August 23 showed slight diffused swelling about foot but no tenderness

Limitation of movements of the foot and ankle joint still present though improved 1000 old tuberculin examination negative X ray examination showed recalcification progressing

September 3 biopsy of left ankle September 14 wound was clear sutures were removed Patient continued to exercise foot and leg in bed until September 20 when he was allowed up Further X ray examination was made September 20 He was discharged from hospital September 28 Recent October 17 1937 report states that he is free from symptoms and disability (Fig 2 a b c and Fig 3)

Over a period of many years the author has had the opportunity of examining a comparatively large number of problem cases These have been referred either by insurance companies, Workmen's Compensation Commissions or individuals who believed that adequate consideration of their disabilities had not been forthcoming In a very large proportion of such cases the differences of opinion existing between the injured person and the body financially responsible have been due to the fact that although no obvious cause of disability had been noted upon examination, the victim has, nevertheless found it difficult, or impossible to carry on with his work In by far the greater proportion of such cases the cause of disability has been found to be due to bone atrophy

The following case exemplifies I believe the major thesis of this contribution

Mr L T aged 35 years was injured October 13 1936 as the result of an accident in a mining shaft He was treated by Dr J L McArthur of Noranda Quebec for a fracture of both bones of the leg at the junction of the middle with the lower third complicated by a small compound injury (infection did not occur)

He was first seen by me January 20 1937 at which time union of the bones had been found to have progressed satisfactorily the wound was substantially healed X ray examination made February 23 that is a little more than 4 months from the date of the accident during most of which time the patient had been treated in padded plaster of Paris showed the bones at the site of fracture to be in perfect position The patient was however unable to bear any weight on account of pain in the foot Later x ray examination of the foot showed marked hallux valgus as shown in the illustration

Fig 3 Photomicrographs of fragment of ligament and bone removed from anterior border of the ankle-joint, in case of H H Left, Low power, shows regressive changes in

ligamentous tissue, right, high power, shows large mononuclear cells and localized area of lymphoid and plasma cells infiltration

An unpadded walking plaster including the knee (of the Gurd (4) type) was applied, and by May 26 recalcification of the bones of the foot was proved to have taken place by x-ray examination, and weight bearing without plaster was commenced. By the end of June, although the limb was still somewhat weak, the man was able to return to somewhat protected work (Fig 4)

The results of treatment appear to prove that the process of both acute and chronic bone atrophy is reversible, the length of time required to bring about clinical cure is likely to be prolonged for from 6 months to an even longer period

With reference to treatment, I believe that the most important memorandum is that pain should be avoided and, more particularly, that anything in the nature of forcible manipulation, either with or without an anesthetic, should be excluded

"In the case of the upper extremity, if further insult to the tissues is avoided the course is toward repair. The patient should be warned that no painful movements of any sort should be undertaken. I have employed both snugly fitting, unpadded plaster casts and physiotherapeutic measures, especially hot bathing¹ at home. In the case of the lower extremity, I am convinced that the unpadded walking plaster cast, which is applied after absolutely all interstitial edema has been disposed of, and to which a felt heel has been added, is the method of choice. If care is applied to remodel the foot, particularly with reference to

overcoming pronation and flattening of both arches, and if the patient walks sufficiently, the results are satisfactory."

Although early active exercise has been, and is, successfully employed by but a small number of surgeons, in general I am convinced that absolute fixation of the fracture with functional activity of the extremity induced without movement of the joints in juxtaposition to the fracture is both more easily and more safely carried out.

It must be clearly understood that massage when employed in the treatment of fractures does not include passive movement. Massage should be used, I believe, only for the effect upon the blood supply to the limb. Since, in the majority of cases in which massage would seem to be indicated, the local blood supply is excessive, the

Fig 4 L T Fracture of both bones of the leg, October 13, 1936. Roentgenogram, February 22, 1937, shows bone atrophy of all bones of the foot. Left, soundly healed fracture line, right, halstheresis of bones of foot

¹The application of heat, we believe, is primarily useful since it increases the local metabolic processes and consequently tends to render the blood circulation in the part inadequate and so to stimulate recalcification

Fig 2 H H Sprained ankle in December 1936 Foot was placed in dangling padded plaster for 5 months a Normal foot for comparison b marked halisteresis July 1937 c recalcification August 18 1937 following active movements and weight bearing with crutches

TWO-PLANE DIRECTION FINDER FOR NAILING FRACTURES OF NECK OF FEMUR

GILSON COLBY ENGEL, M.D., F.A.C.S., and HANS MAY, M.D., Philadelphia, Pennsylvania

WHEN Dr. Hans May and I, working on the service of Dr. George P. Muller at the Lankenau Hospital, began nailing fractures of the femur after the method of Smith-Petersen or Watson-Jones, several things impressed us that called for improvement: first, the difficulty in getting two-plane direction for the nail in its course through the neck of the femur, second, the extensive incision, the cutting of muscles which involved bed immobilization for these elderly patients, third, the shock in these patients from a prolonged extensive operation, and last, loss of function or poor return of function due to long immobilization.

We began to search for a means to correct these bad features. The thought struck us that if we could have a perfect two-plane direction finder we could work through a small incision extra-articularly using the guiding wire after Johansson to thread our nail upon.

From the Lankenau Hospital, Service of Dr. George P. Muller
Presented in the Fracture Symposium, before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937

With this in mind we got a clue from Kuent-scher, of the University of Kiel, who had utilized an aluminum plate with metal lines consisting of steel which would stand out under the x-ray. Using this idea of the lines and two different types of metal, we planned a two-plane direction finder which would give perfect two-plane position and which would contain tubes through which the Kirschner wire could be fed.

The methods previously reported if simple were grossly inadequate for accuracy; if they were accurate they were too complicated and involved complicated technique. We, therefore, realized that any instrument to be worth while must contain two features—simplicity and accuracy. This was always kept in mind.

By means of the direction finder which we received only about 3 weeks ago and which we have used on 2 patients, 73 and 76 years of age, we can do the whole operation through a small incision and can complete the operation in 20 minutes. The incision is made only so large that the impactor, used at the end of the opera-

Fig 1. Front view of the two-plane direction finder with pins for fastening.

effect of massage should be to stimulate the muscles to activity so that the available blood supply will be relatively exhausted. Under no circumstances whatever should massage cause even the slightest amount of pain.

Although forcible manipulation to re-establish joint movement may very occasionally serve a useful purpose, the author is of the opinion that, in general, the harm done by such manipulation enormously outweighs the usefulness obtained.

SUMMARY

The author brings forward the point of view that one of the most common causes for prolongation of functional disability following simple fractures is due to bone atrophy associated as it is with regressive changes in tendons and ligaments. He is of the opinion that such atrophy is the result of hyperemia or a diminution of blood supply to the part.

The chief cause for persistence of hyperemia in the injured limb is repeated or continued irritation at or about the site of fracture.

The two main causes for continued irritation appeared to be operative:

1. Inadequate fixation, i.e. (a) application of padding which shifts its position and permits movement with consequent stimuli (b) a dangling limb.

2. Too short a period of absolute fixation so that pain stimuli become operative after removal of support and attempted function of the unprotected member.

The author has attempted to establish as his major thesis in the prevention of functional disabilities following simple fracture the principles of sufficiently long fixation together with the establishment of function as completely and at as

early a date as possible while the fracture line and joints in proximity remain at rest.

a. In the case of the lower extremities, the major function is weight bearing; therefore protected weight bearing should be accomplished with as few days' delay as possible.

b. In the case of the upper extremities, the major function is delicacy of movement which in turn depends upon joint and tendon function, particularly of the fingers and thumb. Absolute fixation, therefore of the fracture area with as great freedom as possible of the fingers is the *desideratum par excellence*.

Fig 8

neck of the femur after reduction and insertion of the Smith-Petersen nail

Fig 9 Lateral view of same case as in Figure 8

Fig 6 The Smith-Petersen nail is in place and the impactor is screwed onto the head of the nail. The neck impactor is set up against the lateral cortex of the femur so that a blow by hammer on the cap will impact nail and neck at the same time

There is practically no bleeding from this incision. The apex of Plate A is introduced into the incision with the plane parallel to the shaft of the femur pointing just a little upward into the notch formed by the junction of the shaft with the lower border of the great trochanter. Its pin is then inserted and driven into the cortex of the bone fixing Plate A in position. An anteroposterior x-ray plate is then

Fig 9

Fig 2 Assembled instrument with fixing pins in place

tion, can be inserted (2 inches). The patient is allowed to move his leg at once and is up in a chair 48 hours after operation.

The instrument is composed of two plates made of aluminum in sector shape (Fig 1). The one plate we designate as Plate A, the other as Plate B. Plate A has rows of steel dots converging to the apex. Through the center is a hole in the long axis through which a pin is placed to fix it to the femur. Plate B is similar in shape, with a slot passing through its center in the long axis almost to the circumference. This slot which takes Plate A when the two plates are at right angles to each other is reinforced on either side and these reinforcing strips have holes through them in the long axis to take two pins to fix Plate B in the femur. This plate also has converging rows of dots toward the apex. In the long axis of this plate are tubes underlying the rows of dots which will take a Kirschner wire.

Fig 3 Anteroposterior view of femur with Plate A in position. The arrow indicates the line of dots which are in line with the axis of the neck of the femur.

As to the method of use of this direction finder, the patient is first given spinal anesthesia and then placed on the fluoroscopic table with the affected side near the edge of the table. The fracture is then reduced under the fluoroscope by means of the Leadbetter manipulation. The leg finally put in extension abduction and slight internal rotation is held there by an assistant. The skin over and below the great trochanter is prepared and the field of operation is draped. The

Fig 4 Method of taking lateral roentgenogram of neck of the femur with Plate B in position.

Fig 5 Lateral view of femur with Plate B in position and the wire introduced through the tube corresponding to the proper row of dots

lower point of the trochanter is palpated and the incision is made from this point down the lateral aspect of the thigh paralleling the femur for 2 inches. The incision is carried down through skin, subcutaneous tissue, tensor fascia lata, vastus lateralis, to the bone through the periosteum.

neck of the femur after reduction and insertion of the Smith-Petersen nail

Fig 9

Fig 6 The Smith-Petersen nail is in place and the impactor is screwed onto the head of the nail. The neck impactor is set up against the lateral cortex of the femur so that a blow by hammer on the cap will impact nail and neck at the same time

There is practically no bleeding from this incision. The apex of Plate A is introduced into the incision with the plane parallel to the shaft of the femur pointing just a little upward into the notch formed by the junction of the shaft with the lower border of the great trochanter. Its pin is then inserted and driven into the cortex of the bone fixing Plate A in position. An anteroposterior x-ray plate is then

Fig 9 Lateral view of same case as in Figure 8

Fig 10 Postoperative chart of patient shown in Figures 8 and 9

taken, and is developed in 2 minutes by placing it in a warm and concentrated developer (Fig 3). The line of dots which are in line with the axis of the neck of the femur is selected for proper direction in this plane. Plate B is slid over Plate A at right angles to it and swung over an arc until it overlies the selected row of dots in Plate A.

Plate B is then fixed in position by its two pins being introduced into the cortex of the femur. The pin of Plate A is then withdrawn and Plate A is removed by sliding it out of the slot in Plate B. A lateral roentgenogram is then taken with just Plate B in position (Fig 4). Again the line is selected which is in proper direction to go

through the axis of the neck of the femur. As soon as this row of dots is selected a Kirschner wire is introduced into the tube corresponding to the row of dots and drilled into the neck to its head (Fig 5). Plate B is then removed and its two pins are withdrawn, leaving only the Kirschner wire in place in perfect position. The Smith-Petersen nail is then introduced over the wire and driven into the head. As the nail is partly in we impact the fragments with an impactor. This is exceedingly important (Fig 6).

As to selecting the length of nail, we take our first x-ray film of the fracture with Plate A in position. We know the actual length of Plate A and from this we get the length of the nail needed (Fig 7). Actual length of Plate A is to the measured length of Plate A in x-ray film as X distance between lateral edge of femur and the head is to this same distance in the x-ray film. The wire is then withdrawn and about three skin sutures placed in the incision and a small dressing applied. Final check is made with an antero-posterior and a lateral plate for position (Figs. 8 and 9). The patient is up in a chair 48 hours after operation (Figs. 10 and 11).

The points we would like to stress regarding this device are. (1) its real simplicity, (2) the accuracy of the method, (3) the small incision—no muscle cutting—no shock, (4) the short duration of operation; (5) patient starts motion at once; (6) patient is up in chair after 48 hours, (7) no atrophy of disuse.

We present this description of the instrument as a preliminary report. We feel that it will cut down still more the mortality in this type of fracture, first, by the simple, short, non-shocking operation, and, second, by making it possible to get the patient up early, we believe also that it improves the functional end-results by early motion.

SUMMARY

A description has been given of a two-plane direction finder to facilitate the introduction of wire into the femur neck in nailing intracapsular

Fig. 11 Same patient 2 days after operation

fractures after the Smith-Petersen and Sven Johansson methods. The technique has been described in detail.

FRACTURES OF THE BONES OF THE HAND

HUBLEY R OWEN, M.D., F.A.C.S. Philadelphia, Pennsylvania

THE subject of this paper is not of my own selection. A discussion of fracture of any other bone would have been more welcome, my reason being that I have neither a controversial argument to present nor any new suggestion. The question of fracture of the metacarpals and phalanges may be timely as there are not only very few articles on the treatment of fractures of these bones but also I cannot recall a practical demonstration of the method of the treatment of fractures of the phalanges and metacarpals at any meeting of the Pennsylvania State Medical Society, the American Medical Association, or the American College of Surgeons nor can I remember a presentation of this subject being made at any meeting of our central or regional fracture groups. The treatment of fractures cannot be taught with any papers, essays, slides, or films. Practical demonstration is the best method of proper instruction. Through the medium of intensive propaganda along educational lines the sequence of the treatment of a fracture of a long bone is fairly well established. First aid treatment has been duly emphasized and the subsequent methods of permanent dressings discussed at length. There has been no similar emphasis placed upon the treatment of fractures of the bones of the hand.

The treatment of fractures of the bones of the hand has been ably described by McNealy and Lichtenstein with a report of 1323 cases. This

paper was presented before the meeting of the Western Surgical Association in 1934 and was admirably discussed by Magnuson and Speed.

Comparatively few articles dealing with fractures of the hand have been published.

Fractures of the bones of the hand unless associated with more serious injuries are usually treated in the out patient dispensary. If the personnel of the out patient dispensary is under the direct supervision of one interested in and competent to treat fractures, the end results will be satisfactory. Out patient dispensaries are not always properly supervised. The treatment of all fractures should be under the supervision of one directing head whether the injured be a ward or a dispensary patient.

The mechanism of the hand is complex. Its usefulness depends upon the contour of the bony frame, the freedom of motion of the 15 involved joints, and the proper action of muscles and tendons. In some occupations ankylosis of one joint of a finger may impair the usefulness of the whole hand and seriously handicap the patient's ability to pursue his livelihood.

The treatment of fractures of long bones may, if I might use the expression, be more spectacular although of no greater importance. In teaching medical students we may have laid too much emphasis on the treatment of fractures of long bones to the neglect of the treatment of fractures of the hand. Far too often we find a tongue

From the Hospital of the Woman, Medical College of Pennsylvania, Medical Division, Department Public Safety, and the Philadelphia General Hospital.

Presented at the Symposium on Fractures before the Clinical Congress of the American College of Surgeons, Chicago, October 23-29, 1937.

danger of striking a person with their fists. This special emphasis is stressed to prevent the lacerated wound of the knuckle caused by a tooth cut. Complications and sequelæ following this type of injury are well recognized.

The most common cause of compound fracture of the metacarpals and phalanges occurring in the police department is gunshot wound.

To evaluate properly the deformity of any fracture one should be familiar with the action of the muscles controlling the fragments. This does not necessarily mean that all fractures, even though sustained at the same level with regard

depressor used as a splint for all fractures of the phalanges and a roller bandage as a panacea for fractures of the metacarpals.

Fractures of bones of the hand are not as frequently sustained by the personnel of the police and fire departments as one would expect. The police are warned in their first aid lectures of the

Fig 10 Showing 'cock up' position of hand Traction applied for fracture of phalanx

to the origin or insertion of muscles are followed by the same deformity of fragments. The direction of the force causing the fracture may influence to a considerable extent the resulting position of the fragments.

A frequent type of fracture of the distal phalanx is the mushroom fracture—a comminuted fracture caused by a blow or crush of the distal phalanx of the finger, often associated with a hematoma beneath the nail (Fig 1). The patient presents himself with symptoms of a swollen, painful finger. The hemorrhage beneath the nail is recognized and the blood is evacuated. The fracture may be overlooked. The patient may be allowed to resume his work in a few days but returns to the surgeon shortly afterward because of continued pain and tenderness. An x-ray picture may then reveal the fracture. It is imperative, especially in industrial cases, to roentgenograph all injuries of this character.

A fracture through the midportion of the distal phalanx may be associated with separation of the

Fig 12 Pathological fracture of proximal phalanx fourth finger through bone cyst

Fig 13 Pathological fracture through area of osteomyelitis middle phalanx index finger

fragments. The distal fragment may be easily restored and held in contact with the proximal fragment if reduction is made immediately. Subsequent displacement is rather unlikely (Figs 2 and 3).

A simple fracture of the distal phalanx may be treated with the use of a wooden tongue depressor as a splint.

Whereas Smith and Rider have shown that the average time for bony healing of the complete phalangeal fracture is approximately 5 months, yet one naturally does not keep these fractures at rest for this length of time. Immobilization on a splint for 10 days or 2 weeks suffices.

Fig 14 Pathological fracture through bone cyst of proximal phalanx of fifth finger

Fig 14 Transverse fracture of distal end of third metacarpal caused by blow with fist.

A compound fracture of the distal phalanx is treated by débridement. Removal of the nail must depend upon the degree of devitalization of soft tissues and the amount of remaining attachment of the nail. If the soft tissues are badly devitalized and the nail practically detached, it should be removed. If the nail is still attached to fairly healthy soft tissues it may be retained, thereby serving as a partial splint.

In compound fracture of the distal phalanx necrosis of the detached fragment may ensue.

The most difficult fracture of the distal phalanx to treat is the so called "baseball finger." In this type of fracture the posterior articular facet is detached by the pull of the extensor tendon. Failure to correct this deformity may result in the "drooping" finger causing impairment of motion. Fracture of this type should be kept at rest on a splint with the distal phalanx in hyperextension for at least 4 to 6 weeks (Figs 4 and 5).

In the treatment of fractures of the middle phalanx one should consider the insertion of the tendon of the flexor sublimis digitorum regarding the line of fracture. If the line of fracture occurs proximal to the insertion of the tendon the resulting deformity may be readily corrected with a straight dorsal splint, the finger being held in extension (Fig. 6).

If the fracture occurs distal to the insertion of the sublimis tendon the deformity is more readily

corrected with the finger held in flexion (Fig 7). After 10 days at rest, active motion of the finger may be employed at the time of each dressing. The splint should not be permanently removed for 3 weeks.

One should never attempt to elicit crepitus to make a diagnosis of a fracture of a phalanx. This rule applies to a fracture of any other bone of the

Fig 15 Transverse fracture of metacarpal showing action of interosseous muscle

Fig 16 Soft tissue traction for fracture of metacarpal

skeleton Attempting to elicit crepitus may disturb the position of the fragments—disturb a favorable position of the fragments—and render the treatment far more difficult

A compound fracture of the middle phalanx associated with devitalization of soft tissues may require debridement and soft tissue or skeletal traction Traction is also employed in the treatment of interarticular fracture, the line of fracture extending either into the joint between the midphalanx and distal phalanx or between the midphalanx and proximal phalanx (Fig 8)

Soft tissue traction cannot be applied to the distal phalanx In the treatment of fractures of the middle phalanx requiring traction one employs traction utilizing a strand of silkworm gut or wire through the soft tissues of the distal phalanx or skeletal traction with wire or pin through the bone itself We prefer either of the above methods to traction with wire passed through the finger nail

Fracture of the proximal phalanx may be complicated by a V shaped deformity due to the action of the interosseus muscle on the proximal phalanx and extension of the distal fragment by the lumbricale This fracture should be immobilized with the finger held in flexion (Fig 9)

When traction is applied to fracture of any phalanx, the hand must be held in the cock up position If traction is applied with the finger or fingers in complete extension there is an im-

balance of muscle pull which may result in malalignment of the finger (Fig 10)

Pathological fractures of phalanges are not frequent Such fractures may complicate osteomyelitis, bone cysts, or other pathological lesions of bone (Figs 11 12 and 13)

Fractures of the metacarpals are either transverse or oblique The transverse fracture occurs at the distal end of the metacarpal bone just proximal to the head This injury is usually caused by a blow with the fist Unless the existing deformity is corrected obliteration of the knuckle may ensue The fracture should be reduced under anesthesia A straight dorsal splint may suffice, but if the deformity tends to recur traction is imperative This type of fracture, as well as the transverse or oblique fracture through the middle of the metacarpal may be erroneously treated by flexion of the hand over a roller bandage a position which aggravates the existing deformity (Figs 14 and 15)

If the fragments of a fracture of one or more of the 4 inner metacarpals cannot be retained by a posterior splint traction on the phalanges may be employed Soft tissue traction is adequate in the majority of cases Traction may be applied by one of 4 methods lateral and circular strips of adhesive plaster a narrow bandage or tape fastened to the finger with Sinclair's glue or paste silkworm gut or wire passed through the nail or skeletal traction applied by means of a Mock finger caliper or stainless steel pin

In the application of soft tissue traction the distal phalanx must be protected otherwise, excessive pressure over the finger nail causes pain or may cause sloughing of the soft tissues

There are many types of splints on the market for the application of skeletal traction Most of these splints are cumbersome and expensive An adequate fixation splint may be made with plaster of Paris incorporating the forearm (Figs 16 17, and 18)

Fractures of the first metacarpal involve either

Fig 17 Metzler apparatus for skeletal traction

Fig 18 Metzler apparatus for skeletal traction

Fig 19 Lewin Stern thumb splint

the shaft or the base of the thumb. Fracture of the shaft of the first metacarpal is not a frequent injury and when incurred is due to direct violence. This type of fracture is given treatment similar to that of fracture of a phalanx rather than to a fracture of one of the 4 inner metacarpals. The thumb is immobilized in adduction and partial flexion or in the grasping position. Such position may be maintained by the application of a light plaster-of-Paris cast to the wrist and thumb.

Comminuted fracture of the shaft of the first metacarpal may require traction—either soft tissue or skeletal. Traction must be applied so as to maintain flexion in adduction of the thumb.

The more common type of fracture of the first metacarpal is fracture of the base of the thumb which may be an impacted fracture not involving the articular surface or an oblique fracture in which the line of fracture extends through the base of the thumb, the so called Bennett's fracture. The distal fragment tends to be thrown upward and backward. There is usually posterior and outward bowing.

There is acute wincing tenderness in the anatomical snuffbox. It is imperative to make a prompt diagnosis as failure to do so may result in marked disability of the thumb. Treatment of fracture of the base of the first metacarpal consists in reduction under general anesthesia. Reduction is accomplished by traction and hyper-

Fig 20 Treatment of Bennett's fracture. Cast and soft tissue traction with thumb in abduction

abduction. The position of the fragments is maintained by a plaster-of-Paris cast including the wrist and thumb. The position of the thumb is held in hyperabduction. The fracture is immobilized for 3 weeks at the end of which time the thumb may be held in abduction by adhesive plaster. The adhesive plaster should not be removed for an additional 2 weeks (Figs 19 and 20).

CONCLUSION

Kanavel has stressed the anatomy of the hand with regard to the treatment of infections. The anatomy of the hand should also be stressed in the treatment of fractures of the phalanges and metacarpals.

The treatment of fractures of bones of the hand has not received the proper emphasis. There should be at future meetings of national, state, and county societies practical demonstrations of the treatment of fractures of bones of the hand similar to those on the subject of fractures of long bone.

The proper supervision of the treatment of fractures of the bones of the hand is a responsibility of the chief of the fracture service.

An assistant surgeon, experienced in the treatment of fractures, should direct such treatment in the out patient dispensary.

NOTE—Figs 11, 12, and 13—courtesy of Dr. Paul A. Bishop, X-ray Department, Pennsylvania Hospital, Philadelphia.

skeleton. Attempting to elicit crepitus may disturb the position of the fragments—disturb a favorable position of the fragments—and render the treatment far more difficult.

A compound fracture of the middle phalanx associated with devitalization of soft tissues may require debridement and soft tissue or skeletal traction. Traction is also employed in the treatment of interarticular fracture, the line of fracture extending either into the joint between the midphalanx and distal phalanx or between the midphalanx and proximal phalanx (Fig 8).

Soft tissue traction cannot be applied to the distal phalanx. In the treatment of fractures of the middle phalanx requiring traction one employs traction utilizing a strand of silkworm gut or wire through the soft tissues of the distal phalanx or skeletal traction with wire or pin through the bone itself. We prefer either of the above methods to traction with wire passed through the finger nail.

Fracture of the proximal phalanx may be complicated by a V shaped deformity due to the action of the interosseus muscle on the proximal phalanx and extension of the distal fragment by the lumbrical. This fracture should be immobilized with the finger held in flexion (Fig 9).

When traction is applied to fracture of any phalanx the hand must be held in the 'cock up' position. If traction is applied with the finger or fingers in complete extension there is an im-

balance of muscle pull which may result in malalignment of the finger (Fig 10).

Pathological fractures of phalanges are not frequent. Such fractures may complicate osteomyelitis, bone cysts or other pathological lesions of bone (Figs 11, 12 and 13).

Fractures of the metacarpals are either transverse or oblique. The transverse fracture occurs at the distal end of the metacarpal bone just proximal to the head. This injury is usually caused by a blow with the fist. Unless the existing deformity is corrected obliteration of the knuckle may ensue. The fracture should be reduced under anesthesia. A straight dorsal splint may suffice but if the deformity tends to recur traction is imperative. This type of fracture, as well as the transverse or oblique fracture through the middle of the metacarpal may be erroneously treated by flexion of the hand over a roller bandage a position which aggravates the existing deformity (Figs 14 and 15).

If the fragments of a fracture of one or more of the 4 inner metacarpals cannot be retained by a posterior splint traction on the phalanges may be employed. Soft tissue traction is adequate in the majority of cases. Traction may be applied by one of 4 methods: lateral and circular strips of adhesive plaster; a narrow bandage or tape fastened to the finger with Sinclair's glue or paste, silkworm gut or wire passed through the nail or skeletal traction applied by means of a Mock finger caliper or stainless steel pin.

In the application of soft tissue traction the distal phalanx must be protected otherwise excessive pressure over the finger nail causes pain or may cause sloughing of the soft tissues.

There are many types of splints on the market for the application of skeletal traction. Most of these splints are cumbersome and expensive. An adequate fixation splint may be made with plaster of Paris incorporating the forearm (Figs 16, 17 and 18).

tion in the restoration of position. In the upper forearm the ulna has a greater functional value and should, therefore, be accorded more consideration in reduction. In the middle of the forearm the bones are of equal importance. In oblique or comminuted fractures, slight overlapping may even allow a greater surface contact. The traction necessary to restore alignment will usually be adequate for apposition. The fragments in transverse and slightly oblique fractures may become separated by muscle planes and defy reduction by the usual methods. In such cases one bone can usually be gotten into position and the other may be improved by inserting a small lever or pry pin as designed by Thomson. Overlapping of the radius in the lower third, even with good position in the ulna, is not acceptable for transverse fractures. A contact of $\frac{1}{3}$ to $\frac{1}{2}$ under the same conditions is preferable to open reduction. In the author's experience with this type, approximately 10 per cent have required open

reduction. Including the middle and upper end of the forearm, 15 per cent have been operated upon. These figures applied to early cases of our own, and the decision to open was based upon our failure to get a good contact in the major fracture. Also, it was done in the knowledge that a technique used for fastening the fragments in accurate compression is simple in execution and almost certain for union. Fragments held in accurate contact with compression will not unite as rapidly as the same position by closed methods, however, union is much more rapid than a fracture in fair to poor position treated by closed method.

REQUIREMENTS OF GOOD SPLINTING

After the fracture has been reduced to an acceptable degree, provision must be made that splints can be applied without shifting or moving the forearm and allowing displacement of fragments. The elbow and the wrist should be immobilized and the metacarpophalangeal joints

FRACTURES OF BOTH BONES OF THE FOREARM EXCLUDING THOSE AT THE ELBOW JOINT AND WRIST JOINT

W B CARRELL M.D., F.A.C.S. Dallas Texas

FRACTURES of both bones in the forearm result usually from direct violence and may occur at any level between the elbow and wrist. Those in the upper half of the forearm covered by heavy muscular structures are more difficult to reduce, but fortunately will unite with good function even though reduction is not good. Those in the lower third require a more accurate contact for assurance of union, but here reduction is more easily accomplished.

Much of the deformity present is due to the initial trauma, but after the break there is faulty muscular balance producing rotation, deviation, and shortening. It is confusing to attempt in each fracture a complete analysis of the various muscles affecting the position, because with one notable exception manipulation and traction without regard to them will overcome their harmful influence. The exception relates to the rotation deformity caused by unopposed pull of the pronator teres when the radius is broken at a certain location. A working formula is that a position of supination should be imposed if the radial fracture is above the pronator teres insertion. In all other locations midpronation is desirable. Complete pronation is never indicated. Rotation to the desired position should be done before coaptating the fragments; otherwise the rotation is not under control.

Complications of nerve and circulatory damage are not as frequent as in some other regions of the upper extremity, but every case should be examined specifically for this before treatment is started. Roentgenograms are routinely made in two planes. Most fractures of both bones in the forearm except in small children can be properly prepared for reduction by means of local anesthesia injected directly between the fragments.

The usual method of treatment for fractures so easily palpated as are both bones of the forearm should on the whole give reasonably good results, but observation in the author's experience does not warrant this a supposition.

In the study of 100 cases of unsatisfactory progress in fractures of both bones of the forearm some interesting conclusions are reached. These cases were private patients either treated primarily in our clinic, or sent in from 2 weeks to several months after the injury because the progress was not satisfactory. In the analysis of this group it was found that approximately 40 per cent had not been well reduced. The bones were not in good alignment, or the contact was so poor that a satisfactory result could not be expected. In 30 per cent the original reduction had seemed fair, but the splinting was inadequate to maintain reduction and a resulting angulation or displacement had occurred. In 20 per cent there had been good reduction followed by good splinting, but the splints had been removed too early, with a secondary angulation and in some instances non union. In 10 per cent there were fractures with extensive trauma, extreme comminution, etc., and a poor result was inevitable. The obvious questions which arise from these statistics are (1) what constitutes a satisfactory reduction? (2) what type of splinting is best suited to maintain a good reduction? (3) how long should the splints be worn?

ESSENTIALS IN A SATISFACTORY REDUCTION

By manipulation and traction, one should get an acceptable position in 70 per cent of cases; 10 to 15 per cent will require open reduction. Alignment in longitudinal direction and rotation should be restored completely or with only a few degrees of fault, whether the fracture is in the upper, middle or lower third. Apposition cannot be accurately obtained in all cases although it is desirable and influences greatly the early consolidation of the fracture. The requirement for securing better contact in repeated manipulations or open reduction may outweigh in harmful influences the slow union incident to poor apposition. It is therefore a matter of judgment to make the final decision between acceptable and unacceptable positions. It is of some consequence that in the lower third the radius has a greater functional value and should receive more atten-

tion in the restoration of position. In the upper forearm the ulna has a greater functional value and should, therefore, be accorded more consideration in reduction. In the middle of the forearm the bones are of equal importance. In oblique or comminuted fractures, slight overlapping may even allow a greater surface contact. The traction necessary to restore alignment will usually be adequate for apposition. The fragments in transverse and slightly oblique fractures may become separated by muscle planes and defy reduction by the usual methods. In such cases one bone can usually be gotten into position and the other may be improved by inserting a small lever or pry pin as designed by Thomson. Overlapping of the radius in the lower third, even with good position in the ulna, is not acceptable for transverse fractures. A contact of $\frac{1}{3}$ to $\frac{1}{2}$ under the same conditions is preferable to open reduction. In the author's experience with this type, approximately 10 per cent have required open

reduction. Including the middle and upper end of the forearm, 15 per cent have been operated upon. These figures applied to early cases of our own, and the decision to open was based upon our failure to get a good contact in the major fracture. Also, it was done in the knowledge that a technique used for fastening the fragments in accurate compression is simple in execution and almost certain for union. Fragments held in accurate contact with compression will not unite as rapidly as the same position by closed methods, however, union is much more rapid than a fracture in fair to poor position treated by closed method.

REQUIREMENTS OF GOOD SPLINTING

After the fracture has been reduced to an acceptable degree, provision must be made that splints can be applied without shifting or moving the forearm and allowing displacement of fragments. The elbow and the wrist should be immobilized and the metacarpophalangeal joints

Fig 4

Fig 4 a The plaster slab has been placed on back of hand forearm and arm b the anterior felt pad is in place

Fig 5

Fig 5 Bandage has been applied

Fig 6

Fig 6 The anterior plaster slab c completes fixation

left perfectly free. Manufactured splints rarely fit with sufficient accuracy to hold the position. Wooden splints padded and slightly wider than the forearm are used by many, but are difficult to keep at good tension and in the observation of the author have not prevented deviation of the ulna in a posteromedial direction. Circular plasters have been used but should be condemned for general use because of the danger from swelling and circulatory damage. The application of plaster splints well applied, meets the requirement of good fixation with controlled tension and freedom from circulatory damage.

METHOD OF FIXATION

With the forearm held in a mechanical appliance as shown in Figure 1, which is original only in some features¹ a fixed position is maintained which is superior to the most careful holding by an assistant. Increased traction supination and

pronation to any degree, are under complete control. When the position has been accepted and confirmed by roentgenogram then the dressing is deliberately applied. The elbow which is at right angle is first fixed with a sugar tong splint. This extends to within 2 or 3 inches of the axilla, no padding is used on the arm except a felt over the condyles and olecranon. This sugar tong is bandaged smoothly to the arm. After placing a small felt over styloids, a broad slab of plaster, wet is applied to the back of the hand wrist and forearm and bending at the elbow extends up the back of the arm over the bandaged sugar tong splint which has just been applied. This wet plaster is molded smoothly to the posterior medial and lateral surfaces of the forearm. Before bandaging to the forearm a strip of soft, piano felt is placed on the palm anterior surface of the forearm and beyond the bend of the elbow. The wet plaster on the back of the forearm which has no padding is then bandaged over the padded anterior surface and the smooth approximation

¹ The principle is old and several firms manufacture it. Use of the principle of the apparatus described in this paper is not intended to be a criticism of any of the apparatuses now in use.

Fig 8 B E S Comminuted fragments usually approximate well with light traction, skeletal fixation is not required

is made Another plaster splint is now applied to the anterior surface, extending from just proximal to the metacarpophalangeal joint over the palm, anterior surface of forearm, and up the anterior surface of arm This plaster splint is wide enough slightly to overlap the posterior splint on the two sides It is bandaged in position Slight interosseous grooving of plaster with a small pipe, as suggested by Boehler, makes the fit more accurate When the plaster sets, the arm is released from the apparatus and the upper arm section smoothed off with additional bandage

INDICATIONS FOR EXTENSION

When both bones are badly comminuted some extension is necessary to maintain good alignment In oblique fractures it is sometimes necessary to maintain extension to prevent the fragments sliding off into deformity. In occasional cases with transverse fractures one is able to get what appears a fair contact in two views, and yet the reduction may be very unstable A slight extension is beneficial in this type Extension when advisable may be carried out either by weight and pulley methods, when the patient has

Fig 8

Fig 9 F C a Common type of fracture deformity b radius most important in this region fault in ulna will not interfere with function

the arm in bed traction, or it may be done in combination with plaster fixation method. The latter is more efficient. For moderate traction the method just described can be applied so accurately that some degree of traction is maintained without the aid of Kirschner wires. For more positive traction and especially indicated where in addition to the forearm fracture, there is a fracture in the humerus it is best to place a wire through the ulna about 2 inches distal to the olecranon and another either through the lower end of the radius and ulna or

through the medial three metacarpal bones. With the wires in place the plaster can be applied in the usual manner, incorporating the wires and thus maintaining a fixed traction when the plaster hardens. Before the plaster sets the patient is placed in bed with a spreader on the distal wire and suspension for the necessary traction. In the series of unsatisfactory results studied the author was impressed with the slow union which occurred in several patients treated by traction. It should be recognized that very little traction is needed in the forearm because even without wires

Fig 10 V V a Unstable transverse type of fracture b position secured by skeletal fixation

Fig 11 J V Good plating with traction badly comminuted Compound fractures permit more satisfactory reconstruction later

Fig 12 W E W a, Fracture with deformity, b distraction excessive by plaster fixation, c, same in delayed union 2 months after injury

the bones may be put up with too much distraction and consequently delayed union. Rarely should fixed traction be used except in fractures of the forearm, complicated by fracture in the humerus, or in compound fractures of the forearm which are badly comminuted and in which splintage must be disturbed for dressings

LENGTH OF TIME SPLINTS SHOULD BE WORN

Fractures about the middle and lower third of the forearm unite very slowly. Fixation should be maintained until the union is firm. In adults 60 to 90 days is the average period. Removal of splints when the callus is soft seems in our section of the country to be a common error. With early removal there is a gradual angulation, and remodeling at this late stage may endanger final union. Removal of the complete fixation and substitution of a light forearm splint is likewise hazardous. In the full fixation a patient is encouraged to use the shoulder, fingers, and thumb freely, carrying out daily every motion of these joints and working in so far as feasible with the handicap of splinting.

CONCLUSION

The author, through observation of many poor results, has learned that the common errors are

inadequate reduction, imperfect fixation, and removal of splints too early. These errors account for approximately 90 per cent of poor results. With careful reduction accomplished by manipulation combined with traction, a satisfactory alignment should be secured in all cases. A fair reduction should be had in the preferable bone, depending upon its location, and an acceptable position in the other. If this position is maintained by a controlled mechanical appliance as simple as the one illustrated, then proper plaster splinting can be fitted to the forearm in such a manner that it will hold the fragments as they have been reduced and will not compress the forearm unduly. Very few fractures need any supplementary traction, either fixed in the plaster through pins or otherwise. Open reduction should be very seldom required, but with definite indications should be done. The apparatus described is so constructed that it is an ideal sterilizable unit for maintaining position in operations on the forearm. Fifteen per cent of early cases have required open reduction but the percentage is apparently decreasing with better closed methods. There will always be a necessity for open reduction in planning treatment 2 or 3 weeks after the injury, when the fragments are frozen in deformity.

SYMPOSIUM ON CANCER

CORRELATION OF BODY SEGMENTAL TEMPERATURE AND ITS RELATION TO THE LOCATION OF CARCINOMATOUS METASTASIS

Clinical Observations and Response to Methods of Refrigeration

TEMPLE FAY, B S M D, F A C S and GEORGE C HENNY M S, M D,
Philadelphia Pennsylvania

IN 1932 our clinic¹ was engaged in the study of body temperatures from the standpoint of neurological segments or dermatomes (Fig 1) The purpose was primarily to ascertain if tumors or lesions of the spinal cord produced characteristic changes of surface temperatures in the dermatomes at or below the level of the lesion

Irritation, heat, and pain produce hyperemia in the segmental area of stimulation. Conversely, cold produces vasoconstriction and ischemia, in the same neurological reflex arc (Fig 2)

Much time was devoted to the perfection of a thermocouple and galvanometer that would be sufficiently sensitive to give accurate readings to within 0.36 degrees Fahrenheit (0.2 degrees Centigrade). Studies² on normal patients revealed that when the body area was divided into its neurological dermatomes according to nerve roots and segments of the spinal cord, the segments overlying the breast area (fourth and fifth thoracic) in both male and female showed consistently higher temperatures than the adjacent segments above or below.

On the other hand, as might be expected the segments supplying the extremities (sixth cervical to second thoracic and second lumbar to first sacral) fell far below other areas of the body under usual environmental temperatures. With the exception of the breast segments the areas of the trunk maintained a fairly uniform level. The head and neck showed con-

sistently higher temperatures than the rest of the body. The average normal, surface body temperature was found to be 63 degrees Fahrenheit (3.5 degrees Centigrade) lower than that of the mouth. The temperature of the distal portion of the extremities, however, fell from 12 degrees Fahrenheit (6.7 degrees Centigrade) to 20 degrees Fahrenheit (11.1 degrees Centigrade) below the normal mouth readings in certain instances and from 0.18 degrees Fahrenheit (0.1 degrees Centigrade) to 8.3 degrees Fahrenheit (4.6 degrees Centigrade) in the male normal control group (Fig 3).

TEMPERATURE AND GROWTH

It is universally recognized that temperature has a direct influence on growth in all forms of cellular life and that in seeds and eggs particularly a certain range of 'critical temperature' is required to activate the normally fertilized single cell.

One of us (Fay) began a close investigation into this factor as it might apply to the problem of abnormal cell growth and activity in the human body.

When the body segmental areas were divided into the high and low temperature fields a striking correlation appeared to exist between the location of rapidly growing types of metastatic malignancy and the segmental areas of relatively high surface temperatures. The locations favoring metastatic growth fell almost entirely within the segmental areas of highest body temperature whereas it was extremely rare to find records of such lesions in the distal portions of the extremities where the segmental temperatures are lowest even though metastatic tumors were shown to be widespread and, in certain instances undoubtedly blood borne.

Fig 1 The human segmental dermatome pattern as it arises and ultimately becomes differentiated. In order to appreciate the definite relationship and sequence of these segments, the human being must be placed in a position similar to that assumed by the alligator, with thumbs and toes pointing upward and with the oral and anal openings of the gut tube representing the two extremes of segmentation of the organism. (Courtesy William Wood & Co From Purves-Stewart)

Recognizing this factor to be only one among a host of other equally important considerations, a search of the literature was made to determine what information was available on this point.

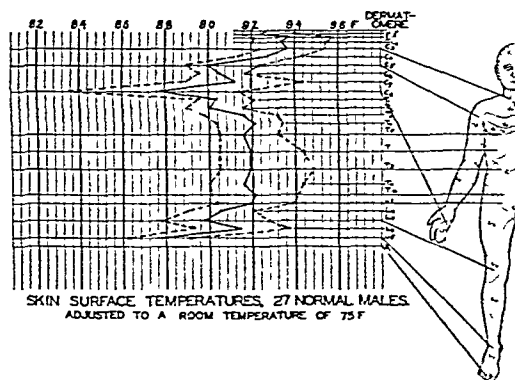

It was disappointing to find no reference in the literature as to the influence of diminished and

subnormal temperatures upon malignant cell growth. Although much has been done in the field of hyperthermia, clinical and pathological studies on tissue response to the principle of "refrigeration" are conspicuous by their absence. Examples of arresting growth and preserving food stuffs, through sustained measures of induced low temperatures, are so common in our agricultural,

SEGMENTATION OF CORD SEGMENTATION OF VASCULAR TREE SEGMENTATION OF SKIN

Fig 2 Segmental pain and temperature arc representing local cord responses to the principles of irritation and counterirritation produced by *pain* and the *extremes of heat and cold*. This neurological arc is the most primitive unit of the sensory system and still retains its original segmental plan for dermatomes of the skin, segmentation of the tubes, and branches of the vascular system as well as the visceral gut tube and its many visceral organ proliferations. Hyperemic and ischemic responses follow the segmental influences arising in the various components of the reflex arc.

SKIN SURFACE TEMPERATURES, 27 NORMAL MALES
ADJUSTED TO A ROOM TEMPERATURE OF 75 F

Fig 3 Composite graph indicating various segmental temperatures in 27 normal males. The range of variation in the group is denoted by the broken line—the average for the group by the solid line. Note the definite peak of temperature curve in the fourth thoracic segment supplying the breast, even in the male. In the female the curve is higher and more variable depending upon the age of the patient and the sexual function of the gland. Favorable sites for metastatic malignancy lie near or above the base body line. Segmental temperatures in the extremities are obviously lower with the exception of the area of the knees. These areas appear to be "unfavorable" for the location of metastatic carcinomatous cell growth.

Fig 4. Hollow instruments devised for application to the area of tumor involvement. Solutions at various regulated temperature levels may circulate within the hollow instrument and thus influence the local temperature of the part adjacent to its surface. a Vaginal cup designed for application about the cervix. b Vaginal bomb designed for insertion into the eroded cavity produced by the tumor. c Hollow knife blade designed for application beneath surface lesions such as the breast or for deep implantation into lesions of the soft tissues and the brain. d Hollow pin designed for introduction into deep tumor masses involving the long bones and accessible surfaces where the instrument can be inserted through the growth itself permitting return of circulation directly through the opposite side of the part involved. (Note—The sharp metal point is removable and fitted to a nipple capable of accommodating the rubber tube used to return solution. Various lengths and shapes of instrument may be required.)

industrial and economic life that they need no mention. The ice box or refrigerator serves this purpose in every home. The fact that the fertilized hen's egg lies dormant as a single cell until activated *alone* by the influence of a critical temperature around 103 degrees Fahrenheit (39.4 degrees Centigrade) is worthy of far deeper consideration than would appear at first glance. The knowledge that we may prevent this event by cold storage, or determine its initiation by controlled means of incubation places temperature as the prime factor of consideration.

The striking fact remains that temperature *alone* is required to bring into existence activation of the rapid embryological cellular division

Fig 5. Coil devised for refrigeration of accessible areas of cranial metastasis.

that in the instance of the egg, follows normally differentiated patterns if allowed to perist.

Certain important factors concerned with plant and agricultural growth, aside from the great seasonal influence of temperatures are worthy of consideration in the hope that they may shed further light on the means of dealing with human cell response.

Given intense sunlight and sustained low temperatures, adaptable plants (moisture and proper nourishment being considered adequate) tend to come slowly to a stunted maturity (viz. mountain vegetation above the so-called 'timber line'). Conversely, darkness and sustained abnormally high temperatures give rise to overgrowth and delayed maturity (viz. plants or tubers in a warm cellar). When sunlight is combined with optimal temperatures (moisture and nourishment being adequate) the combined effect favors both growth and maturity (viz. tropical or hothouse vegetation).

Again a suggestive analogy appears in the clinical history of certain types of malignancy. The slower growing, more mature forms of squamous carcinoma of the exposed hands where temperature is lowest and sunlight exposure greatest are in distinct contrast to the more rapid activity of squamous carcinoma of the cervix where a temperature of from 1 to 3 degrees Fahrenheit above the mouth normal exists, and a complete absence of light prevails.

SCOPE OF INVESTIGATION

The purpose of this presentation is to submit a preliminary report on the steps which have been

Fig 6 Case 1 K. L. Squamous carcinoma cervix grade IV with massive pelvic extension. Original cooling apparatus devised to maintain constant temperature 50 degrees Fahrenheit in the vaginal bomb. Water reservoir allows constant flow of fluid through ice coil and regulation of flow adjusted to give temperature 50 degrees Fahrenheit to fluid returning from the vaginal bomb. Relief of pain and general improvement of physical state followed 5 weeks of constant irrigation.

taken to establish whether in approaching the problem from this new point of view, the factors aforementioned are merely a coincidence, or whether there may exist, as elsewhere, a significant correlation between critical temperatures and growth.

With the encouragement of Dr. James Ewing and the assistance of a grant from the International Cancer Research Foundation, Donner Fund, the following lines of investigation have been undertaken:

1. Thermocouple readings of body surface segments and visceral organs have been taken to establish a normal controlled group to serve as the base line for comparison with the pathological material under study.

2. Thermocouple and temperature studies in the region of malignant tumor masses have been carried out. Where these areas of cellular activity were accessible, apparatus has been devised to modify the local temperature in and about the area of the lesion, over extended periods of time.

3. Comparative biopsy studies of tissue of malignant growth, before and after treatment by methods of refrigeration, have been undertaken under the direction of Dr. Lawrence Smith, professor of pathology.

4. Clinical response of the patient to factors concerned with pain, weight, rapidity of progress of malignant mass, and evidence of metastatic activity have been noted, before, during, and after treatment designed to lower local temperature.

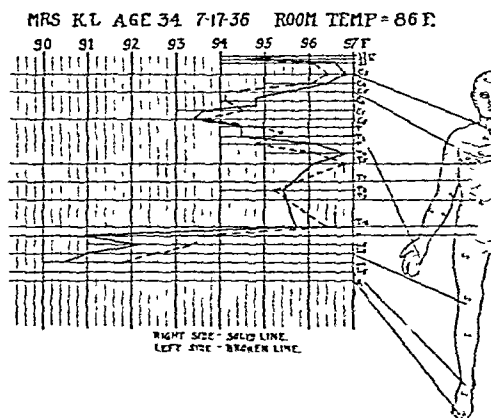

Fig 7 Case 1 K. L. Skin temperature chart showing prominence of surface temperatures in the dermatomeres concerned with the breast segments as well as definite and marked rise in the twelfth thoracic segment in the visceral pelvic zone. Carcinoma of the cervix with pelvic extension.

5. Studies are now under way to determine whether certain temperatures may not be "critical" in the development of the normal cell activity (e.g., fertilized eggs and seeds) with observations directed toward the influence of "subcritical" temperatures and refrigeration on maturity and rapidity of growth.

6. Tissue culture of the normal and pathological human tissue is now being carried out under the direction of Dr. Lawrence Smith by Miss Lillian Sherman, according to George and Margaret Gey's technique.

7. Response of normal and pathological tissue cultures to "critical" and "subcritical" temperatures has been noted.

8. Comparison of biopsy material, *in vivo* and *in vitro*, in which controlled temperature in the patient is duplicated in the tissue culture test-tube and comparative periodic biopsy and tissue studies are being undertaken.

CLINICAL STUDIES

The following patients were considered hopeless cases of extensive metastatic carcinoma and were referred to our care only after all other available means had been considered either unavailing or useless. Quite naturally, we have not accepted for this series any case in which an orthodox method of treatment is indicated.

Patient had been treated on the gynecological service (Dr Hammond) and out patient department since February 15, 1936, receiving radium implantation (5600 mgm. hours) and deep x-ray therapy (5400 roentgens to each front and back of pelvis) Severe pain in the back ensued with reference down the right lower extremity requiring relief Injection of absolute alcohol was made into the lumbar sac (Dr Scott), with relief of pain for 2 weeks

Patient was admitted to the neurosurgical service July 7, 1936, for operative relief of pain (chordotomy) Diagnosis inoperable carcinoma of the pelvis with rectovaginal fistula, nodular involvement of the cervix, induration of the deep pelvic tissue

Excepting for emaciation and obvious extension of carcinoma into the pelvis, Wassermann and other clinical findings were essentially negative X-ray examination of the skeleton and lungs revealed no metastasis Biopsy disclosed squamous cell carcinoma It was decided to attempt local refrigeration and to observe the response Refrigeration unit with vaginal "bomb" (Fig 4b) was constructed and irrigation of solution at temperature of 60 degrees F (15.5 degrees C) was begun July 21, 1936 Thermocouple readings of cervix (July 30, 1936) showed temperature of 77 degrees F (25 degrees C) 5 minutes after removal of vaginal bomb (22 degrees F 15.2 degrees C below mouth temperature) Continuous irrigations maintained Patient required 1/2 grain morphine sulphate every 4 hours prior to refrigeration On third day following

cold irrigations, pain was relieved and morphine was withdrawn Three weeks later, marked improvement was noted by gain in weight, freedom from pain Pelvic examination (Dr Burnett) 1 month after refrigeration revealed that the rectovaginal fistula was partially healed the congestion and induration about cervix and vaginal mass were markedly decreased Patient was discharged September 2, 1936 and returned home where she cared for her children, undertook housework, and was symptom-free for 2 months

She was readmitted, December 31, 1936, with return of pain, requiring narcotics (given by local physician). Examination revealed induration of the broad ligament, rectovaginal fistula greatly increased in size; extension of the malignancy to deeper pelvic structures X-ray examination was negative for bone and lung metastasis A high thoracic chordotomy was performed, January 25, 1937, with destruction of the pain fibers below the umbilicus, resulting in complete relief of pain Reapplication of refrigeration method, 50 degrees F (10 degrees C), February 18, 1937, produced local improvement in gross tissue about the area of application Her general physical condition improved for 3 weeks Extension of the deep portions of the lesion Death was the result of urinary infection and pulmonary infarction with bronchopneumonia, April 8, 1937.

Summary of pathological and autopsy findings Squamous carcinoma of uterus and cervix (grade IV) with extension to bladder, rectum fifth lumbar vertebra, and sacrum Pulmonary embolic infarction and gangrene right lower

Fig 14 Case 3 R W Carcinoma simplex of the breast grade III following extensive radiation. Diffuse metastases to lung liver scalp brain left femur right eighth and ninth ribs. lobe. Rectovaginal vesical fistula—pyelophrenitis chronic cystitis. Carcinomatous thrombosis of right iliac and femoral veins.

Relief of pain following local refrigeration to the area was an outstanding factor. Improvement in the patient's general physical state with gain of weight was noteworthy. Gross reduction in the bulk of the lesion with tendency toward temporary healing of the rectovaginal fistula was grossly evident. The patient prior to treatment, was bedfast and appeared to be in the terminal stages of her malignancy. Two months of a symptom free state followed the local refrigeration. The patient lived 9 months from the onset of refrigeration treatment.

The benefit of the early deep radiation cannot be overlooked even though the generalized improvement appeared to follow promptly the onset of refrigeration.

CASE 2 M V No N S 3112 Temple University Hospital. White female aged 36 years. Diagnosis carcinoma of the left breast with metastasis to spine skull pelvis ribs and humerus.

Patient was admitted to the neurosurgical service December 20 1936 referred by Dr John Frick. Onset occurred January 1936 with pain between shoulders and in neck and weakness of upper extremities. She became progressively worse and was bedfast on admission. Four weeks prior to admission she developed diplopia with failing vision and pain behind right eye. There were signs of spinal cord compression with weakness of lower extremities.

Examination revealed marked deformity of the cervical spine with occiput almost approximating spine of seventh

Fig 15 Case 3 R W Segmental dermatome chart indicating surface temperatures with marked and definite rise in segments involving the left breast. Note that the response is unilateral to the area of primary tumor involvement.

cervical vertebra. Movements of head were limited to about 15 degrees and pain felt when turning to right. A marked kyphosis was noted in mid-dorsal area. An irregular mass was noted in left breast lower half about 5 centimeters in diameter and fixed to the skin. Large lymph nodes were noted in left axilla and supraclavicular areas. Heart and lungs were negative. No abdominal masses present. Pupils were dilated and fixed. Vision for light and moving objects only. Bilateral sixth nerve palsy. Choking of optic disc 5 diopters with infiltration of nerve heads with malignancy (Dr Lillie). Fingers hands and forearms were very weak more on the left. Triceps reflexes were absent. Marked atrophy and impairment of motor power were noted in all extremities slight left ulna anesthesia. X-ray examination at this time revealed metastasis of the spine ribs skull and pelvis and coniform deformity of a number of vertebral segments.

Extensive involvement precluded local refrigeration treatment to individual areas. It was decided to attempt to reduce the entire body temperature by radiation of the pituitary thyroid and ovarian glands in the hope of inducing a state of physiological hibernation (basal metabolic rate +18 per cent). The following deep x-ray therapy was administered: 200 r to each temporal area 400 r to thyroid pelvis 1600 r to each front and back in addition the cervical spine was given 1600 r on each side and left eye 1600 r (as control). Other lesions were not radiated. Patient was discharged January 12 1937 improved.

A recheck on skeletal system by x-ray March 22 1937 revealed marked improvement compared with the previous examination December 24 1936. The basal metabolic rate on this date was -6 per cent.

Readmission to neurosurgical service for study September 22 1937. Patient was symptom free except for poor vision residual claw like deformity of left hand and the cervical and dorsal spine deformity. The tumor in left breast is about 1/2 former size. Vision is improved (secondary optic atrophy). No other cranial nerve involvement. X-ray examination shows marked degree of new bone formation at sites previously showing bone destruction. Basal metabolic rate -11 per cent. Patient is well and asisting in housework. (Patient continues well 13 months following treatment January 1938).

Fig 16 Case 4 T D Metastatic carcinoma (hypernephroma) involving both knees Left knee received deep radiation treatment. Right knee continued local refrigeration Generalized metastases to brain, scalp, chest, lung, and skeletal areas Rapid diminution in size of the lesion following refrigeration

Although the response in this instance has been dramatic and the patient's sight has returned sufficiently to carry on routine household duties, nevertheless, similar improvements have been noted in cases of widespread metastatic carcinoma of the breast following deep radiation of the ovaries alone

Is it possible that the disturbance in the hormonal influences recognized between the ovaries and the breast involves the question of hyperemia and consequently entails a temperature incidence which has formerly been overlooked?

In this instance, at least, body surface temperature was shown to be markedly reduced 3

Fig 17 Case 4 T D Skin temperature chart showing distinct rise in segmental temperatures concerning the knees, more marked on the left than the right Metastatic lesions larger and more active on the left

months following radiation, and there was as well a fall in the basal metabolic rate. A return toward the normal segmental surface temperature pattern was noted 9 months following radiation, although the basal metabolic rate showed further reduction

The prompt disappearance of the malignant cells seen in the eye grounds afforded an opportunity to observe the cellular response under the ophthalmoscope. The left eye was treated with deep x-ray therapy, but the right eye was permitted to escape treatment in order that it could be observed as a control. The malignant cells disappeared simultaneously in both eye grounds, and there was evidence of healing processes in the areas of untreated bone, indicating the influence of some contributing factor aside from the direct influence of radiation upon the secondary lesions.

The response of untreated secondary lesions to ovarian radiation is well recognized. The close relationship between ovarian function and vasomotor responses concerned in the normal physiology of the breast and other organs is generally recognized So far as the authors can determine, thermal studies have not been made upon cases of primary breast carcinoma with metastasis to determine comparative temperatures before and after treatment of the ovaries As this is the only case so far recorded in which such comparative studies have been made, the observations must be considered as a coincidence until further material has been studied Attention is merely called to the fact that a deliberate attempt was made to reduce the general body temperature and

Fig 18 Case 4 T D Skin segmental temperature chart showing generalized fall in body temperature following radiation of pituitary, thyroid and gonads Note left knee area shows distinct fall in surface temperature which corresponds to distinct clinical improvement in the size and growth

Fig 19 Case 5 M T Irrigation unit with constant thermal control used for clinical observations of the effect of refrigeration on accessible carcinomatous areas Note vaginal bomb connected with irrigating system

the result obtained followed combined deep radiation therapy to the pituitary thyroid and ovarian glands in an attempt to produce a state of subnormal body temperature and metabolism approximating the phenomena of hibernation. Patient continued well and symptom free 9 months after treatment (See final note)

CASE 3 R W No V S 3320 Temple University Hospital White female aged 48 years Diagnosis carcinoma

Fig 21 India ink injection showing reticulo-endothelial system of the bone marrow in the rat Note newborn rat on the left maintains red bone marrow in the segments of the tail and small bones of the feet Illustration to the right indicates adult rat with retention of red bone marrow if the portion of the tail is buried in the abdominal cavity (portion distal to the ring) loss of red bone marrow in portion of the tail exposed to lower temperatures Note disappearance of red bone marrow in the distal portions of the extremities secondary to unfavorable thermal influences (From Huggins and Noonan)

Fig 20 Case 5 M T Surface segmental temperature chart in case of carcinoma of the cervix with extension into the pelvis and visceral segments Note high point of curve correspond strikingly with the underlying visceral areas involved

of left breast with metastasis to skull ribs, left femur spine and pelvis

Patient was transferred to neurosurgical service from x ray and orthopedic departments May 16 1937 with diagnosis of carcinoma of left breast and pathological fracture of left femur Diagnosis of inoperable carcinoma had been made in the surgical diagnostic clinic October 26 1936 Between November 20 1936 and December 8 1936 15 treatments totalling 3 000 r were given over the left breast left axilla in addition 600 r each to anterior and posterior aspect of pelvis to produce artificial menopause February 10 1937 350 r to anterior and posterior aspect of left knee Metastases to pelvic bones and first lumbar vertebra were treated with 4 800 r over sacrum and lumbar spine The secondary lesions persisted and pathological fracture of left femur occurred in May 1937

Examination revealed a mass in the inferior lateral quadrant of left breast about 5 by 6 centimeters The tumor was hard and free to movement but adherent to overlying skin There were palpable lymph nodes in the left axilla The left chest was tender to pressure over fifth rib The remainder of examination was negative The left lower extremity was in a plaster cast There was a radiation scar of left axilla

A knife like hollow refrigeration blade (Fig 4c) was passed laterally from the midline beneath the growth (May 22 1937) for the purpose of local refrigeration The hollow knife blade was sutured to the skin surface and water was circulated with temperature regulated to 60 degrees Fahrenheit (15.5 degrees Centigrade) in the out flow Daily skin temperature readings over the four quadrants and nipple of each breast showed a temperature over the cooling blade consistently cooler 1.8 to 3.5 degrees Fahrenheit (1 to 2 degrees Centigrade) than the other parts of the same and opposite breast while previous to refrigeration the left breast was 1.8 degrees Fahrenheit (1 degree Centigrade) warmer than the right Diameter of tumor mass was 4.5 centimeters May 24 1937 and 4.3 centimeters May 27 1937 Three weeks after onset of refrigeration the entire breast tumor was removed for study The tumor was very firm and measured 2 1/2 to 3 centimeters Patient died June 17 1937 with metastasis to the lungs pleural effusion and pulmonary atelectasis

Summary of pathological findings—Autopsy Carcinoma of left breast medullary carcinoma simplex lungs meta

static carcinoma, bilateral diffuse atelectasis, left lower lobe with effusion; liver, metastatic carcinoma; head, metastatic carcinoma of bones of skull, femur, metastatic carcinoma with pathological fracture, metastatic carcinoma of ribs, spine and pelvic bones; pituitary, metastatic carcinoma

A late case of inoperable metastatic carcinoma was studied after radiation to the ovaries and areas of secondary involvement had been extensively carried out. Secondary lesions, however, persisted and gradually increased. The primary lesion to the left breast was grossly unchanged

The patient's condition was considered terminal and hopeless. Thermal studies were made upon the area of the primary growth. The left breast at all times maintained a segmental temperature higher than the corresponding area on the right.

A hollow blade was designed so that it could be inserted above the pectoral fascia and beneath the growth, permitting cold irrigation to be maintained continuously from beneath the tumor mass. The mass itself was not disturbed at the time of inserting the refrigerating blade and the instrument was maintained in the fascial plane beneath the growth, care being taken not to disturb local circulation to the part. The procedure was completed without bleeding, excepting for the local point of the skin incision near the midline

Gross measurements made of the tumor mass showed a reduction to approximately one-half of its former size, within a period of 5 days after the application of the cooling instrument.

Pathological studies of the tumor itself, by Dr. Lawrence Smith, revealed a cell necrosis similar to that noted in the normal tissues surrounding the point of entry of the refrigerating blade. There appeared to be a direct relationship between the advent of "refrigeration" and the tissue changes, both in the normal and in the pathological areas.

The case is noteworthy only in that surface temperatures demonstrated a response to local refrigeration. The size of the tumor mass diminished to a more firm and compact nodule, which probably can be ascribed to the ischemic effect produced by cold applications in the region of the tumor.

CASE 4. T. D., No. N. S. 3390, Temple University Hospital. White male, aged 24 years. Diagnosis hypernephroma—metastasis to pelvis, femur, knee joints, and lungs.

Patient was admitted June 14, 1937 to neurosurgical service for relief of pain. He was referred from x-ray and orthopedic departments with diagnosis of metastatic carcinoma of pelvic bones and distal end of both femurs. Biopsy was done December 12, 1936, from right ischium (carcinoma, renal? or prostatic? in origin).

Prior to admission June 14, 1937, he had been treated by radiation; 2,000 r. given to anterior right pelvis; 2,900 r. to posterior aspect of pelvis on right, and 3,200 r. to each anterior and posterior aspect of left knee.

Fig. 22 Geschickter's chart¹ showing the most common sites for bone metastasis for carcinoma in the human (and sarcoma), according to skeletal localizations. Note striking similarity to Huggins' and Noonan's observations regarding the areas concerned with thermal influence upon growth and development of red bone marrow.

Examination revealed the following. The positive findings were marked emaciation; subcutaneous nodule in the scalp 1 centimeter in diameter; liver edge about 5 centimeters below right costal margin, diffuse tender indurated area in right buttock posterior to right hip and under scar of operation for biopsy. A large indurated swelling was present in the distal end of right thigh and knee which was hyperemic and tender. Movements of right knee limited.

Refrigeration to right knee was started June 25, 1937. The return flow of the circulating water was kept at 55 degrees Fahrenheit (12.7 degrees Centigrade). July 12, 1937, there was a very evident improvement in the right knee. The swelling and tenderness subsided. Pain was controlled in the area covered by the refrigeration apparatus but pain in hips and left lower extremity became so severe that opiates were given. A high dorsal bilateral chordotomy was performed (Dr. Scott) July 27, 1937. August 9, 1937, the circumference of right knee, 36 centimeters, left knee, 33 centimeters. The refrigeration apparatus was applied again and temperature of return flow of water was lowered to 45 degrees Fahrenheit (~2 degrees Centigrade). Biopsy from right tibia and scalp tumor on August 10, 1937, revealed metastatic carcinoma, adrenal in origin. August 16, 1937, circumference of right knee 34 centimeters, left knee, 31.5 centimeters. Patient died August 25, 1937, from urinary obstruction and infection.

Summary of pathological and autopsy findings: Lungs, metastatic tumor; adrenals, primary hypernephroma; left femur, pathological fracture, metastatic tumor, right knee, metastatic tumor. A small metastatic area was noted in the middle third of the right tibia. No other metastasis noted distal to elbows and knees.

¹Geschickter, Charles F., and Copeland, Murray. *Tumors of Bone*, 1936, p. 481. Published by Am. J. Cancer.

SUMMARY OF FIVE CASES

Case	No	Age Sex	Diagnosis and complaints	Metastatic locations	Treatment	Clinical observations	Result
1 (A)	NS 1959	K.L. F 34	Carcinoma of cer- vix. Bedfast. Intractable pain	Pelvic organs (rectovaginal vesicle fistula) gth lumbar verte- bra and sacrum. 5	NS 1950	M.T. F 41	Carcinoma of cer- vix. Intractable pain. Bedfast	Pelvic organs (rectovaginal vesicle fistula) Lungs	Radium 7200 mgm. hr X ray 5500 r each A. and P. pel- vis. Refrigeration to cervix —13 wks	Local improvement of pri- mary growth. P. ce. fr. m pain. Increase in weight	Terminal renal infection and uterine hemor- rhage

The generalized metastasis noted in this patient progressed in spite of full radiation. The rapid progress of the disease was characteristic of metastatic hypernephroma.

An opportunity was afforded to compare the results of deep x ray therapy to the left knee with refrigeration treatment to the right. The response to the radiation therapy on the left was definitely more pronounced than the response to surface cooling in the area of tumor on the right. Pain, however, was relieved in the right knee following refrigeration, whereas this symptom persisted in the left. Pathological studies by Dr. Smith revealed marked degeneration and necrosis of the cells of the tumor mass on the right with almost complete disappearance of the tumor excepting for a firm plaque within the capsule of the knee joint. The gross reduction in size of the tumor following refrigeration was measurable the circumference diminishing 2 centimeters in 10 days.

Surface temperature readings indicated a level in the involved knee joint approximating the surface temperature of the trunk and comparison between the two sides indicated that local refrigeration reduced surface temperature on the right 1.8 degrees Fahrenheit (1 degree Centigrade) below the left.

The case is of interest in view of the widespread metastasis of the scalp throughout the entire

body with the exception of the upper extremities and the areas below the knees. A small nodule was found deep within the right tibia.

A fall in general body surface temperatures was noted following radiation of the pituitary, thyroid and gonads (see Case 2).

CASE 5. M. T. No. NS 3369. Temple University Hospital. White female aged 41 years. Diagnosis: squamous carcinoma of cervix with pelvic extension.

The patient was admitted to the neurosurgical service on June 13, 1937, from the gynecological department for relief of pain. Diagnosis: inoperable carcinoma of cervix with rectovaginal fistula. Squamous carcinoma of cervix (grade III). Radium (1200 mgm. hours) had been given August 6, 1936. Between September 14, 1936, and January 24, 1937, total implantation of radium was 6000 mgm. hours. X-ray therapy over pelvis November 6, 1936, to January 8, 1937, five treatments of 500 r each were given over anterior and posterior aspects of pelvis.

The lower abdominal and back pain was not relieved by x-ray and radium therapy and at the time of admission to the neurosurgical service opiates were necessary to control pain.

The physical examination was essentially negative except the secondary anemia and pelvic findings. Biopsy of the cervix and pelvic examination were made by Dr. C. S. Miller June 15, 1937. The pelvis was completely filled by a large mass of tumor. A thick hard rim extended as a ridge along the left broad ligament. The normal structures could not be identified and a fistulous opening about 2 centimeters in diameter opened directly into rectum just posterior to the cervix. The biopsy from cervix was diagnosed squamous carcinoma of cervix grade III (Dr. Lawrence W. Smith).

Continuous refrigeration was started June 17, 1937, by applying a cooling bulb to the cervix. The circulating water through the bulb returned at a temperature of 60 degrees Fahrenheit (15.5 degrees Centigrade).

The pelvic pain was completely relieved when the cooling bulb was in apposition with the cervix and fistulous opening into rectum. Patient's general condition was improved. The cervix became hard and contracted. Spontaneous hemorrhage of uterus occurred September 10, 1937. There was marked pyelitis. Patient died September 12, 1937.

Summary of pathological and autopsy findings. Lungs, metastatic tumor of right lower lobe, abdominal retroperitoneal lymph nodes, metastasis from pelvic carcinoma; cervix uteri, malignant erosion—squamous carcinoma, grade IV.

In this instance, the gross results of treatment to the primary growth were not as striking as in Case 1, but the prompt and full relief of pain was a most gratifying sequence to the induced local refrigeration. The patient insisted upon maintaining the cold vaginal "bomb" and on several occasions when the apparatus required adjustment, was impatient for its reapplication. The tumor mass became firmer to palpation and the fistula became slightly contracted. Degeneration in the area of refrigeration was noted in the tissue at necropsy but the classification of malignancy from grade III to grade IV indicated actual increased activity of the cells, as determined by mitotic figures.

With the relief of pain, the patient's general condition improved sufficiently to occasion the desire of discharge from the hospital because of her subjective freedom from symptoms.

Pyelitis was a complication in this instance and a sudden spontaneous hemorrhage into the uterus, 2 days before death, was followed by subsequent hemorrhage. The patient expired, pain-free until the end.

EVALUATION OF STUDY

Definite relief of local pain followed the application of subnormal temperatures in the region of active growth complicated by pain. There was apparent gross retardation in growth as well as diminution in the size of the carcinomatous lesion in the cases so far treated.

Dr. Lawrence Smith summarizes the microscopic changes noted in tissues obtained from this group of cases as follows:

"In a study of the tissues removed from a preliminary series of 5 patients who have been treated by chilling the tissues over a considerable period of time, by one or another of the instruments described, it has been found that more marked degenerative and necrotic changes seem to occur in the treated lesions than were present in the original biopsy material or in other untreated metastatic foci. With the amount of ma-

terial thus far available, it is impossible to state whether or not these changes will occur regularly or whether they are merely coincidental. It is of interest in this connection to note that in one of the cases (Case 3), an instance of breast carcinoma, similar degenerative lesions occurred around the point of insertion of the instrument, suggesting that the relative avascularization occasioned by prolonged chilling may well play a part in the development of such retrogressive tissue changes."

Important observations relative to thermal influence of the blood-forming organs in mammals and birds have been noted by Huggins, Blockson, and Noonan.¹ Loss of red bone marrow function occurred in the periphery exposed to low temperatures, activity being retained when the thermal levels approached those of the deep body areas.

Blood cells may be considered as products of a normal "metastatic tumor," the bone marrow. Observations relative to the response of this tissue may be of significance in the consideration of malignant cellular proliferation. The fields of malignant cellular activity (according to Geschickter's chart) closely correspond to the selective fields of higher temperature requirements of red bone marrow. The peripheral fields of lower segmental temperature are apparently unfavorable for rapid activity of either "normal" or "malignant" cell proliferations.

SUMMARY

1. Segmental body temperatures vary in the normal individual and there is a striking elevation of temperature in the region of the breast segments, fourth and fifth thoracic, when compared with adjacent areas of the thorax.

2. The incidence of metastatic malignancy lies almost entirely within the zone of higher segmental temperatures of the body (Fig. 22) whereas the distal portions of the extremities rarely harbor metastatic lesions. These portions represent the lowest segmental temperatures recorded.

¹Huggins, C., and Blockson, B. H., Jr. Changes in outlying bone marrow accompanying a local increase of temperature within physiological limits. *J. Exp. Med.*, 1936, 64, 253.

Experiment to determine the relative response of bone marrow in the distal bones with changes in temperature. "A common factor in all of the experiments was an elevation of temperature beyond that prevailing in these distal regions and it is felt the evidence warrants the opinion that the cause of the improvement is thermal."

Huggins, C., and Noonan, W. J. An increase in reticulo-endothelial cells in outlying bone marrow consequent upon a local increase in temperature. *J. Exp. Med.*, 1936, 5, 275.

"In adult mammals and birds there is a great quantitative difference in the reticulo-endothelial system content of the bone marrow of the central bones as compared with the distal outlying bones." After an intravenous injection of India ink it was at once apparent in all mature mammals studied, that the amount of carbon taken up by the central bones was much greater as compared with that of the outlying bones of the extremities (limbs and tail).

in the normal, as well as in the pathological, cases so far studied

3 In the hopeless and far advanced cases of metastatic malignancy where pain was a prominent symptom the method of refrigeration, when applied to the area of involvement, brought about prompt and gratifying relief of pain Temporary improvement in the general nutritional state of the patient was also noted

4 Where the principle of "refrigeration" has been applied directly to the region of the malignant growth, certain favorable gross clinical and pathological changes have been noted in those cases so far studied

5 The principle of "hibernation" was induced in one case in this series by means of radiation to the pituitary, thyroid, and ovarian glands A fall

of 20 per cent in the basal metabolic rate followed with a corresponding fall in segmental surface temperature Widespread metastatic lesions disappeared within 3 weeks and at the present time (9 months following treatment) the patient is free from the symptoms of malignancy

Further observations, both as to comparative biopsy studies of the cell areas treated by "refrigeration," as well as controlled tissue growth *in vitro*, under various "critical" thermal levels will be presented later by Dr Lawrence Smith and his staff

The authors wish to express their indebtedness to Dr Lawrence Smith professor of pathology Dr W Edward Chamberlain professor of roentgenology and Dr Augustus McCravey fellow in the International Cancer Research Foundation for their assistance advice and critical analyses in this problem

PAGET'S DISEASE OF THE NIPPLE

Sir GEORGE LENTHAL CHEATLE, K C B., C.V.O., F.R.C.S., F.A.C.S. (Hon.), London, England

IN 1874, Sir James Paget described superficial changes on the surface of the nipple which became known as "Paget's disease of the nipple." Sir James also stated that these signs were often associated with carcinoma of the breast. Hence a description of Paget's disease naturally divides itself into first a description of the superficial changes and second of the conditions of the underlying breast. Emphasis should be laid upon the fact that no history of a case of Paget's disease is complete unless the state of the underlying breast is included.

SUPERFICIAL CHANGES

The superficial changes are a slowly spreading, rosy red, dry rash covered by fine, white scales, and with a hard defined edge. It should be understood that Paget described purely the clinical picture and that he did not publish a description of the microscopical appearance of the rash. His colleagues, Butlin and Bowlby, made the earliest such descriptions but they were indeterminate in character. The finding which they emphasized was the presence of certain large cells with clear cytoplasm and lateral and often crescentic nuclei, these cells received the dignified name of "Paget's cells." Their nature probably gave rise to a greater amount of speculation than they deserved. Some people for a time regarded them as psorosperms and believed that they were the cause of all the trouble associated with their presence.

Dr. R. J. Ludford has recently examined these cells from a cytological standpoint. He concluded that they arose in the basal layers of the epidermis. A cell will first enlarge, then undergo mitosis, and the daughter cell will eventually desquamate. Dr. Ludford regards "Paget's cells" as degenerative. Whether they are or are not genetically related to the carcinoma cell with which they are often associated is by no means clear. It is not known whether they appear before or after the carcinoma.

The classical clinical signs enumerated by Paget are caused by different types of disease, hence, it appears that the cause should be determined on merits of each example after microscopical study.

From the Kings College Hospital, London and the Chicago Tumor Institute

Presented in the Symposium on Cancer, before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937

Some of these lesions are described as follows:

1. Jacobaeus and more recently Sir Robert Muir have pointed out with truth that the most frequent cause of the surface lesion is a direct spread of carcinoma cells, arising from the upper duct, into and among the normal epidermic cells of the nipple surface where they remain confined to the normal boundaries of the epidermis for considerable periods. The surface of the nipple often is lined with these cells when the normal epidermis has been shed. The nipple becomes level with the areola chiefly by its atrophy and retraction. This type of duct carcinoma is always non-papillomatous and can be distinguished as causing the surface disease in 15 of 19 cases exhibiting the classical signs of the superficial disease. In 13 of the 19 cases "Paget's cells" were also present. In 3 of the 16 cases there were no changes in the underlying breast. Except in 2 cases no anatomical continuity existed between the carcinoma of the upper ducts and other changes that occurred in the remaining cases. This lesion, being the most commonly associated with the surface changes, was most probably occurring in the cases described by Paget.

It would be interesting to be able to state definitely how far only the intra-epidermal spread from an upper duct carcinoma can extend. I believe that it is capable of only limited extension. When clinical signs of Paget's disease extend to opposite side, for example, the extension consists in the formation of Paget's cells that Ludford described and contains no breast carcinoma cells.

The carcinoma in the upper duct which always exists may extend downward in the duct for a considerable distance but a place is reached where the extension downward ceases and there is an interval of varying length in different cases of normal duct before the epithelial neoplastic lesions in the depths of the breast are reached. This statement is true for all my cases except 2 in which the epithelium of the whole breast from the upper ducts downward was in a state of carcinoma.

The malignancy of the carcinomas of the upper ducts in all the 16 cases was of a low grade and no lymphatic vessels below the epidermis were invaded except in 1 instance the subdermal vessels were invaded but the axillary glands were free.

2. "Paget's cells" alone can be seen in the epidermis of the superficial lesion exhibiting the

classical clinical signs of the disease. As before indicated, Dr Ludford regards them as being degenerative. I have 1 case in which only Paget's cells can be detected on the nipple surface and no carcinoma can be seen in an upper duct, but the neoplastic epithelial changes in the underlying breast are remarkable. They look like carcinoma and the natural boundaries of terminal ducts and acini are greatly distended but not transgressed. There is no direct continuity between these deep changes and the superficial lesion, and no superficial duct carcinoma could be detected.

3 A carcinoma arising not in the upper duct but spreading upward from elsewhere in the breast can give rise to the signs of Paget's disease by causing shedding of the epidermis and appearing on the surface of the nipple.

4 Carcinoma of the sebaceous glands on the surface of the nipple have caused the clinical signs of Paget's disease. I have one such case.

No "Paget's cells" appear in types 3 and 4. At present it is impossible to say whether the superficial lesions of types 1 and 2 precede or follow those of the underlying breast.

NEOPLASTIC CHANGES IN DEPTHS OF BREAST

Lesions of the deep structures may be described as follows:

1 This type is remarkable in that the epithelial neoplasia distends, but does not penetrate natural boundaries. Despite this fact the condition looks malignant. It occurs chiefly in the terminal ducts and acini, not in the acini alone, and in more than one part of the breast. The changes in the ducts are often papillomatous. There is no evidence whatever to show the existence of a direct anatomical continuity of disease between the epithelial neoplasms in the depths of the breast and the non papillomatous duct carcinoma in the upper ducts. In one case I could detect only the formation of Paget's cells on the nipple surface and could not discover a carcinoma in the upper duct region. In the depths of this breast were found marked epithelial neoplastic developments in the terminal ducts and acini which were distended by them but there was no transgression of their normal boundaries. In some instances benign looking papillomas exist in the ducts of middle caliber while carcinoma exists in the deeper distribution of the duct.

2 Definite carcinoma has established itself sometimes in one part only and more rarely in two or more parts. The lesions are found to occur chiefly in the terminal ducts and acini which are separated from the carcinomas in the upper duct by intervening, perfectly normal ducts. The type

is often papillomatous and is much more malignant than its accompanying non papillomatous lesion in the upper duct or ducts. The lymphatic glands in the axillæ are usually affected.

From our description it will have been seen that in type 1 of the surface lesions, carcinoma of the upper duct may extend upward within the epidermis and downward into the duct, also that there are usually changes in the underlying breast which in some instances are definitely carcinomatous and in others the epithelial neoplasias are confined within normal boundaries and cannot be described as being carcinomatous.

DISCUSSION OF FINDINGS

Reference is here made only to those cases in types 1 and 2 in the surface lesions. In all except 2 of these cases a very definite and varying length of the duct connecting the upper and lower lesions remained normal. In the 2 cases just mentioned in which the whole breast epithelium was in a state of carcinoma the diseased condition was too chaotic to form any opinion as to its origin. In the other cases, the upper and lower lesions appeared to be separate foci of disease for important reasons, as follows: the upper lesion may exist without deeper epithelial neoplastic changes in the depth of a breast, the deeper lesion may exist and yet there may not be carcinoma but only Paget cell formation on the surface of the nipple; the deeper lesions may not be definitely carcinomatous although those in the upper ducts are carcinomatous; the carcinoma of the depths is much more malignant than that of the surface, and the disease of the depths, whether benign or malignant, is often papillomatous whereas that of the surface lesion is always non papillomatous.

The answers to the questions (a) why should there be separate lesions or (b) why should there be 2 lesions at all, are wrapped in mystery.

Continuity of growth, either downward or upward and transplantation, do not explain their separate existence. Can it be that inducing agents of disease can pass downward from the surface to reach the underlying breast or can they reach it via the blood stream?

SUMMARY

1 The classical signs of Paget's disease refer to several separate conditions.

2 The description of Paget's disease of the nipple is incomplete unless the conditions of the underlying breasts be also described.

3 These conditions have been given.

4 The merits of each case should be decided after the examination of whole microscopic sections of the breast including the nipple.

THE TREATMENT OF CANCER OF THE RECTUM

J. P. LOCKHART-MUMMERY, F.R.C.S. (Eng.), London, England

WHEN first I began to practice surgery and to assist the late Herbert Allingham of St Mark's Hospital, excision of the rectum for cancer was a horrible operation and the results were very bad. Two methods were in vogue.

First, for a growth low down in the bowel the rectum together with the growth was dissected free from the surrounding tissues, the surgeon's left forefinger inside the rectum being used as a guide. The bowel was divided above the growth and the stump was brought into the upper angle of the wound and sutured to the skin. The large wound was left open and packed with gauze. No preliminary colostomy was performed. A great deal of suppuration occurred and the patient was usually confined to bed for 4 to 6 months, and the result, if the patient survived, was that the bowels acted through a fecal fistula in the situation of the coccyx. There was no control and considerable prolapse of mucous membrane was common.

The other method was that first advocated by Kraske. The coccyx and part of the sacrum were removed, and the rectum was exposed by incising all the tissues posterior to it. That portion of the rectum containing the growth was cut out and the ends were joined together over a rubber tube, the back wound being partly closed. The join in the rectum almost invariably broke down, there was considerable sepsis, and if recovery took place, there was often a bad stricture at the point of union and a fecal fistula behind. Not only were the immediate results unsatisfactory, but the ultimate results were bad. Early recurrence of the growth was frequent and the functional results were poor.

The two factors which chiefly handicapped the surgeon at that time were shock and sepsis. However carefully the operation was performed, or however satisfactory the result appeared at the end of the operation, subsequent sepsis broke everything down and spoiled the most carefully planned operation. To escape from these difficulties we performed a preliminary colostomy and so redesigned the operation that it could be performed without soiling the wound. A very great improvement in the results was immediately obtained, and the mortality in my own cases per-

formed by the perineal method, which I first described in 1920, came down to about 6 per cent. Since then steady progress has been made in improving the operation and reducing risks, so that today my mortality for private patients operated upon by the perineal route is only 4 per cent for the last 150 operations.

Primary sepsis should no longer occur, but a large cavity is inevitably left by the removal of the rectum which has to heal slowly by granulation.

The perineal operation for cancer of the rectum is now an established procedure for growths of the rectum proper and has shown the best results of any method for growths situated in the ampulla or lower part of the rectum. It is not, of course, suitable for growths at the upper end of the rectum, where some form of combined operation is necessary.

For a long time the abdominoperineal operation, which has been described by Miles, was the usual method employed for high growths, but in recent years better results have been obtained by doing the perineal part of the operation first and finishing in the abdomen. There are still differences of opinion as to the exact technique to be employed in dealing with tumors at the upper end of the rectum, but my own preference is for a two-stage operation with preliminary colostomy and removal of the rectum by the perineo-abdominal route. I have completed this operation in 55 minutes and consider it both quicker and easier than the abdominoperineal technique.

When we are discussing the relative values of different kinds of treatment for the same disease, it is obvious that it is both undesirable and impossible to arrive at any satisfactory conclusion until a considerable number of cases have been traced over a long period of years. I think everyone will agree that we are not justified in claiming any case of cancer as cured unless the patient is alive at least 5 years after the removal or disappearance of the growth. Many cases are claimed as cures on a 3 years' basis, but it is becoming increasingly evident that this period of time is too short and that at least 5 years' survival is necessary before we can claim a cure. It is a debatable point whether one is ever justified in using the word "cure" in such a disease as cancer, and in taking 5 years' survival as a cure, we have to bear in mind that it is merely a conventional phrase. Practically it is necessary, if we are to gain any

accurate knowledge of the relative values of different operations and methods of treatment, that we should take some definition of cure, and I think it will be generally agreed that a 5 years' survival period is the best compromise.

Fortunately, the results in a very large number of cases are now available, and it is a recognized principle both in the best hospitals here and in London, that when the results of operations for cancer of the rectum are published the cases should be traced for a period of 5 years or longer. I do not propose to trouble you with a great mass of statistics; moreover the personal experience of one man is probably of more interest than the accumulated experience of many, provided the figures are large enough, and it has the further advantage that a more or less uniform technique has been used in all the operations.

As regards the perineal operation in two stages there are 388 cases. The immediate mortality was in the private cases only $4\frac{1}{2}$ per cent and in the hospital cases 10 per cent.

The increased mortality in the hospital cases is, I am sure, not accounted for by any difference in the quality of the nursing or facilities for after treatment, but by the fact that as a rule hospital patients present themselves for treatment at a more advanced stage of the disease than the private patients, and that they are in poorer general condition. This is, I think, proved by the fact that the St. Mark's Hospital statistics show that there was no immediate mortality at all among those hospital cases in which patients were operated upon before the tumor had passed through the rectal wall and invaded the neighboring tissues, all the deaths occurring in the advanced cases.

You will see, therefore, that the risks of the operation are not serious, as $4\frac{1}{2}$ per cent may be considered a low operation risk for a severe operation on persons whose average age is well over 60 years.

The combined operation for growths at the upper end of the rectum does not show such good results as regards operative risk. The fact that the operation necessarily takes considerably longer and that it involves interference with the abdominal cavity, no doubt accounts for the difference. It must also be remembered that surgeons are obliged, in bad borderline cases when the tumor is large and there are many glands, to use the combined method, as sufficient removal cannot be ensured by the perineal route alone, there thus being a tendency for the perineal operation to be chosen in favorable cases and vice versa. The mortality rate for the combined operation as we now perform it at St. Mark's Hospital is about 20 per cent.

It will be evident that from the point of view of the immediate risks of the operation the perineal method gives the best results, but another factor which is quite as important is the recurrence rate. It is no use performing an operation with a low operation risk if the patient is going to get early recurrence of the tumor.

There are 142 patients who have survived the operation 5 years or more, giving a percentage cure on a 5 years basis of $52\frac{1}{2}$ per cent.¹ It is interesting to note that there are in all 58 patients who have survived the operation 10 years or longer. The figures for the combined operation show only 28 per cent cures so that the perineal operation comes out as the best on both counts. For this reason my usual practice now is to make use of the perineal operation for cases in which the growth is confined to the rectum only, and to use the combined operation for cases in which the growth is at the rectosigmoid junction, and in advanced cases in which adequate removal can not be obtained by the perineal route.

The most interesting results, however, are seen when we study those cases that have been graded. There are two methods of grading now in use: Dr. Broder's method and Dr. Cuthbert Dukes's.

Broder's method. This relies upon the amount of differentiation of the cells comprising the tumor as seen under the microscope. Actually we have found that the decision as to the grade of malignancy depends more on the relative arrangement of the cells than on the number of so called undifferentiated cells. This method has the advantage that it makes it possible by examining biopsy specimens before operation to obtain some idea of the type of tumor with which we have to deal. The examination of a single specimen is not very trustworthy and several removed from different parts of the tumor should be examined if possible.

The result of grading 600 cases by this method at St. Mark's Hospital gives the following:

50 per cent of the cases were found to be in Grade 2
26 per cent of the cases were found to be in Grade 3
12 per cent of the cases were found to be colloid growths
6 per cent of the cases were found to be in Grade 1
2 per cent of the cases were found to be in Grade 4

When these cases were traced it was found that the survival rate in the first 3 years was—

	Per cent
Grade 1	80
Grade 2	65
Grade 3	52
Grade 4	34
Colloid growths	60

¹In calculating these figures patients dying from other causes than cancer or who are untraced are disregarded.

This shows that the patient's chances are better for Grades 1 and 2 than for the other grades

This form of grading, while certainly useful, leaves entirely out of account the most important factor from the point of prognosis, namely, the extent of spread of the tumor at the time of operation

Dukes's method This method depends upon the extent of invasion of the surrounding tissues at the time of removal of the tumor. The whole removed rectum is carefully dissected and the limits of the growth are defined. All glands are examined microscopically and their situation is charted, and all veins are also examined. The tumors are then graded A, B, and C. This histological method of grading has only been in use since 1928.

The survival rate on a 5 years' basis of cases thus graded shows:

93 per cent survival in A
65 per cent survival in B
23 per cent survival in C

This demonstrates what might have been expected, namely, that the prognosis from operation is in direct proportion to the stage which the growth has reached at the time of operation, but it was not till these results had been worked out that we realized the enormous importance of early operation. If the growth can be removed by operation while it is still in the A stage, the chance of a cure on a 5 years' basis is approximately 100 per cent, while if it has reached the C stage, it is under 25 per cent.

Still another important fact emerges from these figures. The operative risk is in direct proportion to the stage of the tumor at the time of operation, almost all the operative deaths having occurred in the C cases.

We can hardly hope by operation to obtain better results as regards the cure of cancer of the rectum in cases in which the tumor is still in the early stage at the time of operation, and we must now concentrate on attempting to improve our results by (1) getting the patients to submit themselves for treatment at an earlier stage of the disease when the prognosis is good, and (2) improving our treatment of those cases which are in the advanced stage of the disease when they are first seen.

Unfortunately, the latter cases still form the great majority of the total and it is deplorable that we seem to have no means at our disposal of remedying this state of affairs. It is sad to think that we have discovered how to treat cases of cancer of the rectum so successfully as to cure just on 100 per cent, but that we are not able to apply treatment to more than a small percentage

Fig. 1. A, Growth limited to wall of rectum. B, Extension of growth to extrarectal tissues but no metastases in regional lymph nodes. C, Metastases in regional lymph nodes (Reproduced by kind permission of Dr. Cuthbert Dukes from "Histological Grading of Rectal Cancer," *Proc Roy Soc Med*, 1937, 30: 25-30)

of the total cases for reasons which are outside our control.

TREATMENT BY RADIUM AND X-RAYS

No satisfactory statistics are here available. There are several reasons for this. The early cases of cancer of the rectum treated by radium were so unsatisfactory that for a time the treatment was almost abandoned, and it is only in the last few years that any real success has been achieved.

The earlier cases were all treated by radium needles and with large doses acting for a short period. The result was almost invariably extensive sepsis and sloughing. Occasionally a good result was obtained, and there are a few patients who have survived 5 years, but most of them were made worse rather than better. The practice now is to use much smaller doses, acting over a longer period, and my own practice and that of most of my colleagues is to use radon seeds instead of needles.

I can give you today only my own opinion with regard to this form of treatment, for what it is worth. In cases in which the tumor is so advanced that operative removal is contra-indicated radium and x-rays are of no use. In fact my own experience would tend to show that by such treatment the unfortunate patient is only rendered more unhappy and distressed without any material prolongation of life.

In cases in which the tumor is in an early stage, but owing to advanced age, concomitant disease, or even total refusal of the patient to submit himself to operative removal, operation is impossible, radium may be used with success. I have seen quite a number of small, early, rectal carcinomas

TABLE SHOWING RESULTS AND SUBSEQUENT HISTORY OF PATIENTS TREATED BY PERINEAL EXCISION

Private Cases

8	1916	M	61	A	C	R	2 yrs.	Died of recurrence in liver
9	1916	M	52	B	R		9 mos.	Died of recurrence
10	1916	M	43	A	R		12 yrs.	In Oct 1930 developed and P.T. which was operated upon D
11	1917	M	66	B	R	R	15 yrs.	Untraced since May 1932
12	1917	M	67	B	R	R	2 yrs.	d.o.c.
13	1917	M	53	B	R	R	2 yrs.	Died of recurrence
14	1917	F	63	B	R	R	2 yrs.	Died of recurrence in pelvis
15	1917	M	68	B	R	R	6 mos.	Died of recurrence
16	1917	M	68	A	R	R	5 yrs.	Untraced since
17	1917	M	57	A	R	R	14 yrs.	d.o.c. 1931
18	1917	M	53	A	R	R	7 yrs.	Died of and P.T. in colon which recurred after removal
19	1917	M	57	A	R	R	15 yrs.	d.o.c. 1932
20	1918	M	55	B	C	R	18 yrs.	
21	1918	F	40	A	R	R	6 yrs.	Died of recurrence in vag. na
22	1918	F	62	A	R	R	2 yrs.	Died of recurrence
23	1918	F	58	B	R	R	3 yrs.	Died of recurrence
24	1918	M	50	B	R	R	4 yrs.	Died of recurrence
25	1918	F	36	B	R	R	3 yrs.	Died of recurrence in col. n
26	1918	F	36	B	R	R	1 yr.	Died of recurrence in vagina
27	1918	F	70	B	R	R	1 yr.	d.o.c.
28	1918	F	56	B	R	R	17 yrs.	(Had Graves' disease for 20 yrs.)
29	1918	F	44	B	R	R	2 yrs.	Recurrence in lumbar glands
30	1919	M	56	B	R	R	18 yrs.	
31	1919	M	72	B	R	R	11 yrs.	d.o.c. 1931
32	1919	M	51	B	R	R	6 yrs.	Died of recurrence
33	1919	M	64	B	R	R	6 yrs.	Died of recurrence Had Hodgkins disease at time of operation
34	1919	M	54	A	R	R	18 yrs.	
35	1919	F	67	B	R	R	18 yrs.	
36	1919	F	54	B	R	R	0 yrs.	d.o.c.
37	1920	F	54	B	R	R	4 yrs.	Died of recurrence
38	1920	F	52	B	R	R	14 yrs.	d.o.c.
39	1920	F	44	A	R	R	1 yr.	Died of recurrence
40	1920	F	60	B	R	R	17 yrs.	
41	1920	F	43	A	R	R	16 yrs.	
42	1920	F	57	A	C	R	13 yrs.	Untraced since
43	1920	M	51	B	R	R	1 yr.	Recurrence in lymphatic system
44	1920	F	63	B	R	R	4 yrs.	Recurrence in liver
45	1922	M	72	A	R	R	3 yrs.	d.o.c. during 6th yr.
46	1922	F	45	A	R	R	7 yrs.	Recurrence in sacral glands
47	1922	M	61	B	R	R	7 yrs.	Untraced since
48	1922	F	51	B	R	R	2 yrs.	Recurrence
49	1922	M	61	A	R	R	15 yrs.	
50	1922	M	52	A	R	R	12 yrs.	Untraced since
51	1922	F	52	C	R	R	4 yrs.	Recurrence
52	1922	M	62	A	R	R	2 yr.	Recurrence
53	1922	M	60	A	R	R	4 yrs.	d.o.c.
54	1922	M	60	A	R	R	4 yrs.	Recurrence
55	1922	F	53	A	R	R	3 yrs.	Recurrence
56	1922	M	52	C	R	R	Few months later local recurrence died after ray burn	

A, very favorable B, medium cases C, border line cases D, death from operation R, recovery from operation D.O.C., died from other causes and P.T., and primary tumor

TABLE SHOWING RESULTS AND SUBSEQUENT HISTORY OF PATIENTS TREATED BY PERINEAL EXCISION—Continued

Private Cases						
Case	Year of operation	Sex	Age	Type of case	Result of operation	Length of survival and remarks
57	1922	M	47	B	R	3 yrs. Recurrence
58	1922	F	40	A	R	27 yrs. In 1954 had 2nd P.T. removed and radium applied
59	1922	F	39	C	R	3 yrs. Recurrence
60	1922	M	53	C	R	Sepsis
61	1922	M	58	A	R	3 yrs. Recurrence
62	1922	M	40	A	R	15 yrs.
63	1922	F	47	B	R	3 yrs. Recurrence
64	1922	F	75	C	R	Heart failure 3 wks after operation
65	1922	M	50	B	R	5 1/2 yrs. Died of 2nd P.T. in lung
66	1923	M	45	B	R	2 yrs. Recurrence
67	1923	F	64	A	R	11 yrs. d.o.c.
68	1923	F	64	A	R	Site of failure
69	1923	M	64	A	R	4 yrs. d.o.c.
70	1923	F	63	A	R	6 yrs. In Dec 1929 of 2nd P.T. in stomach
71	1923	M	59	A	R	1 yr. Recurrence (had diabetes and diverticulosis)
72	1923	F	60	A	R	3 yrs. d.o.c.
73	1923	F	70	B	R	8 yrs. d.o.c.
74	1923	F	68	C	R	Recurrence
75	1923	F	63	B	R	12 yrs.
76	1923	F	60	B	R	1 yr. Recurrence in liver
77	1923	F	60	A	R	8 yrs. Died probably 2nd P.T.
78	1923	F	50	A	R	12 yrs. d.o.c.
79	1923	M	50	A	R	Untraced since operation
80	1923	M	71	B	R	12 yrs.
81	1924	M	72	B	R	4 yrs. Recurrence
82	1924	M	63	B	R	1 yr. Recurrence
83	1924	M	65	B	R	13 yrs.
84	1924	F	71	B	R	2 yrs. d.o.c.
85	1924	M	64	B	R	2 yrs. Recurrence
86	1924	M	59	B	R	6 yrs. d.o.c.
87	1924	M	64	B	R	Untraced since operation Went to Australia
88	1924	M	67	B	R	13 yrs.
89	1924	F	61	A	R	6 yrs. Recurrence
90	1924	F	56	A	R	11 yrs.
91	1924	M	50	A	R	5 yrs. Recurrence during 6th year
92	1925	F	63	A	R	8 yrs. October 1933 died of growth in uterus 2 1/2 P.T. died
93	1925	F	58	B	R	7 yrs. Untraced since
94	1925	M	55	B	R	2 yrs. 2nd P.T. got stenosis Died

entirely disappear after treatment with radium. In some of these cases there has been recurrence and the patients have been treated again; in some there has been no recurrence.

When, as sometimes happens, we see an adenocarcinoma of the rectum as large as a dollar entirely vanish in 3 to 4 weeks, leaving not even a scar behind, we see what, to my mind, is a modern miracle. By no other known means could such an amazing result be obtained!

In order to obtain it, however, it is necessary that exactly the right dose of radium should be given, and that all the seeds should be correctly placed. Unfortunately this is not easy to achieve. The correct dose for any individual tumor cannot be accurately estimated by any means now at our disposal, and the placing of the seeds is at best a somewhat haphazard performance. But we must not be discouraged. What can be done once, or a few times, can be done again, and our technique is improving.

At present radium should be used only in cases in which the tumor is easily accessible, so that the seeds can be more or less accurately placed, and only in cases in which operative removal is for some reason contra-indicated. We bring both our-

selves and the treatment into discredit if we attempt, even at the patient's urgent wish, to do the impossible by treating an inaccessible and unsuitable growth with radium.

My own practice is to scrape away as much of the growth as possible with a Volkmann's spoon, and then plant the seeds beneath and around the base as evenly as I can at 1 centimeter distance from each other, the dose being approximately 2 millicuries per centimeter with 0.5 screening.

Squamous epithelioma of the anal margin is in my opinion better treated by radium than by operation at the present day, and in such cases I now always advise radium.

As regards the use of x-rays or radium to prevent recurrence after operation, my own opinion is that they are of little use. It may satisfy the patient and his relatives, and help to distribute the responsibility in a bad case, but practically I do not think it is much good. Rays cannot be used on the liver, where most of the recurrences take place, and local recurrence should now seldom occur if the operation has been properly performed and the case was originally a suitable one for operation.

Fig. 1 Incision starts in seventh interspace in mid-clavicular line and is carried posteriorly. It extends upward between the vertebral border of the scapula and the spine. The seventh, sixth, fifth, and fourth ribs are divided as indicated.

For example, the second case of 3 to be described presently, noted a rather sudden intolerance to hot liquids. Swallowing of hot fluid produced a burning sensation retrosternally. It is possible that this may be considered the earliest symptom of carcinoma of the esophagus. Careful analysis of a large series of cases will be necessary to prove this point. In any event, more attention must be paid by the physician to the patient's complaints and more exact methods utilized to establish diagnosis.

Any patient who develops a disturbance of the act of deglutition should be referred immediately to a competent radiologist for x-ray examination. It is possible to miss an early growth of the esophagus with the barium mixture usually employed

Fig. 2. An incision is made in the mediastinal pleura, exposing the esophagus.

for gastro-intestinal study. I wish to emphasize this point because this is exactly what happened with the second case reported herewith. The initial fluoroscopic and x-ray examinations were negative. The persistent efforts of the radiologist finally disclosed a very small filling defect in the esophageal wall which was visualized with the aid

Fig. 3 The esophagus is dissected free from its attachments and a tape is placed around it. Traction on the tape aids materially in the subsequent dissection.

Fig. 4 The mediastinal pleura above the aortic arch is incised and the esophagus is freed from the surrounding structures. The tumor-bearing portion of the organ with a wide margin of normal tissue is removed after double ligation and division.

THE SURGICAL TREATMENT OF CARCINOMA OF THE THORACIC ESOPHAGUS

With a Report of Three Successful Cases

JOHN H. GARIOCK, M.D., F.A.C.S., New York New York

SINCE Torek's report of the first successful resection of the thoracic esophagus in 1913, progress in the field of esophageal surgery has been slow indeed. The anatomical location of the organ, the technical difficulties often attending the operative procedure, the poor general condition of the patients when first seen by the surgeon, the prohibitive mortality rate which has come to be associated with the operation, all have been factors in retarding the progress of this branch of surgery. In addition, the medical profession has for a long time, regarded x-ray therapy as the only form of treatment for this disease. That this generally accepted view is erroneous is proved by a casual survey of the literature dealing with the late end results of x-ray therapy. The 2 or 3 isolated cases that have been reported to have survived at least 2 years following radiation have in the final analysis no real significance. The most recent report of a large series of cases comes from the Memorial Hospital in New York. The paper was published by Watson in 1936 and includes a group of 666 cases. These Watson divided into 2 series. The second group constituted those most recently treated. In this group, 68 patients were treated by divided doses of x-ray. Of these 33 were alive at the time of his report, 8 for 1 year or more, and 2 for 2 years. In the first series the average length of life was only 4.8 months. When one considers that carcinoma of the esophagus is usually a slow growing tumor, the prolongation of life with radiation therapy may have only relative significance, especially inasmuch as preliminary gastrostomy was performed in almost every case, thus insuring an adequate food intake.

The use of radium applied directly to the carcinoma by means of the esophagoscope has little to commend it. The danger of necrosis of the esophageal wall with perforation and fatal mediastinitis, is too obvious to warrant consideration of this remedy. It can be seen therefore, that radiotherapy holds little promise of complete

eradication of the disease and that serious consideration of this form of treatment for esophageal carcinoma should be reserved for the obviously inoperable cases.

The rapid advances made in recent years in the field of thoracic surgery have given impetus and encouragement to a few surgeons to attempt surgical excision of the thoracic esophagus for carcinoma. That initial attempts have been attended by a high mortality is natural and to be expected. The same has been true in the development of every other surgical procedure of any magnitude. Constant persistence in one's efforts until a mature judgment in the selection of cases suitable for operative intervention has been developed and until the operative technique itself has become standardized and possibly simplified, will, undoubtedly, have the effect of rapidly lowering the mortality rate to a more reasonable level.

Unfortunately, the patient with carcinoma of the esophagus usually comes to the surgeon after the lesion has advanced so far locally as to preclude excision, or when his general condition because of malnutrition and dehydration, is so poor that any surgical procedure would result in a fatality. When one remembers that most of these patients are elderly, and that there may be associated organic disease of other organs, such as myocardial damage, pulmonary disease, nephritis, and arteriosclerosis, it is not surprising that the number of patients that may be submitted to operation is indeed small.

As with carcinoma of other organs, early diagnosis is of the greatest importance. This means that the patient will reach the surgeon in good condition and so be better able to withstand the severity of the operation. A lower mortality will necessarily follow. One should not wait for the effects of starvation and dehydration to become evident before considering surgical intervention. Usually when great weight loss has occurred the condition will probably be found inoperable. One should regard, therefore, changes in the act of swallowing in a person past 40 years of age, with the same suspicion as he does change in bowel habit in the diagnosis of carcinoma of the colon.

Fig 10. Roentgenogram of esophagus following ingestion of barium, showing an irregular stenotic defect between the eighth and tenth dorsal vertebræ. Case 1.

tration of high caloric intake, 1 or 2 transfusions, and the performance of a preliminary permanent gastrostomy, preferably of the Janeway type. Extending the preparatory period over 1 to 3 weeks is time well spent. The patient's general condition may be so greatly improved that he will be able to withstand successfully the severity of the operation. In order to cleanse the ulcerated surface of the neoplasm and possibly thereby diminish considerably the peri-esophageal inflam-

Fig 12. Microscopic section of specimen showing infiltrating squamous cell tumor with epithelial pearl formation. Case 1.

Fig 11. Gross specimen of resected esophagus. Unfortunately, the organ was opened through the neoplasm. Case 1.

mation which often exists, I have recently suggested repeated washing of the esophagus for 3 or 4 days before the operation. A Levin tube is passed to a point just above the neoplasm and through it saline or boric acid solution is irrigated past the growth. The washings descend into the stomach and emerge through the gastrostomy tube. This method of cleansing the surface of the

Fig 13. Photograph of patient 4 months after esophagectomy was performed, showing the rubber esophagus in place. Case 1.

Fig 5 Beginning suture of the mediastinal pleural flaps is shown. The infra aortic remains of the esophagus are brought to lie entirely above the arch.

of a much heavier mixture of barium by the method known as the mucous membrane technique.

It is fair to state, therefore, that a patient past 40 years of age who presents any disturbance in swallowing which persists for longer than 2 or 3 weeks should be submitted for x ray examination by a competent radiologist, who, should the initial findings prove negative, must employ the mucous membrane technique to prove or disprove the results of the first examination. If the symptoms persist despite completely negative findings, a repetition of the examination after a month would be in order. Or better still, esophagoscopy can be

Fig 6 The cervical portion of the esophagus is exposed and the remainder of the organ is drawn out of the chest.

performed. This would definitely establish the diagnosis. If the x ray findings are suggestive of a tumor, the patient must be esophagoscoped by a competent operator. This phase of the examination is most important because the esophagoscopist is able to localize the tumor accurately, note its size, determine the presence or absence of ulceration and the relative fixation of the tumor, and, what is most important, remove a small section for microscopic study.

If a patient's condition is fairly good, and if the findings by x ray and esophagoscopy indicate that the tumor may be operable, then the patient may be prepared for the radical operation. This entails careful attention to mouth hygiene, adminis-

Fig 7

Fig 7 A subcutaneous channel is made extending from the lower end of the cervical incision as far as the second rib.

Fig 8

Fig 8 The esophagus is drawn through the channel and

Fig 9

its end is sutured to the transverse skin incision as shown. Fig 9 The thoracic wound is closed by enclaving the contiguous seventh and eighth ribs with heavy catgut sutures.

Fig 15. Gross specimen showing the very early lesion. This photograph indicates the extent of contraction of the resected organ. The specimen was about twice as long when first removed. Case 2.

Fig 16. Microscopic section showing squamous cell carcinoma with pearl formation. The absence of infiltration beyond the mucosa is noteworthy. Case 2.

A vertical incision is made in the mediastinal pleura from the under surface of the aortic arch down to the diaphragm (Fig. 2). The pleural edges are dissected away from the underlying esophagus so as to form two flaps. These should be carefully preserved because they must be used later on in the operation to close the mediastinum. It is not difficult to free the esophagus bluntly throughout its circumference at one point. A tape is placed around the organ at this site and traction permits the surgeon to free the esophagus throughout its extent (Fig. 3). It is important to ligate the small esophageal arteries rising from the aorta and to divide the small branches of the vagus nerves. If care is exercised in ligating all small vessels, there will be surprisingly little loss of blood. This is important.

Unless the neoplasm is hopelessly attached to the aorta, the operation should be continued. Not infrequently, the tumor may be fixed to the mediastinal pleura on the right side. Our first case presented this complication. It was found necessary to excise a piece of the right pleura along with the tumor in order to effect a radical removal. This resulted in a bilateral pneumothorax, but the effect on the patient was barely discernible. The opening in the pleura was packed and later closed with a running stitch of catgut. During the course of the operation, probably every 10 or 15 minutes, it is advisable to remove all packings and retractors, close the gaping wound and have the anesthetist expand the lung by increasing the pressure in his apparatus. Any circulatory or respiratory depression that may have occurred is immediately overcome.

An incision is made in the mediastinal pleura above the arch of the aorta and is extended as far

as the apex of the thorax (Fig. 4). Pleural flaps are fashioned here also and the underlying esophagus is freed from its surrounding attachments by careful finger dissection. The most shocking part of the operation occurs when the esophagus is separated from the posterior surface of the aortic arch. This maneuver must be executed with great care and with as little trauma as possible. The next step consists of division of the esophagus with the carbolic acid cautery between heavy silk ligatures about 1 inch above the diaphragm. The distal end is inverted into the stomach with two pursestring sutures of silk. This may be reinforced by a layer of mattress sutures of chromic catgut. The esophagus is again divided between heavy silk ligatures above the neoplasm, and the tumor-bearing portion is removed (Fig. 4). This, I believe, is an important modification of the original Torek technique. Removal of the tumor immediately eliminates the infected portion of the esophagus and decreases greatly the possibility of spillage and contamination of the pleural cavity. It also obviates dragging the tumor-bearing area through the thoracic aperture into the neck wound. It was at this point that the ligature slipped off the end of the esophagus in our first case and permitted contamination of the pleura with the highly infected fluid present in the ulcerated surface of the carcinoma. An almost fatal empyema soon followed. It was because of this accident that the technique was changed as described.

The remaining segment of the esophagus is brought to a position above the aortic arch by means of a curved clamp placed from above downward behind the arch and grasping the ligature

Fig. 14. Roentgenogram following ingestion of heavy mixture of barium. This shows a small filling defect in the esophageal wall. Case 2.

carcinoma which is usually infected should materially decrease the incidence of postoperative mediastinitis.

During the 7 to 10 days following the gastrotomy, considerable improvement may be noted. The patient should be given about 6 ounces of high caloric fluid food through the gastrotomy tube every 3 hours. The necessary vitamins and minerals must be included in these feedings. The patient should be encouraged to take additional food by mouth because it has been found that the admixture of saliva is beneficial. Often, it is wise to transfuse the patient before operation. A transfusion during or immediately after the operation is imperative. This helps materially in combating operative shock.

Anesthesia. The combination of avertin and ethylene gas anesthesia seems to be an ideal one. Ethylene is the least irritating of all the inhalation anesthetics, and causes little or no circulatory depression. The only objection to its use is that the actual cautery cannot be used to divide the esophagus during the operation. But its many advantages far outweigh this minor inconvenience. The combination of avertin and ethylene was very satisfactory in the 3 cases reported here with it. It is important that the services of a competent anesthetist be obtained. The anesthetic

must be administered under varying degrees of positive pressure during the operation to vary the extent of inflation of the lung. I am convinced the recovery of our 3 patients was in no small measure due to expertly administered anesthesia.

OPERATION

The operative technique to be described is a modification of the operation developed by Torek and reported by him in 1913. The operation is more tedious than difficult. The steps of the procedure should be carried out methodically without haste. It is important to avoid unnecessary bleeding and to prevent infiltration of the mediastinum with blood. This requires careful hemostasis. The lobes of the lung should be handled as gently as possible and care should be exercised not to traumatize the arch and descending portion of the aorta. These precautions will have the effect of greatly decreasing the operative shock.

The patient is placed on his right side with the head resting on the abducted right arm and his back close to the edge of the operating table. The left arm is elevated and wrapped in sterile towels after preparation and placed in the care of a sterile nurse. One or two sandbags placed against the anterior chest region will prevent the patient from rolling forward on the operating table. After the usual skin preparation the patient is draped in such a way as to leave exposed the chest, upper abdomen, left shoulder and arm and neck.

The incision begins in the seventh interspace in the mid clavicular line and is continued posteriorly along the course of the seventh interspace (Fig. 1). It is then carried upward between the vertebral border of the scapula and the spine as far as the third rib. The thoracic musculature is divided in the line of the skin incision. All bleeding points are carefully ligated before the thoracic cavity is entered. An incision is made in the seventh interspace dividing the parietal pleura with the intercostal muscles. The seventh, sixth, fifth and fourth ribs are quickly divided about 1 inch from the spine and the intercostal vessels are ligated with hemostatic sutures. A rib spreader is inserted thus affording a clear view of the left thoracic cavity. The lobes of the lung usually collapse when the chest is opened but complete collapse should not be permitted to take place because of possible circulatory embarrassment. The extent of collapse can be controlled by the anesthetist. The arch and descending aorta stand out in sharp relief. The esophagus which lies to the right of the aorta in the mediastinum can neither be felt nor seen. It may be possible to palpate the carcinoma.

Fig 23 Side view showing the close approximation of the tube to the skin surface.

which makes for added precaution against contamination (Fig. 6). A subcutaneous channel $1\frac{1}{2}$ inches in width is made extending from the lower end of the neck incision down to a point on the left side opposite the second rib (Fig. 7). A transverse incision $1\frac{1}{2}$ inches in length is made at this site and the esophagus is drawn through this tunnel. The esophagus is sutured to the skin incision with interrupted silk stitches. The cervical incision is closed and a dressing is applied (Fig. 8).

Finally, the patient is turned again on his right side. Here also care must be exercised to maintain asepsis. Gowns and gloves are again changed and clean instruments are utilized for the final steps. The chest wound is reopened and the mediastinum is inspected. All blood clots are removed and overlooked bleeding points ligated. The mediastinum both below and above the arch of the aorta is closed by suturing the two flaps of mediastinal pleura with a running stitch of catgut (Fig. 5). I believe it is important to drain the thoracic cavity in every case. Many intrathoracic complications may develop and it is a comfort to have a vent for at least the first 3 or 4 days after operation. For this purpose, a stab wound is made posteriorly in one of the lower intercostal spaces and a medium sized soft rubber tube is inserted for 2 or 3 inches. This should be fastened to the chest wall by means of a suture passed

Fig 24. Photograph of tube devised for patient by Dr Margolin. The small side vent allows for the escape of swallowed air. There is no leakage at any time. Case 2.

through a cuff. When the patient is returned to bed, the outer end of the intercostal tubing should be placed under water in a bottle beside the bed, insuring a closed system.

The thoracic wound is now ready for closure. The ribs are approximated by passing heavy chromic gut sutures around the seventh and eighth ribs (Fig. 9). The parietal pleura and intercostal musculature are closed together with a running stitch of catgut. Previous to this step, the lobes of the lung should be inflated by the anesthetist. The divided thoracic musculature is next repaired with interrupted sutures of plain catgut and the skin is closed in the usual way. After the dressing is applied, the anesthetist should again inflate the lungs until air bubbles no longer appear at the outer end of the intercostal tube which has been placed in a basin of water.

Postoperative care. When the patient is returned to bed, he should be placed in a semirecumbent position. The Gatch bed is ideal for this purpose. Measures should be instituted to combat shock. Although hypodermic medication, stimulating enemas, external heat, etc., have undoubted value, the most effective remedy is a transfusion of whole blood. Sufficient morphine should be given to relieve pain. During the first 3 or 4 days, fluids should be given by clysis or, preferably, by the continuous intravenous drip method. Five per cent glucose in saline solution makes an ideal combination. If the inversion of the esophageal stump into the stomach has been satisfactory, fluid may be given by the gastrostomy tube. If the inversion has not been quite satisfactory, it is wise to delay gastrostomy feeding until the sixth or seventh day. Regular feedings should be given as soon as the general condition of the patient permits.

The care of the esophageal stump is important. Beginning the second day the patient should be encouraged to swallow fluids, which must be caught in a basin. This cleanses the esophagus

Fig 19

Fig 19 Front view showing the rubber esophagus in place

surrounding the cut end of the organ (Fig 5). It will be noted in the drawing that the end of the esophagus has been protected with an envelope of rubber dam in order to minimize contamination. Warm packs are placed in the mediastinum, all other packings and string pads and retractors are removed, and the wound is temporarily closed with a few through and through sutures.

The patient is now turned on his back. In doing so, great care must be exercised to maintain asepsis. The neck and anterior chest region are exposed and prepared. A complete clean instru-

ment tray should be at hand for this stage. Gowns and gloves should be changed. An incision is made along the anterior edge of the left sternocleidomastoid muscle. The latter structure and the great vessels are retracted externally. The lateral thyroid vein is ligated and divided and the thyroid lobe is retracted medially (Fig 6). The cervical portion of the esophagus is easily identified and dissected free. A blunt hook is placed beneath it and traction draws the remaining portion out of the thoracic cavity. This is another modification of the Torek technique.

charge from the hospital is chiefly that of experimenting with various sizes of rubber tubing until the rubber esophagus fits snugly into the fistula above. Leakage of ingested fluid from the upper end may be obviated by having the patient compress the orifice against the rubber tubing. Due to the fact that the ability to belch gas has been removed by the operation, mechanical disturbances may develop which become distressing to the patient. For instance, our second patient could not eat without swallowing considerable air. It soon became evident that a column of air formed in the rubber esophagus, gradually rising to a higher level as the patient continued eating. Finally, a reservoir of air collected in the remains of the esophagus above the fistula. A violent contraction of the esophageal stump forced the air and considerable fluid food out of the fistula around the tube and no amount of finger pressure could overcome this tendency. The constant soiling at meal time became very distressing to the patient. In order to overcome this, a partial antethoracic esophagoplasty was performed about 8 months after her original resection, forming a skin-lined tube continuous with the upper esophageal stump and ending at a point opposite the lower sternum (Figs 21, 22, and 23). Food is now conveyed the remainder of the distance to the stomach by a removable rubber tube (Fig 24). At the present time, there is no leakage whatsoever from the lower end of the skin-lined esophagus.

The suggestion has been made that the newly formed skin-lined esophagus be extended by another plastic operation so that it becomes con-

tinuous with the gastrostomy opening, thus obviating the use of any tube. This should not be difficult from the technical standpoint. However, the experiences of Eggers and others with this procedure indicate that the reflux of gastric juice into the skin-lined esophagus, causes digestion of the epithelium with the formation of ulcers and fistulas. For this reason and because the patient has no inconvenience from the use of the short rubber tube, we have not completed the esophagoplasty beyond its present stage. The use of a loop of small or large bowel placed subcutaneously to restore esophageal continuity involves an operation of too great magnitude and risk to warrant serious consideration in the type of case under discussion. If the object of our original operation, namely, eradication of the malignant growth, has been attained, little will be accomplished by attempting difficult procedures to restore esophageal continuity, especially if the patient is comfortable with a removable rubber esophagus.

Up to the present writing, there have been reported 6 successful resections of the thoracic esophagus for carcinoma. The cases reported in this paper constitute the seventh, eighth, and ninth. Undoubtedly other attempts have been made, but these have not appeared in the literature probably because of the fact that the patients died after operation. Despite this small number of successful recoveries, I am convinced that the operation should be undertaken more often and that the incidence of operability can be greatly extended. The operation need not be followed by a prohibitive mortality if the preoperative preparation is carefully done and if the

Fig 25. X-ray of esophagus following ingestion of barium showing an almost complete occlusion beginning at the ninth dorsal vertebra. Case 3

and helps to restore the act of deglutition. It is important to maintain good mouth hygiene and toward this end, patients should be encouraged to chew gum.

The intrathoracic situation must be watched closely and will usually give the surgeon concern during the first week. Some indication of what is

Fig 26. Gross specimen showing neoplasm completely encircling the esophagus. Case 3

going on within the chest may be obtained by the temperature, the pulse rate, physical signs, x-ray examination of the chest, and the amount and character of the drainage through the intercostal tube. If there is no dyspnea if the temperature, pulse, and physical signs are within normal limits and if the drainage becomes less and less each day, the tube may be removed permanently. If x-ray examination and the clinical course indicate the presence of an empyema, surgical drainage will be indicated. It is important not to delay this step too long because these patients, in view of their precarious condition, cannot stand infection for very long.

As soon as the patient's condition warrants it, usually about the third week, the continuity of the esophagus should be established by inserting a rubber tube into the upper fistula and connecting it with the gastrostomy tube (Figs 13 and 19). The tube is held in place by carrying a tape around the patient's neck and attaching it to a safety pin which is inserted transversely into a rubber cuff placed about the tube about 2 inches below its upper end. The patient is now encouraged to take all nourishment by mouth. In order to swallow solid food, he must thoroughly masticate it and mix it with more fluid than the normal person so that it will descend more easily through the tube into the stomach. From the experience with our 3 cases, I am convinced that the admixture of saliva is important for the well being of the patient. From the moment that eating by the usual route was commenced, these patients began to improve rapidly and gained weight. It is hardly necessary to add that the rubber esophagus should be removed frequently and cleansed.

The care of the patient subsequent to his dis-

Fig 27. Microscopic section showing infiltrating squamous cell carcinoma. Case 3

postoperative day. On this day also, the rubber esophagus was inserted and the patient began taking most of her feedings by mouth (Fig. 13).

During the following 2 months, the patient continued to improve slowly. All feedings were being taken by mouth. A regular schedule for these feedings had been prepared for the patient and it was assumed that she was following the directions implicitly. The empyema cavity gradually contracted down and was represented by a narrow cleft extending toward the upper portion of the pleural cavity for a distance of about 6 inches. The lining of this cavity became rigid, and it was felt that surgical closure at some future date would be necessary.

Around the beginning of August, which was approximately 3 months after the original esophageal resection, the patient began to develop edema of the legs and feet, irregular reddish-brown skin lesions on the dorsum of the hands, a beefy-red tongue, and gastro-intestinal symptoms consisting of bouts of diarrhea and abdominal cramps. Upon closer questioning, it was found that the patient had been taking nothing but clear broths for a period of 3 weeks. She presented the picture usually associated with pellagra. When placed upon an adequate intake of protein, concentrated vitamins, fats, carbohydrates, and minerals, these symptoms disappeared. The lesions on the dorsum of the hands were no longer noticeable after 2 weeks of treatment. The patient began to recover her lost weight and gained an average of 3 pounds a week.

About the middle of November, 1936, approximately 6 months after esophagectomy, there was noted a small swelling mesial to the cervical scar and just above the inner end of the left clavicle. This lump appeared to be quite superficial and measured about an inch in diameter. It was firm and not tender. Through a small incision, a biopsy specimen was taken which showed the same histological characteristics as the original esophageal growth. This may very well represent an implantation carcinoma, the implantation occurring at the time of the original operation when the ligature slipped off the distal end of the cut esophagus and gross spilling occurred. I do not believe that this represents a metastasis or an extension along lymphatic channels because the tumor was attached to the skin, was not situated in the anatomical location of lymph nodes, and was not part of the wall of the esophagus. The mass was treated intensively with x-ray and apparently completely disappeared during the following 6 weeks. Up to the present time there has been no recurrence at this site.

Since then, repeated check-up roentgenograms were taken of the chest and the long bones for possible metastases. These have been consistently negative.

In May of 1937, 13 months after the original esophagectomy, the patient was admitted again to the hospital for operative closure of the chronic empyema cavity. This was accomplished in 2 stages which consisted of removal of the ribs overlying the cavity, thus permitting the overlying soft parts to fall in so as to obliterate it.

At the present writing, 18 months after esophagectomy, the patient is slowly regaining the weight which she lost during her stay in the hospital. She is taking all her food by mouth and utilizes the rubber esophagus. She has no difficulty with her makeshift swallowing mechanism and takes care of the cleaning and manipulation of the tubing herself.

CASE 2. Mrs. H. M., aged 53 years. This patient was first seen on November 2, 1936. She presented the following history: Eight weeks before she noted an uncomfortable sensation behind the lower sternum when she swallowed warm liquids. She described it as being similar to the sensation following the swallowing of a fish bone. This discomfort persisted and was noted only at meal time when drinking hot liquids. A few weeks later she noted that solid

foods produced the same discomfort. She was referred for x-ray studies on October 17, 1936, exactly 6 weeks after the onset of symptoms. Films taken by the ordinary technique failed to disclose any esophageal abnormality. Dr. Bendick repeated his examination and was able to demonstrate a small irregularity in the esophagus only after he employed a heavier mixture of barium (Fig. 14). The findings indicated a small tumor mass measuring about an inch in diameter situated approximately 3 inches above the cardia. There was no obstruction to the passage of the barium. He ventured the opinion that this tumor was probably malignant. One week later esophagoscopy was performed by Dr. Kramer, who found a small sessile growth situated in the lower esophagus 34 centimeters from the incisor teeth. The surface of the tumor did not appear ulcerated. A biopsy specimen revealed squamous cell carcinoma. Past, family, and personal histories were irrelevant except for the fact that a cousin died of carcinoma.

Physical examination was completely negative. The heart and lungs were negative. Blood pressure: systolic 140, diastolic 85. The situation was discussed freely with the patient who possessed more than average intelligence, and radical surgical excision of the esophagus was offered as the only definite method of curing her of her condition. She finally elected to undergo the operation.

She was admitted to the Mt. Sinai Hospital on November 14, 1936. Preliminary studies showed a normal urine; hemoglobin, 75 per cent; red blood cells, 4,650,000; white blood cells, 7,000; polynuclear leucocytes, 57 per cent; monocytes, 1 per cent, lymphocytes, 42 per cent. Wassermann was negative.

On November 16, a Janeway gastrostomy was performed under avertin, gas-oxygen anesthesia. Her convalescence following this procedure was uneventful. Feedings through the catheter were started on the second postoperative day.

Resection of the esophagus was performed on November 28, under avertin, ethylene anesthesia. The technique of this operation is described in the text. After the esophagus had been mobilized, a small tumor was felt in the right lateral wall about 3 inches above the diaphragm. Considerable difficulty was encountered in inverting the stump of the esophagus into the stomach, due, first, to the depth of the opening, second, the short esophageal stump, and third, because of the wide excursion of the diaphragm during respiration. The ligature around the distal end slipped off, but there was no soiling. It was possible to invert the esophageal end with 4 Lembert stitches of chromic catgut.

The patient's pulse during the course of the operation, which consumed 2½ hours, varied between 88 and 98. The breathing was regular. A continuous intravenous drip of 5 per cent glucose in saline was started during the middle of the operation. More as a prophylactic measure, a transfusion of 500 cubic centimeters was given about an hour after the operation.

Examination of the specimen. Specimen consists of a resected portion of the esophagus, 6 centimeters in length (Fig. 15). The adventitia of the esophagus appears to be covered with a layer of muscular tissue which shows no external evidence of any tumor invasion. Within the center of the specimen is a small, somewhat soft mass which, after the esophagus is opened, is disclosed to be a flat sessile tumor mass situated approximately 2 centimeters from either end of the specimen. This mass is 2 centimeters long, 14 millimeters wide, and is elevated from the surface of the mucous membrane about 1-centimeter. The mass is attached by a broad base to the mucous membrane of the esophagus. It is light pinkish gray in color, and has a number of small surface depressions. Microscopic examination shows a hornifying squamous cell carcinoma with epithelial pearls. There is no infiltration beyond the mu-

operation is performed with due consideration of the need for careful hemostasis, the avoidance of rough handling of the thoracic structures, and the necessity of preventing contamination of the pleural cavity. The 3 cases reported herewith constitute 3 attempts at surgical excision of the thoracic esophagus for carcinoma with no operative mortality.

CASE REPORTS

CASE 1. Mrs B. B., aged 48 years. Was first seen on April 11, 1936. She presented the following history: Six months before admission to the hospital, she noted substernal pain, shooting in character, which radiated from the upper epigastric region toward the throat and occurred 4 to 6 times daily. This was not related to her meals. In the last 4 months she experienced a continuous dull burning sensation in the lower chest anteriorly and also, posteriorly near the spine. During this period there was increasing difficulty in the swallowing of solid food. For the last 2 months she subsisted only on fluids and some solid food. She lost 12 pounds in the last 3 months. The past family and personal histories were irrelevant.

Examination showed a well developed and fairly well nourished woman weighing 141 pound. Blood pressure systolic 110, diastolic 90. Patient had no teeth. Gums were in good condition. Heart and lungs were negative. Peripheral vessels were thickened. X-ray examination by the usual technique disclosed a stenotic lesion about 2½ inches in length in the middle third of the esophagus extending from level of eighth to tenth dorsal vertebrae. The margins of this lesion were irregular and the lumen of the esophagus was displaced anteriorly (Fig. 10).

The patient was admitted to the Mt. Sinai Hospital on April 12, 1936. Laboratory examinations: Wassermann negative, urine negative, hemoglobin 84 per cent, red blood cells 4,850,000, white blood cells 9,000, polymorphonuclear leukocytes 65 per cent, lymphocytes 32 per cent, monocytes 3 per cent. Esophagoscopy by Dr R. Kramer showed an ulcerated granular neoplasm beginning on the posterior wall of the esophagus 30 centimeters from the region of the upper incisor teeth. A biopsy specimen revealed a horrifying infiltrating squamous cell carcinoma.

On April 20, 1936, a Jareway gas trotomy was done through a small left upper rectus incision. The wound healed by primary union. Feedings through the tube were started on the second postoperative day. They were given every 2 hours at first; the interval between feedings was gradually increased to every 4 hours.

Nine days later radical resection of the esophagus was performed following the original Torek technique. After ethylene anesthesia was used. Palpation revealed a thickening in the esophagus about 3 inches below the arch of the aorta. The tumor did not seem to be fixed to the aorta. After the esophagus had been freed the carcinoma was seen to be fusiform in shape and measured about 3 inches in length. Because of its intimate attachment to the mediastinal pleura on the right side, it was found necessary to remove a small piece of the right mediastinal pleura, thus producing a bilateral pneumothorax. This caused little change in the patient's condition. As the esophagus was being drawn out of the chest into the neck wound, the silk ligature at the distal end of the esophagus slipped off, with the escape of a considerable quantity of esophageal contents. From the subsequent course the thoracic cavity was contaminated at the same time. During the course of the operation the patient received a transfusion of 500 cubic centimeters by the citrate method.

Examination of specimen. The specimen consists of a portion of the esophagus measuring 9.5 by 2 centimeters (Fig. 11). The external aspect is distinctly roughened, dull pinkish in color, and shows the presence of numerous fine adhesions. On one side near the center are seen a cluster of 3 lymph glands, the largest about 1 centimeter in diameter, the others 0.7 centimeter. These nodes are soft and elastic. On section there is seen a small grayish white area in the periphery of one of them. On opening the specimen the mucous membrane is seen to be smooth and glistening, pale grayish pink in color and freely movable except over the tumor growth. Two centimeters from the proximal portion of the specimen is an elevation in the mucous membrane 1 centimeter above the surface, which appears somewhat soft and over which the mucosa is not movable. This portion had been opened before receipt of the specimen and is seen to consist of grayish pink strands of tissue, having a finely granular appearance and suggesting an infiltrating neoplasm. On the wall opposite this area is a similar infiltrating mass with the same characteristics. Extending distally from each of these nodules for a distance of 3 centimeters and lying on the surface of the muscularis are 2 irregular areas containing an ulcer base which is covered by yellowish green slough in places and in other situations by finely granular tumor tissue. The border of these ulcerated areas are firm and inelastic. The lumen of the esophagus over the site of the neoplasm is distinctly narrow, measuring 2.5 centimeters when opened in comparison with 5 centimeters in the uninvolved esophagus. Microscopic examination reveals an infiltrating, hornifying squamous cell carcinoma with epithelial pearl formation. One lymph node shows early metastasis (Fig. 12).

Postoperative course. First day: Temperature 104° to 102° degrees Fahrenheit. General condition was good. Air bubbles and several ounces of bloody fluid drained through the thoracotomy tube.

Second day: Temperature 103° degrees Fahrenheit, pulse 128. No dyspnea was noted. Straw-colored fluid drained from the left pleural cavity.

Third day: Temperature was 104° degrees Fahrenheit. Patient was slightly dyspneic and restless. The heart was not displaced to the right. Percussion 100% tympanic posteriorly on the left side. Red blood cells numbered 2,000,000, hemoglobin 43 per cent, white blood cells 20,800, polymorphonuclear leukocytes 80 per cent.

Fourth day: Transfusion of 500 cubic centimeters was given by the citrate method.

Seventh day: Under local anesthesia an incision was made over the left ninth rib posteriorly and a portion of the rib was resected. A small walled-off empyema cavity containing grayish turbid fluid smelling foul was found. The cavity was packed with iodoform gauze. Following this procedure the temperature dropped to a lower level. It varied between 101° to 100° degrees Fahrenheit. X-ray examination of the chest revealed a large encapsulated collection of fluid and air in the left upper chest extending from the apex to the seventh rib posteriorly.

Accordingly another operation was done on the seventh postoperative day. The upper end of the original operative incision was reopened. The sixth and fifth ribs were found exposed. Parts of the sixth fifth and fourth ribs were excised, unroofing a large collection of foul smelling pus and air which was supra-apical in location. The surface of this empyema cavity was lined with a spongy grayish membrane. The cavity was packed with iodoform gauze and the wound was left wide open.

Following this procedure, the patient's convalescence proceeded rapidly. The temperature dropped to normal and her general condition improved. Another transfusion of 500 cubic centimeters was given on the twenty-seventh

were approximated with sutures of fine chromic catgut. A second layer of sutures approximated the subcutaneous tissues over the skin sutures. The remaining skin edges on the chest wall were now undermined extensively on each side. They were then sutured together with ease in front of the newly formed tube. The esophageal fistula was now circumscribed by an incision which left attached to the mucous membrane a small rim of skin. The anterior and lateral borders of the esophageal stump were now sutured to the upper end of the newly formed skin tube. The remaining skin above was then sutured to the upper edges of the lateral chest flap on each side. It was necessary to make two small relaxing incisions on each side of the chest wall at the lower end of the lateral flaps in order to relieve tension.

Convalescence following this procedure was uneventful. The wounds healed by primary union and the patient was discharged on the twelfth day. In the meantime, gastrostomy feedings were being continued. Since then the patient has utilized an ingenious short rubber esophagus devised by Dr. Margolin to bridge the short distance between the lower end of the newly formed esophagus and the gastrostomy (Figs 21, 22, 23 and 24). It will be noted in the photographs that the tube bears a small side vent in the form of a catheter which extends upward into the esophagus and permits escape of swallowed air, but no food. The patient now eats normally without discomfort or leakage.

At the present writing, it is 11½ months since esophagectomy. The patient is approaching her original weight and has returned to her profession of teaching school.

CASE 3. History No 413618. J. T., aged 49 years, was admitted to the Mt. Sinai Hospital on September 3, 1937, presenting the following history. Five weeks ago the patient began to experience difficulty in swallowing solid foods. He noted a sensation of obstruction at about the level of the ensiform cartilage, and, while eating, he felt the food slowly passing the site of obstruction. This passing was accompanied by heartburn. These symptoms rapidly became worse during the succeeding 2 or 3 weeks. He noted gurgling sounds beneath the ensiform cartilage while swallowing liquids. About 2 weeks before admission he began to regurgitate small quantities of food immediately after the ingestion of his meals. The patient lost 20 pounds in weight, and became progressively weaker. There was no back pain.

Personal history. The patient was a painter of structural steel and had worked on ship and subway construction. His habits were regular, and, aside from occasional indulgence in alcohol, the patient had never been given to excesses of any sort. His average weight when well was 155 pounds. His weight on admission was 135. The past history was irrelevant.

Examination showed a well developed, well nourished, middle-aged man who presented considerable difficulty in swallowing fluids and solids. There were no enlarged lymph-nodes. The heart and lungs were negative. Blood pressure was systolic 125, diastolic 80.

Laboratory examinations. Gastric contents were negative for blood. Hemoglobin 86 per cent, red blood cells, 4,800,000, white blood cells, 10,700, polynuclear leucocytes, 57 per cent, lymphocytes, 35 per cent, monocytes, 7; eosinophiles, 1 per cent. Stool was brown, formed, and negative for blood. Urine was negative. Urea nitrogen was 5 milligrams.

X-ray examination by the usual technique disclosed an almost completely obstructing lesion in the esophagus beginning at the upper border of the ninth thoracic vertebra. A small trickle of barium passed by the obstruction into the stomach (Fig 25).

Esophagoscopy was performed on September 9, 1937, and

disclosed a fungating mass occluding the esophagus a distance of 35 centimeters from the upper incisor teeth. A biopsy specimen revealed a hornifying squamous cell carcinoma.

On September 13, 1937, a Janeway gastrostomy was performed through a small left upper rectus incision. The wound healed by primary union. Feedings through the tube were instituted on the second postoperative day.

Three days later, cleansing irrigations of the surface of the carcinoma were instituted, as described in the text. Under fluoroscopic control, a Levin tube was passed to a point just above the obstruction and saline solution was flushed past the growth, the washings emerging from the gastrostomy tube. This was repeated twice daily up to the day of the radical operation.

Seven days later, resection of the esophagus was performed under avertin-ethylene anaesthesia. The technical features are described in the text. Palpation of the mediastinum revealed a thickening beginning about 2 inches below the arch of the aorta and extending downward for another inch. This indicated the site of the carcinoma which seemed fairly well fixed to the surrounding tissues. After mobilization of the esophagus below the growth, it was found that the tumor was intimately adherent to the right mediastinal pleura. However, it was possible to find a plane of cleavage and the esophagus at the site of the tumor was freed without entering the right pleural cavity. The tumor-bearing area with a wide margin of normal tissue was excised between ligatures of heavy silk. In drawing the infra-aortic portion of the esophagus upward behind the arch, the ligature closing off its divided end slipped off, but no visible spilling occurred. The ligature was reapplied and the operation proceeded without further incident.

The patient's pulse during the operation, which consumed 2 hours and 20 minutes, varied between 88 and 106. The breathing was regular. A continuous intravenous drip of 5 per cent glucose in saline was started during the operation. A transfusion of 500 cubic centimeters was given at its termination.

Examination of the specimen. Specimen consists of a portion of resected esophagus measuring 7 centimeters in length (Fig 26). The serosal surface is reddish pink, shows the presence of many adhesions, and has a firm yellowish white and pink nodular area near one end. In this same region there can be felt within the wall a firm, slightly irregular mass which completely encircles the wall of the esophagus. On opening the esophagus there is seen to be present, 15 centimeters from the distal end, a somewhat raised irregularly outlined 2-centimeter mass completely encircling the lumen and showing a shallow ulceration at its center. It appears to extend below the mucosa at its periphery. Both above and below the tumor mass there are present several discrete, firm yellowish nodules several millimeters in size within the mucosa. On section the muscularis shows definite infiltration with grayish granular tumor tissue. Microscopic examination shows an infiltrating squamous cell carcinoma with metastatic involvement of one adjacent lymph node (Fig 27).

Postoperative course. **First day.** Patient's general condition good. The pulse varied between 108 and 124; respiration, 28 to 32. The temperature reached 106.6 degrees Fahrenheit on the evening of this day. The patient's general condition, however, did not suggest any serious difficulty.

Second day. Temperature dropped during 12 hours to 100.2 degrees Fahrenheit. The sharp temperature rise of the preceding day was thought to be due, in part, to a post-transfusion reaction. Four ounces of serosanguineous fluid drained through the intercostal tube. No respiratory diffi-

cous membrane. The muscle layer of the esophagus is free of tumor tissue (Fig 16).

Postoperative course First day. No cyanosis or dyspnea, few complaints. The esophageal stump was inspected and found viable. Patient was able to swallow water without difficulty. The gastrostomy tube was opened every half hour to decompress the stomach and take the tension off the suture line at the cardiac end. Blood tinged serum was draining from the thoracotomy tube. Continuous intravenous drip was maintained.

Second day. No drainage came through the thoracotomy tube. Evident pneumothorax was present on the left side but there was no displacement of the heart. No respiratory difficulty was noted. Temperature was 101 degrees, pulse 90.

Third day. Greenish colored clear fluid in small amounts drained through the thoracotomy tube. Test for bile was negative. Temperature was 101 degrees, pulse 92. The general condition was excellent. Portable x ray of the chest showed some fluid at the left base. There was no evidence whatever of pneumothorax and practically no cardiac displacement. All fluid was given by vein in order to avoid risk of separation of the suture line at the cardiac end of the stomach.

Fourth day. Hemoglobin 70 per cent, red blood cells 4,560,000, white blood cells 24,000, polynuclear leucocytes 87 per cent, monocytes 3 per cent, lymphocytes 10 per cent. Patient showed marked resistance to all forms of hypnotics. In order to obtain rest patient was given a basal dose of avertin by rectum, i.e., 70 milligrams per kilogram and she slept 7 hours.

Fifth day. Patient was considerably improved as a result of rest induced by avertin anesthesia. Her general condition was excellent, pulse 96, temperature 101.8 degrees, respiration 24 to 30. Patient was washing fluids through esophageal stump. The redundant portion of this stump was excised. Examination of the chest fluid was negative for bile. There were scattered white blood cells. Portable x ray of the chest showed an increased amount of fluid in the left pleural cavity.

Sixth day. Patient appears to be a little more dyspneic, no cyanosis, not much change in pulse and respirations. Both operative wounds have healed by primary union and all the sutures were removed. Chest was aspirated at 2 sites in the fifth and sixth interspaces posteriorly. No fluid was obtained. The thoracotomy tube was not draining. The heart was not displaced. Blood pressure was 150/90. A policy of watchful waiting was adopted.

Eighth day. Condition markedly improved today. Temperature was 99 degrees Fahrenheit, pulse 90, respiration 22. The intercostal drainage tube was removed. Small amounts of fluid fed through gastrostomy tube.

Tenth day. Hemoglobin was 70 per cent, red blood cells 4,420,000, white blood cells 24,000, polynuclear leucocytes 84 per cent, monocytes 1 per cent, lymphocytes 15 per cent.

Eleventh day. Condition was steadily improving. Regular feedings by gastrostomy tube were given every 2 hours. Examination of the chest indicates signs of fluid at the left base posteriorly and in the axillary line. Aspiration in the eighth interspace showed clear yellow serum. Culture was reported negative.

Thirteenth day. Patient became ill with dyspnea, pain over the front of the left chest, a temperature rise to 103.2 degrees, pulse 120, respiration 40. Examination showed signs of fluid in the left chest below the spine of the scapula with a definite pleuro pericardial friction rub.

Fourteenth day. About 4:00 a.m. a large amount of serous fluid escaped from the original intercostal drainage incision and all of the patient's symptoms abated. X ray

examination of the chest showed a moderate amount of fluid in the left pleural cavity displacing the heart and mediastinum slightly to the right. The fluid showed a distinct level in the mid portion of the chest. Accordingly aspiration was performed in 2 places: (1) the axillary line in the sixth interspace and (2) in the scapular line of the eighth interspace. In both situations clear yellow fluid was obtained. This was thought to represent a sympathetic effusion due to an underlying collection of pus within the chest. A clamp was inserted in the original intercostal incision and thick pus was encountered. A tube was inserted for drainage.

On the basis of this finding the patient was taken to the operating room on the fifteenth postoperative day. The intercostal incision in the eighth interspace was enlarged. With adequate retraction it was not necessary to resect a rib. There was found a small walled-off abscess cavity situated apparently in the lower portion of the posterior mediastinum. This contained about 1½ ounces of greenish white odorless pus. In addition there was a sympathetic effusion with beginning turbidity in the anterior portion of the chest. The mediastinal infection was packed with iodoform gauze and tubes were inserted to drain the anterior pleural effusion. From that day on the patient's condition improved rapidly. Another transfusion of 500 cubic centimeters of blood was given on the sixteenth day. The abscess cavity in the left chest gradually contracted down and all drainage stopped during the next 2 weeks.

In the meantime the patient had been receiving gastric feedings with a daily caloric value of 2600 and containing approximately 250 grams of carbohydrates, 75 grams of proteins and 160 of fat. The food contained all the necessary vitamins and minerals. During the third week a rubber esophagus was inserted and the patient began to take most of the feeding by mouth. The patient lost approximately 20 pounds during her stay in the hospital. She was discharged exactly 8 weeks after the resection in excellent condition, taking all her feedings by mouth and with the thoracic wounds solidly healed (Figs 17, 18, 19, 20).

During the following 2 months the patient began to have considerable difficulty with the rubber esophagus. This consisted mainly of sudden leakage of food around the tube at the upper fistula with its attendant soiling and discomfort to the patient. After considerable study the cause for it was finally determined. It was noted that the patient while eating swallowed a considerable amount of air. During the course of the meal the column of swallowed air was seen to rise higher and higher in the rubber esophagus until a considerable reservoir was formed in the esophageal stump above the fistula. There soon followed a strong contraction of the remaining esophagus with ejection of air and food food from the fistula. Various ingenious devices were made by Dr S. Margolin to overcome this but leakage still occurred.

Finally it was decided to construct a skin lined esophagus continuous with the esophagus above and terminating a few inches above the gastrostomy opening in the hope that it would act as a reservoir for the food ejected downward by the esophagus above. Accordingly the patient was readmitted to Mount Sinai Hospital and operated upon on June 24, 1937. The operative note reads as follows: Two parallel incisions were made extending from the level of the upper esophagus stump downward to about the level of the ensiform cartilage, thus creating a flap 3 inches wide and 5½ inches long. The skin and subcutaneous tissues on the lateral margins of the flap were undermined for a distance of 1 inch on each side leaving the middle portion attached to the underlying tissues in order to ensure a good blood supply. The flap was turned forward so as to have the skin surface face internally. The skin edges

CYSTECTOMY AND TRANSPLANTATION OF THE URETERS INTO THE BOWEL FOR CARCINOMA OF THE BLADDER

CHARLES C. HIGGINS, M.D., F A C S, Cleveland, Ohio

IN RECENT years, transplantation of the ureters into the pelvic portion of the colon and cystectomy have become accepted as standard surgical procedures in the treatment of certain pathological lesions

Prior to the advent of intravenous urography, it was impossible to study the physiology and dynamics of the upper urinary tracts following transplantation, but a method is now available by which visual interpretation of results may be secured years after operation. In view of these investigations, the excellent clinical results, and low morbidity and mortality, the applicability of this method of treatment of exstrophy of the bladder is not a subject of controversy. The same procedure is also accepted for conditions such as vesicovaginal fistula in which a plastic operation does not suffice to render a cure, certain groups of patients with chronic interstitial cystitis, tuberculous cystitis with marked diminution in the bladder capacity and intolerable pain in which a nephrectomy has been performed previously for renal tuberculosis while the other kidney and ureter remain normal, and carcinoma of the bladder in a selected group of patients

The reluctance of surgeons to accept the operation of total cystectomy has been due not to the technical difficulty of removing the bladder, but rather to a divergence of opinion as to the most satisfactory method of disposing of the ureters. For this, 4 methods are available: (1) nephrostomy, (2) pyelostomy, (3) ureterostomy, (4) transplantation of the ureters into the rectosigmoid

While the first 3 procedures may satisfy the immediate requirements, they possess distinct disadvantages. Early and serious renal infection ensues and this is followed by impairment of renal function. The patient must also endure the inconvenience of wearing a receptacle to collect the urine, the unavoidable odor of which renders it difficult to maintain social and business activities. But, by the implantation of the ureters into the bowel, experience has conclusively demonstrated that the rectum serves adequately as a

From the Cleveland Clinic.

Presented in the Cancer Symposium, before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

reservoir for the urine without distressing the patient with frequent excursions to the toilet. In addition, intravenous urograms have revealed normal upper urinary tracts years after operation in many instances. Conversely, it is true that years following transplantation of the ureters into the rectosigmoid, intravenous urographic studies may reveal dilatation of the ureters and hydro-nephrosis due to ureteral obstruction. With refinements in operative technique, however, this complication is gradually occurring less frequently

In advocating cystectomy and transplantation of the ureters for carcinoma of the bladder, several important factors must be taken into consideration.

Accurate diagnosis early in course of disease
The cardinal symptom of a bladder tumor is hematuria. As a general rule, this alarms the patient sufficiently that he consults a physician for advice.

The report of the Registry of Carcinoma of the Bladder of the American Urological Association (4) offers valuable information regarding the period of time elapsing from the onset of symptoms until an accurate diagnosis is established. In the series of 694 cases in which the character and duration of the initial symptoms were known, it was found that in 10.8 per cent of the cases the diagnosis was established within 1 month after onset of the initial symptoms, in 32.13 per cent within 5½ months, and in 51.7 per cent before a year had elapsed, while in 48.3 per cent a diagnosis was established more than 1 year after the appearance of the initial symptoms. The initial symptom in 63.5 per cent of the cases was hematuria; therefore, an early diagnosis of this condition can frequently be established and by routine employment of the cystoscopic examination the percentage of accurate diagnoses will increase considerably.

Various other symptoms, such as the passage of clots, frequency, and dysuria, may similarly induce the patient to seek relief. It is evident then that carcinoma of the bladder produces symptoms sufficiently alarming that medical advice is sought relatively early. This is in contrast to malignant processes in some other parts of the body where more vague, bizarre complaints

culty was noted. Pulse varied between 116 and 138. Heart was not displaced. Patient was encouraged to swallow water thus helping to flush the esophageal stump.

Third day Temperature was 100.4 degrees Fahrenheit. pulse 100 respiration 20. General condition of patient was excellent. Two ounces of serosanguineous fluid drained through the intercostal tube. Feedings by gastrostomy tube were instituted today.

Fourth day Condition good. Temperature 101 degrees Fahrenheit. Respiration was 20 pulse 102.

Sixth day Temperature was 100.4 degrees Fahrenheit. His general condition was excellent. Two ounces of slightly blood tinged serous fluid drained through the intercostal tube. The cervical incision was dressed and silk sutures were removed. The wound healed by primary union.

Seventh day General condition was excellent. Intercostal drainage tube was removed. The thoracic incision was inspected and found clean. Skin sutures were removed. Patient receiving regular gastrostomy feedings.

Eighth day Temperature was 100 degrees Fahrenheit. pulse, 90 respiration 20. Patient was allowed out of bed. X-ray examination of chest showed complete expansion of the left lung with slight haziness in the lower portion which was interpreted as representing a small amount of fluid. The stump of the esophagus was healing nicely.

At present writing 2½ weeks after operation patient is in excellent condition. Thoracic wound has healed. Rubber esophagus is in place and patient is taking all food by mouth. It is expected patient will be discharged from hospital shortly.

less than 2 centimeters in diameter were controlled for 5 years, but if the tumors were larger than 5 centimeters, only 15.8 per cent of the patients were alive at the end of 5 years.

In conclusion as to the general end-results in carcinoma of the bladder at the present time, the registry stated of 658 patients operated upon before January 1, 1931, 151 survived for 5 years. Of this entire group, 104 or 15.9 per cent *were reported to be without evidence of cancer*. Therefore, can we prognosticate that only 15.9 per cent of patients with carcinoma of the bladder will survive for 5 years without evidence of cancer unless cystectomy and transplantation of the ureters are employed? In answering this question, the causative factors responsible for death of patients with carcinoma of the bladder obviously must be considered.

The incidence of metastasis is a disputed question. Of 902 cases carefully studied by the carcinoma registry, metastases were present in 72 instances. However, no accurate report could be given as to the number of examinations made in which no metastases were found. Metastases occurred in the following locations, arranged in order of their frequency: bones, lungs, regional nodes, liver, retroperitoneal nodes. At the Mayo Clinic, metastases were found at autopsy in 30 per cent of the cases and visceral involvement was present in one-half of these. Caulk states that metastases were present in 25 per cent of his cases. Smith, at the Massachusetts General Hospital, reports a higher incidence—40 per cent; Beer has stated that metastases were present in about 10 per cent of his cases, while in our group at the Cleveland Clinic, between 10 and 12 per cent showed metastatic lesions. Therefore, metastasis from the primary growth is not the cause of death in the majority of cases.

The site of predilection for carcinoma of the bladder is the region near one of the ureteral orifices. As the growth enlarges, ureteral obstruction ensues and this is followed by irreparable damage to the upper urinary tract. Caulk, in 1935, admirably discussed this problem and emphasized the fact that death frequently does not occur from the malignant lesion *per se*, but rather from urosepsis. As the obstruction induced by the involvement of the ureteral orifice continues, dilatation of the ureter, stasis, and hydronephrosis occur. The infection which invariably follows is attended by pyelonephritis, pyonephrosis, and eventually impairment of renal function occurs with complete destruction of the kidney.

The location of the tumor influences the results that can be anticipated, aside from the grade of

the tumor. A small grade I tumor involving the ureteral orifice may already have destroyed the kidney when a patient is first seen, while a grade II or III tumor which is located higher on the lateral wall may be radically excised before it involves the ureteral orifice with secondary involvement of the upper urinary tract. Interpretation of the cystoscopic picture may be misleading and involvement of the ureter, though present, may not be suspected. When involvement of the ureter is present, however, the cystogram may show more extensive infiltration of the bladder wall and ureteral regurgitation may be evident. We believe that a cystogram should be made in all cases of carcinoma of the bladder.

Postmortem study on several occasions has revealed urosepsis to be the cause of death while the carcinoma was still limited to the confines of the bladder. In reviewing 300 cases, Caulk stated that evidence of renal infection was present in 21 per cent while Barringer found infection in 16 per cent of his cases. In our series, evidence of renal infection was found in 19 per cent. Perhaps the most striking statistics on the cause of death are those of Caulk who found records of death in 90 of his 300 cases, and of these, 25 came to post-mortem. He found evidence of renal disease in 34, or 38 per cent. Of the 25 cases which came to autopsy, 15, or 60 per cent, died a renal death.

It is likewise well to recall that repeated fulgurations of tumors near the ureteral orifice may lead to stenosis of the ureteral orifice with resultant involvement of the upper urinary tract. It is therefore estimated that in over 50 per cent of all cases, renal failure and urosepsis secondary to involvement of the ureters are contributory factors causing death.

CYSTECTOMY AND TRANSPLANTATION OF URETERS

Age of the patient. In considering cystectomy and transplantation of the ureters as a treatment for carcinoma of the bladder, certain problems arise which are in contrast to those present when the operation is designed for the relief of exstrophy in children. While the age of the patient is of considerable importance, the presence of co-existing pathological processes is more evident, such as hypertension, myocardial degeneration, general disability, or renal insufficiency. Individualization is necessary to determine whether cystectomy can safely be advocated or whether less radical procedures should be instituted. In our series of 34 cases of carcinoma of the bladder in which transplantation of the ureters into the sigmoid and cystectomy have been performed,

are produced, these being of insufficient severity to cause the patient to seek medical consultation until the lesion is well advanced.

Results secured by treatment other than cystectomy and factors influencing the end results. A review of the methods employed in the treatment of carcinoma of the bladder reveals that no standard method has been adopted and further that various factors influence the procedure instituted.

The size of the tumor and its character—whether infiltrating or papillary—definitely influence the end result and are of prognostic significance. The grade of the tumor, according to Broders' classification, the position of the tumor in the bladder, and whether single or multiple tumors are present are all of definite clinical significance and are of importance in evaluating the suitability of cystectomy as the procedure of choice.

The 854 tumors of the bladder reported by the Carcinoma Registry were found in the following locations: trigone, 32.2 per cent, lateral walls 35.3 per cent, posterior wall, 10.2 per cent, bladder neck 9 per cent, vault 7.5 per cent, and the anterior wall 5.7 per cent. More important however was the observation that of the 854 cases one area of the bladder only was involved in 473, namely trigone, 27.37 per cent, bladder neck 5.89 per cent, lateral walls, 41.89 per cent, posterior wall 10.92 per cent, anterior wall 6.12 per cent and the vault, 7.58 per cent.

These statistics are of great importance in determining the treatment to be employed. Tumors on the low lateral walls usually involve the ureteral orifice on the same side. In our series we found that if tumors of the trigone and bladder neck were included, complete excision of the growth without injury to the ureters or damage to the vesical sphincter, the later resulting in incontinence, was technically impossible in 72.5 per cent of the cases. Obviously when the tumor occupies a position low on the lateral wall, wide excision of the bladder with reimplantation of the ureter into another portion of the bladder is possible. Thus, in only 27.5 per cent of our series—and this figure agrees closely with that of the Carcinoma Registry (23.4 per cent)—was complete excision possible without either reimplanting a ureter into another part of the bladder or injuring the bladder neck. While carcinoma involving the vault of the bladder is readily accessible to resection, it is extremely malignant and metastasis occurs to the liver by way of the lymphatics of the obliterated hypogastrics.

Considerable stress has been placed upon accurate grading of the tumor according to Broders'

classification. What is the incidence of bladder tumors of low grade malignancy in which the prognosis should be more favorable?

Of a series of 902 cases studied by the Carcinoma Registry, 436 were papillary carcinoma while 446 were infiltrating carcinoma, and 20 were not definitely classified. Let us now note the end results secured for tumors of varying degrees of malignancy according to Broders' classification, the analyses being made from a series of 658 epithelial tumors reported by the Carcinoma Registry. Of 133 tumors classified as grade I, 61 or 45.9 per cent of the patients were alive 5 years, of 194 patients with grade II tumors 50 or 25.7 per cent were alive at the end of 60 months, of 244 with tumors grade III, 34 or 13.9 per cent survived 5 years and in 70 with tumors grade IV, 4.3 per cent were alive 5 years. This report, however, contains only data on patients who survived 5 years and does not exclude patients with recurrences who may not survive 6 or more years. The report indicates that the cancer may be under control.

The question arises as to what results may be obtained in the treatment of carcinoma of the bladder and why there is such discrepancy when end results of treatment of carcinoma of the bladder are compared with those for carcinoma in other accessible parts of the body.

In dealing with tumors of the bladder of the lowest grade of malignancy according to Broders' classification (i.e. grade I) should we be satisfied that only 45.9 per cent of the patient survive for 5 years and for the 2 lowest grades of malignancy (i.e. grades I and II), can we expect only 35.8 per cent of the patients to live for 5 years? It is true that these statistics were compiled from the reports of many surgeons and that more favorable results have been presented by some authors but they do represent an average of the results being secured at the present time.

It is also true that these results are for both infiltrating and papillary tumors, however of 151 patients surviving 5 years the tumor in 109 cases was of the papillary type 34 were infiltrative and 8 were not classified. In the group of 31 patients who were operated upon for papillary tumors 34.9 per cent survived for 5 years. Is this the best result that can be secured in this type of tumor which is not infiltrating in character? It is likewise interesting that only 13.9 per cent of the patients with the infiltrating type of carcinoma of the bladder were stated to be cured.

The size of the tumor in the bladder is of prognostic significance. The report of the carcinoma registry stated that 30.3 per cent of the tumors

such that their implantation into the bowel is technically possible.

4. As Quinby has mentioned, demonstration of an actively growing carcinoma should be made by microscopic examination (biopsy).

During the last 2 years, cystectomy has also been performed in a selected group where radical segmental excision of the bladder was not possible and where we believed that insufficient radium could be implanted in the tumor to completely destroy it. Similarly, when a cystogram revealed evidence of much more extensive involvement of the bladder wall than was suspected by the cystoscopic picture, the radical operation was recommended.

Pre-operative care. In discussing carcinoma of the colon Dr Fred Rankin states, "No operative step in the treatment of malignancy is of more importance than the initial preparation, particularly in the face of obstruction. The chronic obstruction does not necessitate an emergency procedure and operative measures are greatly facilitated and end-results influenced by giving some time to pre-operative measures."

In transplanting the ureter into the rectosigmoid, preparation of the bowel is likewise essential. Our pre-operative routine is similar to that used by Dr T. E. Jones in preparing patients for operations on the colon.

1. A liquid, non-residue diet is supplemented by candy, glucose, and gelatin.

2. One thousand cubic centimeters of a 10 per cent solution of glucose are administered intravenously each day. The glucose is given with saline solution if the kidney function is not impaired but, if the function is decreased, distilled water is substituted for the saline solution.

3. Magnesium sulphate is administered orally each day. One ounce of magnesium sulphate is dissolved in 8 ounces of water, 1 ounce of this mixture being taken every half hour starting at 7 a. m. None, however, is used on the day prior to the operation.

4. The bowel is cleansed with an enema daily.

5. Provided there are no other complications, the number of days of preparation before operation depends upon the renal function and the cleanliness of the bowel. When all enemata return clear, the bowel is considered clean. The day before operation, an enema is given both in the morning and at night.

6. Three doses of paregoric, each of 2 drams, are prescribed at intervals of 2 hours, usually from 4 to 8 o'clock the night before operation.

7. Blood transfusions are used when indicated by condition of patient and blood picture.

8. Complete study of upper urinary tract is made by tests of function and intravenous urography.

9. Urinary antiseptics intravenously or orally are administered as indicated.

10. Miscellaneous supportive measures are employed as necessary.

Since this pre-operative routine has been employed, convalescence has been more smooth and complications have definitely been reduced. Certainly the adequate pre-operative preparation of the colon minimizes the possibility of peritonitis and of acute ascending infections of the kidney following the operation. Many of these patients are debilitated, and increased resistance to infection, restoration of the water balance to normal, and improvement of the renal function are essential measures which result in elimination or reduction of postoperative complications.

Operation. The operation to be recommended in a given case is influenced by the general condition of the patient, renal function, caliber of the ureters, and the presence or absence of renal infection. One of two surgical procedures is usually employed—either the Coffey I operation or that advocated by us in 1933 (5).

When the Coffey I technique is employed, unilateral transplantation of the ureters is advisable. This is attended by a lower mortality than is the case when both ureters are simultaneously transplanted by this method. At the time the right ureter, which is the first to be transplanted into the rectosigmoid, is done, it is advisable to explore the abdomen for metastasis, glandular involvement, or extravesical extension. Ten to 12 days later, the left ureter may be transplanted into the rectosigmoid if there are no contraindications. After the transplanted ureters are functioning well, as indicated by intravenous urographic studies, cystectomy is performed. The postoperative reaction following transplantation of the first ureter is usually more pronounced than that following transplantation of the second ureter, an elevation of temperature and increase in the pulse rate usually occurring for a few days and then gradually returning to normal.

The Coffey I procedure is preferable in cases of impaired renal function or in instances when varying degrees of dilatation of the ureters are present.

In another group of cases, however, when the ureters are of normal caliber or are only slightly dilated, when the renal function is only slightly impaired, and when the physical condition of the patient is satisfactory, we believe that both ureters may be transplanted simultaneously by the

1 patient was 77 years of age 9 were more than 60 years of age, 8 were between 50 and 60 and the 16 remaining were less than 50 years of age

The maximum age limit at which the operation is advisable is influenced by the general condition of the patient, the findings at cystoscopic examination, the status of the kidneys and ureters, and the presence or absence of co-existing pathology

Treatment A discussion of the various types of treatment of carcinoma of the bladder is beyond the scope of this paper Only facts of significance regarding carcinoma of the bladder are discussed and our opinion regarding cystectomy at the present time is presented

In the treatment of carcinoma in general there has occurred an extension of the range of operability with an accompanying decrease in the morbidity and mortality This is evidenced by the results secured by laryngectomy for intrinsic carcinoma of the larynx, by radical operations for carcinoma of the stomach and colon, and now lobectomy for carcinoma of the lung

Rankin states that since 1900 radical operations for treatment of cancer of the colon have gradually evolved into satisfactory technical procedures and this has been accompanied by a slow but gradual decrease in the mortality We believe the same thing will happen in cystectomy and transplantation of the ureters into the bowel for selected cases of carcinoma of the bladder At the present time cystectomy is looked upon as a 'court of last resort' in many instances and is instituted only for well advanced carcinoma of the bladder or when conservative procedures have failed

Obviously, if the operation is employed in the group of patients who already have pyelonephritis impaired renal function, and large dilated ureters, thus rendering the operation technically difficult or impossible, a higher mortality will result than when no complicating factors are present Certainly the range of operability is by no means 100 per cent, even if the bladder can be removed *in toto* As the continuity of the sigmoid or rectosigmoid cannot be restored in all cases following the radical removal of a carcinomatous lesion in like manner the condition of the upper urinary tract may not justify implantation of the ureters into the colon or even cystectomy in all cases and palliative treatment must be advised in certain instances That cystectomy and transplantation of the ureters into the rectosigmoid can be accomplished with a low mortality in adults is evidenced by the results secured in a selected group of patients with interstitial cystitis and vesicovaginal fistula Here

again the low mortality and morbidity are due to good renal function, absence of or minimal amounts of renal infection, and normal caliber of the ureters

Thus in patients with carcinoma of the bladder in whom infection of the kidneys is either not pronounced or entirely absent, when renal function is not impaired, and when the ureters are normal or only slightly dilated, we can expect satisfactory end results and a material reduction in the mortality If cystectomy were employed would not more than 15 per cent of patients, as reported by the carcinoma registry in which other types of treatment were used, be free from cancer at the end of 5 years?

We now recommend cystectomy and transplantation of the ureters into the rectosigmoid in the following groups of cases

1 When the carcinoma is located at the base of the bladder and the ureteral orifices are encroached upon or the vesical sphincter is so involved that adequate local treatment would exert a destructive action on the ureteral orifice or would cause incontinence

2 When more extensive single or multiple infiltrating tumors are present

3 When multiple, recurring tumors develop rapidly and cannot be controlled by fulguration so that they eventually fill the bladder

In addition to these 3 groups of cases certain other factors must be taken into consideration before the radical operation is recommended

1 Renal function must be satisfactory, preferably in both kidneys, but at least normal in one kidney In 3 instances we have transplanted the ureter from the normal kidney into the bowel, finally performing the cystectomy after removing the opposite kidney because of infection and complete loss of function as the result of a bladder tumor obstructing the ureter

2 The presence of metastases or evidence of local extension of the malignant lesion must be taken into consideration If, at the time of transplantation of the ureters, clinical evidence of extension of the carcinoma beyond the confines of the bladder is noted we believe that the radical operation is inadvisable Palpation of the regional lymph nodes and those at the bifurcation of the aorta is a routine procedure As these glands are not removed in their entirety if involved, local recurrence would obviously ensue Roentgen ray study to exclude the possibility of metastasis to the chest is advisable in all such cases

3 Intravenous urograms should be made to demonstrate that the calibers of the ureters are

ureter protruding into the lumen of the bowel may become markedly edematous and the site of an acute inflammatory reaction for a few days. This is conducive to obstruction of the passage of urine into the bowel. As a general rule, however, intravenous urographic study reveals that stasis disappears in a few days. If temporary obstruction occurs when the ureter from a single kidney has been transplanted, a temporary pyelostomy or nephrostomy may be employed. We have not, however, found it necessary to employ this procedure.

Immediate use of urinary antiseptics as a preventive measure is also made. We have employed salihexin which is administered intravenously or more recently we have used mandelic acid by mouth.

Later complications may be: (1) dilatation of ureters and hydronephrosis; (2) renal infection; (3) impairment of renal function; (4) recurrence of malignancy.

In some instances urographic studies reveal the presence of hydro-ureters and hydronephrosis years after implantation of the ureters into the bowel. In other cases, similar studies reveal the ureters and kidneys to be in fairly normal condition years after operation. Again the causative factors responsible for the dilatation of the ureters are not clearly understood. It does appear, however, that with experience and refinements in operative technique, the incidence of this complication is progressively diminishing. Even though this complication may occur, years of comfort are added to the lives of the patients and they may be restored to society for a long period of time before succumbing to other diseases remote from the one for which operation was performed.

Some patients may be free from urinary sepsis for years, in fact, we have patients in whom evidence of renal infection is absent 10 to 15 years following transplantation of the ureters. The late infection usually occurs in patients in whom stasis, dilatation of the ureters, and hydronephrosis are demonstrated by intravenous urography. These patients may have periodic attacks of renal infection which subside rapidly upon the administration of urinary antiseptics. It is undoubtedly true that some degree of ureteral obstruction, with resulting stasis, is the responsible etiological factor in this group.

The presence of late ureteral obstruction frequently antedates impairment of renal function. When a superimposed renal infection occurs, renal function may be damaged rapidly. If pyelonephritis does not occur, however, the function may not be impaired to any pronounced

degree for years. We have patients who have had periodic attacks of pyelitis years following transplantation of the ureters into the rectosigmoid but the intravenous urogram revealed only slight impairment of renal function.

It is likewise true that impaired renal function may not be demonstrated in many cases several years after the implantation has been performed and the dynamics and physiology of the upper urinary tract remain fairly normal.

Recurrence The incidence of a local recurrence of carcinoma following cystectomy at the present time is difficult to determine. Before statistics are reliable, a sufficient number of cases must be followed for a period of years. In this series of 34 cases, insufficient time has elapsed since operation to present statistics which may reveal the true picture. If, however, no evidence of distant metastases is noted at the time of operation, if glandular involvement is absent, and extravesical extension cannot be demonstrated, recurrence should occur in but a small percentage of cases.

CONCLUSIONS

1. Cystectomy and transplantation of the ureters has been performed in 34 of our patients with carcinoma of the bladder.

2. A reduction in the mortality has been observed by performing the operation before dilatation of the ureters, renal infection, and impairment of renal function have occurred.

3. Less radical operative procedures should be employed in advanced cases of carcinoma of the bladder associated with large dilated ureters, pyelonephritis, and impaired renal function. Such vesical carcinomas lie beyond the range of operability for this type of surgical procedure.

4. The question is raised as to the advisability of earlier transplantation of the ureters and cystectomy before irreparable damage to the kidneys has developed.

5. In the group of patients surviving operation—and this percentage is gradually increasing—control of the urine is satisfactory and they may return to their social and business activities in comfort.

6. Insufficient time has elapsed to warrant statements as to the percentage of 5 year cures. The immediate results are, however, gratifying and we are quite optimistic concerning the results that may be secured.

transfixion suture method. As the continuity of the ureters is not interrupted until new channels are established, there is no interruption of kidney function throughout the entire operation.

In some instances in which considerable fat is present in the mesentery it has been found impossible to employ this technique without too much tension upon the line of anastomosis. Thus individualization is necessary and the operative procedure to be employed depends upon the familiarity of the surgeon with the various operative techniques and the clinical findings prior to and during the operation.

The use of ureteral catheters is usually unnecessary. We have utilized the catheter principle in two instances in which the ureters from solitary kidneys were transplanted into the rectosigmoid to eliminate the possibility of temporary obstruction.

Postoperative care. An exacting postoperative regimen is essential, and the following routine has given the most satisfactory results in our hands.

1 The patients are maintained in a supine position for at least 8 hours if spinal anesthesia is used; then they are placed in Fowler's position.

2 The blood pressure is taken every 15 minutes until it returns to normal.

3 No fluids are administered by mouth for 48 hours and then small amounts of water are taken orally for 12 hours. During the following 12 hours, clear fluids are started with 1 ounce hourly, and this amount is gradually increased. A low residue diet is then given for a period of 5 to 7 days.

4 The fluid intake is maintained at 3,000 cubic centimeters daily. For the first 2 days, 2,000 cubic centimeters of 10 per cent solution of glucose is administered intravenously and 1,000 cubic centimeters of saline solution infusion daily. After this period, fluids are given intravenously as indicated by a study of the blood chemistry and the amount of fluid taken by mouth.

5 Narcotics are given as necessary.

6 A rectal tube is inserted at the time of operation. This may be changed but is replaced and left in the rectum for a period of 8 to 10 days. The rectal tube is irrigated gently at intervals of 2 to 3 hours to insure patency. When the transfixion suture technique is employed, gentle traction is made on the rectal tube at the end of 24, 36, and 48 hours until the tube containing the silk sutures is expelled. A plain rectal tube is then reinserted for a period of 5 to 7 days.

7 Studies of the blood chemistry (urea and creatinine) are made daily until the levels return to normal.

8 Ten cubic centimeters of salixerin are combined with the intravenous glucose as a urinary antiseptic for the first 3 or 4 days following operation.

9 General supportive measures are prescribed as indicated.

Anesthesia. Spinal anesthesia has been the anesthetic of choice in our patients. The complete relaxation induced by this type of anesthesia facilitates the ease with which exploration of the abdomen for metastases may be accomplished without excessive manipulation of the intestines. Similarly, exposure may be adequately secured without undue or excessive packing off of the operative field with numerous tapes.

More important is carrying the operation down to the colon so the danger of tenion on the ureter or kinking of the ureter does not occur, a condition which is always a possibility if the anastomosis is performed with the rectosigmoid delivered well up into the incision.

Obviously if contra indications to the use of spinal anesthesia exist it is not used and gas-ether anesthesia is employed.

Complications. The immediate complications are (1) peritonitis, (2) acute renal infection (pyelonephritis), (3) temporary ureteral obstruction.

Careful pre-operative preparation of the bowel and utilization of the Coffey submucous technique for transplantation of the ureter into the rectosigmoid have reduced the incidence of peritonitis to a minimum. By adequate preparation of the colon the danger of leakage of the contents of the bowel into the abdominal cavity at the time of operation is eliminated as one source of peritonitis. Second, the submucous principle of implantation prevents leakage following the operation.

Acute infections of the urinary tract constitute the major complications following transplantation of the ureters into the bowel. The exact mechanism instrumental in the production of the acute pyelonephritis is a debatable question. Certainly, however, we have noted a decrease in the incidence of this complication since an adequate pre-operative regimen has been established. Likewise, prevention of stasis in the upper urinary tract by not approximating too tightly the layers of the bowel over the ureter is an important technical consideration.

Temporary obstruction of the ureter may occur. This may be due either to edema at the site of the incision in the bowel wall in which the ureter is incorporated or as demonstrated experimentally by Vermooten and ourselves, the portion of the

ureter protruding into the lumen of the bowel may become markedly edematous and the site of an acute inflammatory reaction for a few days. This is conducive to obstruction of the passage of urine into the bowel. As a general rule, however, intravenous urographic study reveals that stasis disappears in a few days. If temporary obstruction occurs when the ureter from a single kidney has been transplanted, a temporary pyelostomy or nephrostomy may be employed. We have not, however found it necessary to employ this procedure.

Immediate use of urinary antiseptics as a preventive measure is also made. We have employed salihexin which is administered intravenously or more recently we have used mandelic acid by mouth.

Later complications may be: (1) dilatation of ureters and hydronephrosis; (2) renal infection; (3) impairment of renal function, (4) recurrence of malignancy.

In some instances urographic studies reveal the presence of hydro-ureters and hydronephrosis years after implantation of the ureters into the bowel. In other cases, similar studies reveal the ureters and kidneys to be in fairly normal condition years after operation. Again the causative factors responsible for the dilatation of the ureters are not clearly understood. It does appear, however, that with experience and refinements in operative technique, the incidence of this complication is progressively diminishing. Even though this complication may occur, years of comfort are added to the lives of the patients and they may be restored to society for a long period of time before succumbing to other diseases remote from the one for which operation was performed.

Some patients may be free from urinary sepsis for years, in fact, we have patients in whom evidence of renal infection is absent 10 to 15 years following transplantation of the ureters. The late infection usually occurs in patients in whom stasis, dilatation of the ureters, and hydronephrosis are demonstrated by intravenous urography. These patients may have periodic attacks of renal infection which subside rapidly upon the administration of urinary antiseptics. It is undoubtedly true that some degree of ureteral obstruction, with resulting stasis, is the responsible etiological factor in this group.

The presence of late ureteral obstruction frequently antedates impairment of renal function. When a superimposed renal infection occurs, renal function may be damaged rapidly. If pyelonephritis does not occur, however, the function may not be impaired to any pronounced

degree for years. We have patients who have had periodic attacks of pyelitis years following transplantation of the ureters into the rectosigmoid but the intravenous urogram revealed only slight impairment of renal function.

It is likewise true that impaired renal function may not be demonstrated in many cases several years after the implantation has been performed and the dynamics and physiology of the upper urinary tract remain fairly normal.

Recurrence. The incidence of a local recurrence of carcinoma following cystectomy at the present time is difficult to determine. Before statistics are reliable, a sufficient number of cases must be followed for a period of years. In this series of 34 cases, insufficient time has elapsed since operation to present statistics which may reveal the true picture. If, however, no evidence of distant metastases is noted at the time of operation, if glandular involvement is absent, and extravascular extension cannot be demonstrated, recurrence should occur in but a small percentage of cases.

CONCLUSIONS

1. Cystectomy and transplantation of the ureters has been performed in 34 of our patients with carcinoma of the bladder.

2. A reduction in the mortality has been observed by performing the operation before dilatation of the ureters, renal infection, and impairment of renal function have occurred.

3. Less radical operative procedures should be employed in advanced cases of carcinoma of the bladder associated with large dilated ureters, pyelonephritis, and impaired renal function. Such vesical carcinomas lie beyond the range of operability for this type of surgical procedure.

4. The question is raised as to the advisability of earlier transplantation of the ureters and cystectomy before irreparable damage to the kidneys has developed.

5. In the group of patients surviving operation—and this percentage is gradually increasing—control of the urine is satisfactory and they may return to their social and business activities in comfort.

6. Insufficient time has elapsed to warrant statements as to the percentage of 5 year cures. The immediate results are, however, gratifying and we are quite optimistic concerning the results that may be secured.

CARCINOMA OF THE THYROID

HAROLD L FOSS MD FACS, Danville Pennsylvania

THE incidence of malignant disease of the thyroid gland among goiters of all types averaged from the reports of 11 authors, is 2.37 per cent (5, 9, 18, 20, 24, 25, 26, 27, 28, 31, 32).

According to Joll, about 90 per cent of thyroid malignancies are epithelial in origin, and Broders agrees with Ewing that practically all primary malignant neoplasms of the thyroid are carcinomas. These malignant epithelial tumors are usually subdivided into 3 main groups: papillary adenocarcinoma, adenocarcinoma in adenomas, and the so called diffuse adenocarcinoma.

Papillary carcinomas constitute a well defined group and in the early stages are soft and friable but may later become cystic and calcified. Their growth is slow, sometimes with multiple localized foci. Their malignancy varies but it is usually of low grade (I or II). Their histological picture is in a degree, similar to that of papillary tumors of the ovary. Blood vessel invasion is not common. Extension is nearly always local but early, and is by way of the lymphatics. Recurrence is common and is apt to take place within a year if at all. These are the most radiosensitive of all thyroid cancers. The incidence is, roughly, 30 per cent.

Adenocarcinoma in adenomas. The tumors are large and solid, well encapsulated and with a lobulated texture. They have a reddish color due to high vascularity and are frequently soft. They usually arise in a pre-existing goiter, a goiter usually produced by a fetal adenoma. This type metastasizes late, and, through the blood vessels to distant organs. It represents about 45 per cent of thyroid carcinomas.

From the Geisinger Memorial Hospital.

Presented in the Cancer Symposium, before the Clinical Congress of the American College of Surgeons, Chicago, October 25-29, 1937.

Diffuse adenocarcinomas constitute the third group of carcinoma of the thyroid and are the most malignant variety. Grossly and macroscopically there is but little distinct division from adenocarcinoma. The onset is acute, with or without a preceding goiter. Metastasis occurs early, and both locally and distantly. Their structure varies from that of adenocarcinoma to diffuse solid masses of carcinoma cells with no alveolar formation. Prognosis is grave.

Squamous cell epithelioma occasionally occurs in the thyroid gland. Not infrequently it appears as an extension from carcinoma of the esophagus or trachea yet cases have been reported which arose from metaplastic thyroglossal duct epithelium.

Sarcoma of the thyroid should be mentioned, yet Ewing denies its existence, stating that so called sarcomas are anaplastic carcinomas belonging in the diffuse group.

Other malignant tumors that appear in the thyroid gland are hemangio-endotheliomas and teratomas. Metastatic tumors to the thyroid are rare but include hypernephroma, carcinoma of the tongue, breast, stomach, esophagus and lung.

It has long been felt that all tumors of the thyroid originate in fetal adenomas. Habermel (1934) believes that 90 per cent of thyroid cancers arise in fetal adenomas and that these are true neoplasms in themselves arising from one of embryonal cells which may, for years, remain dormant. Crile (7) and Lahey agree with Habermel. Habermel stated that thyroid malignancy is more common in endemic goiter districts, and most frequent in long standing, nodular goiters. This latter statement is universally recognized, namely, that a pre-existing goiter, of from 1 to 25 years duration has been present in almost all

carcinomas of the thyroid. The sex incidence is predominantly female in all reports, although the proportion varies.

Blood vessel invasion has become an important criterion in determining malignancy. European authors, Wylegshanin and Viallefont, as well as many American authors, notably Graham, have emphasized it. Means (1937) emphasizes Warren's earlier findings that simple colloid goiters never show blood vessel invasion. T. B. Mallory, however, demands that a vessel large enough to possess muscularis be penetrated by the malignant tissue, in order to exclude artefacts. The slow growing, less malignant papillary tumors and the very malignant anaplastic ones seem to have a tendency toward local spread with production of compression symptoms while an encapsulated adenocarcinoma may show distant blood borne metastasis regardless of its degree of malignancy.

Metastases from carcinoma of the thyroid gland are found, primarily, in the cervical and axillary nodes, lungs and mediastinum, bones, liver, brain, kidney, and pleura, in about that order.

Among the bones the skull, long bones, spine, and thoracic cage are most frequently involved.

The histological appearance of metastasis may differ considerably from the original tumor, i.e., both may appear benign or both malignant, or either one may be malignant and the other benign (Ewing). The so called benign metastasizing goiter is now regarded as a form of adenocarcinoma.

Aberrant lateral thyroid tissue as a source of carcinoma of the thyroid has been considered by Cattell (3), Forty, Greensfelder and Bettman, Greteman and Russum, and Moritz and Bayliss. Lateral aberrant thyroid tissue is frequently unrecognized or is mistaken for lymph-nodes or branchiogenic cysts. There seems to be a well recognized tendency for this tissue to become malignant. The carcinoma, it is claimed, is usually papillary and of low grade malignancy and responds well to treatment. In regard to this question, it should be mentioned that some pathologists, including Broders, question whether carcinoma of the thyroid originating in aberrant thyroid tissue is frequently or ever seen.

Carcinoma of the thyroid has been reported in children by Cattell (4) and by Kennedy. It is usually of the papillary adenocarcinomatous type and of low grade malignancy. In Cattell's series trauma seemed to be frequently associated with a development of the thyroid tumor.

CLINICAL DIAGNOSIS

It has been stated that, if carcinoma of the thyroid can be recognized clinically, it is usually too late to cure the patient. The usual clinical picture is one of a distorted, hard, lobulated, rapidly growing goiter, associated with hoarseness, respiratory stridor, dysphagia, and neuralgic pains in the head and neck. Sympathetic eye signs may occur, and redness of the overlying skin sometimes occurs with ulceration. Hemoptysis may appear as a result of pulmonary metastases, or erosion into the trachea or larynx. Walton states that carcinoma usually becomes fixed to the trachea before adhering to the overlying skin.

Means stresses the point that the presence of either hyperthyroidism or hypothyroidism is against the diagnosis of cancer. Chronic thyroiditis such as the struma lymphomatosa of Hashimoto, and chronic non-suppurative thyroiditis, or metastatic infections, must be ruled out in the differential diagnosis of cancer of the thyroid. It must be remembered, however, that infection is often superimposed on malignancy. Tuberculous and syphilitic infections of the thyroid are exceedingly rare.

The diagnostic value of the absence of hyperthyroidism has been stressed by some authors. Others report the frequent association of hyperthyroidism with malignancy. Clute and Warren state that there is no evidence that hyperthyroidism arises as the result of the activity of malignant tissue, although malignant thyroid tissue may secrete colloid. Means goes so far as to say that hyperthyroidism is "insurance against carcinoma of the thyroid." George Crile, Jr. notes the marked disagreement in the literature over this point.

TREATMENT

Successful prophylactic treatment of carcinoma of the thyroid depends upon the enucleation of all thyroid adenomas as they appear. It is impossible to recognize nearly 50 per cent of carcinomas, clinically, before operation. When the diagnosis is made before operation by the usual signs of rapid growth, fixation, hoarseness, and weight loss the situation is usually out of hand. However, in 50 to 60 per cent of all cases of carcinoma of the thyroid the diagnosis is promptly made in the laboratory, affording the opportunity for adequate and appropriate treatment. The importance of postoperative microscopic examination of all goiters removed, to assure the early discovery of malignancy, has been repeatedly stressed.

The accepted treatment of carcinoma of the thyroid is widespread removal, followed by irradi-

ation with radium and x ray (1, 23, 29, 30) Many of the earlier operations were radical, and the mortality high, but the present trend is to excise only as much tissue as is safely possible, attempting to remove all involved tissue, following which irradiation is carried out. It is now well recognized, I believe, that the various forms of malignant processes attacking this gland require different therapeutic procedures. The plan of operation varying considerably according to the pathologist's histological findings. This has been repeatedly emphasized by Pemberton who has had the largest experience of anyone living in the treatment of this disease.

End results in various types of treatment. Portmann, reporting from the Cleveland Clinic, compared results of various forms of treatment. Operation alone gave 9 per cent 5 year cures. Irradiation alone gave no 5 year cures. Operation plus irradiation yielded 22.6 per cent 5 year cures.

Bowing in 1927 reported a Mayo Clinic series of 167 patients. Of 91 patients treated by operation plus irradiation, 31 per cent were living 5 years or more. Of 76 patients treated with irradiation alone there were 11 per cent 5 year cures.

Pemberton and Fricke in 1933, reported a Mayo Clinic series of 161 cases. Of 107 patients treated by surgery plus irradiation 63 per cent were living and well 5 to 10 years after treatment. In the group remaining the extent of malignancy precluded surgery. Irradiation alone was carried out. Of these 54 per cent died within a year but 10 per cent were living at the end of 5 years.

Pemberton and Dixon, in 1934, gave the Mayo Clinic experience from January 1, 1907 to July 1, 1928. There were 423 patients with cancer who were operated upon. In 56 cases of biopsy, irradiation alone was carried out. The 267 remaining received partial or nearly complete thyroidectomy with or without removal of the cervical lymph nodes. Eleven of the 313 patients died in the hospital, a mortality of 3.4 per cent. Of the 312 patients remaining 44 per cent have lived 5 years or more and nearly 20 per cent lived more than 10 years. Of the 137 patients who lived 5 years or more, the treatment in 7 per cent was irradiation alone and in 93 per cent radical removal with or without postoperative irradiation.

These end results establish two points: (1) the value of the combined surgical removal and irradiation, (2) carcinoma of the thyroid is by no means, the utterly hopeless condition it has been thought to be.

Operability. The operability of carcinoma of the thyroid depends largely upon the judgment of

the surgeon. If the neoplasm is attached to deep structures operation is inadvisable. If, on the other hand, attachment appears to be only at one point, resection may be performed with hope of dissecting the growth away from the involved structure. If the growth is encapsulated enucleation is all that is usually indicated. If some doubt exists as to the presence of extension into the surrounding gland, then the entire lobe should be excised. It is rarely necessary to perform a resection of both lobes. Joll leans to wide resection of muscles, fascia, vessels and nerves, yet the general viewpoint is that very radical operations often do more harm than good and that better results are obtained from the excision of as much tissue as is safely possible followed by irradiation.

Metastasis is not of itself a contra indication to operation. If the primary lesion is resectable the procedure may well be undertaken for many cancers of the thyroid are of a low degree of malignancy, and a patient even with metastasis may live in comfort for some years.

Cervical node extension from an adenocarcinoma of an adenoma is of much graver import than from a papillary carcinoma, for in the former distant metastasis has probably already taken place before local extension occurs.

Diffuse adenocarcinomas are rarely operable.

Irradiation. Carcinoma of the thyroid gland like carcinoma of the ovary, holds a unique position among malignant processes in that while it is usually of a low grade of malignancy it is relatively radiosensitive, this being true especially of the papillary type. It has already been shown that the combination of surgery and irradiation gives the best statistical results. It has been noted by Pemberton and Fricke that 10 per cent of the non operable, apparently hopeless patients treated only with irradiation were living after 5 years.

CONCLUSIONS

We can sum up that the salient features of our present knowledge of this subject are about as follows:

1. While the neoplasm's life history varies markedly from that usually known to be characteristic of malignancy of other organs, yet the essential biological characteristics are the same as with cancer elsewhere. The mystery regarding 'metastasizing benign adenomas' has been thoroughly dispelled. From the investigations of Simpson, Wilson, Crotti, Collier, and many others it is known definitely that benign thyroid tumors do not undergo metastasis and that such extensions as have been considered to be benign are, invariably, carcinomatous.

2. It is established that, while many carcinomas may be readily detected before operation, in many instances the disease is present and unrecognized until the tissue is in the laboratory.

3. It is known, only too well, that, in a large percentage of cases, only under the microscope can the exact diagnosis be made and then only when the examination is conducted by an especially skilled pathologist. In no form of neoplastic disease is error so possible as with early cancer of the thyroid gland. "Of all adenocarcinomas in any situation, I know of none with a wider range of structure than adenocarcinomas of the thyroid. They may be so undifferentiated that they are with difficulty distinguished from sarcomas, and, on the other hand, they may be so well differentiated that they produce structures closely resembling the normal thyroid gland, toxic adenoma or exophthalmic goiter, with the actual production of hyperthyroidism" (Broders).

4. One is led to believe that many reports of high percentages of cures following surgical extirpation of assumed carcinomatous thyroids, have been misleading, due to a fallacious histological diagnosis. On the other hand, from the clinics where the largest series have been studied it is evident that a gratifying percentage of 5 year cures may result from early and total extirpation followed by irradiation. Thus, in what is probably the largest series reported, that of Pemberton, of nearly 700 cases, in which group 267 patients were subjected to partial or complete thyroidectomy, 43.9 per cent lived for 5 years or longer.

5. Of the many complex pathological classifications, the one followed at the Mayo Clinic is simple and adequate: (1) papillary adenocarcinoma, (2) adenocarcinoma in malignant adenomas; (3) diffuse adenocarcinoma; (4) epithelioma; and (5) sarcoma (rare).

6. The high incidence with which carcinoma has developed in pre-existing adenomas is now well recognized and is mentioned by practically all recent writers. It is accepted that probably 85 per cent to 90 per cent of all carcinomas originate in a pre-existing adenoma. From this conclusions have been reached that, while relatively few adenomas become carcinoma, as a prophylactic measure, in view of the extremely low mortality with our present technique, all tumors of the thyroid gland, at least in adults, should be extirpated.

7. While the criterion of vascular invasion as an evidence of malignancy, advanced by Graham, is an interesting viewpoint, it is not entirely accepted, for while such invasion indicates positively a neoplastic process, malignancy of the

thyroid gland exists without such invasion being demonstrable.

8. It is accepted that with the three commoner types of neoplastic thyroid disease there is a wide variation in degree of malignancy. Papillary adenocarcinoma is known to be of a relatively low grade with the tendency to spread by lymphatic invasion. The metastasis usually becomes localized and remains relatively quiescent over a long period of time, resembling, as has been pointed out, the characteristics of papillary adenocarcinoma of the ovary.

9. The relative importance of aberrant thyroid tissue in the production of carcinoma is still an open question. While it is claimed that these are true supernumerary islands of thyroid tissue which are prone to carcinomatous change, it is claimed by others that such lateral aberrant masses are merely metastatic extensions from an original neoplasm within the gland itself.

10. It is accepted that the majority of carcinomas of the thyroid are malignant adenomas or carcinomas, originating in fetal adenomas and papillary adenocarcinomas, diffuse adenocarcinoma being less common and being the most highly malignant form. Within this group falls the fulminating malignant cancer of the thyroid for which so little can be accomplished.

11. Squamous epitheliomas are extremely unusual and sarcoma so rare that its actual existence has been questioned, notably by Ewing.

EFFECT OF SUBCUTANEOUS INJECTIONS OF CONCENTRATED SPLEEN EXTRACT ON MOUSE SARCOMA 180

RICHARD LEWISOHN, M.D., F.A.C.S., New York, New York

IT IS a well known fact that mouse sarcoma 180 is most refractory to any form of treatment and that this tumor shows a very low incidence of spontaneous regressions. Haagensen and Prime state that sarcoma 180 is the most reliable experimental instrument among all transplantable animal tumors with which they are familiar. They use this tumor in preference to any other for testing the therapeutic efficacy of chemical and physical agents on cancer. In reference to the question whether transplantable or spontaneous tumors are preferable for experimental cancer research, these authors conclude that "although new methods have recently been developed by which rat and mouse tumors can be induced with ease, the well known strains of transplantable tumors will continue to be used, for they afford the most convenient means of testing new forms of cancer therapy."

The experiments which are reported in this paper are based on the well known observation that in general abdominal carcinomatosis the spleen is usually free from any metastases. This observation has suggested the idea of using spleen extract in the treatment

From the Laboratories of Mount Sinai Hospital
Read before the New York Pathological Society, October 28, 1937

of human or animal malignancy. Many attempts have been made in this direction (Bauer, Chaletzka, Lyslowa and Schabad; Ludwig and Ries; Aueler; Roskin; and others.) However, they failed to give practical results, probably because, as will be seen in this paper, the concentration was too weak. It seemed to me advisable to use much higher concentrations than had previously been used.

In order to obtain a concentrated spleen extract a number of pharmaceutical houses were approached during the last few years. They were reluctant to experiment along these lines as the results seemed to be problematical.

About 2 years ago I submitted the same problem to Dr. David Klein, chief chemist of the Wilson Laboratories. He consented to prepare concentrated spleen extract. After some months of experimentation I received from him an extract in which 1 cubic centimeter represented 40 grams of beef spleen. Later a more concentrated extract representing 100 grams of spleen per cubic centimeter was made. While the manufacturing process is still being changed, in accordance with the experimental observations in the laboratory, the concentration of 100 grams of spleen in 1 cubic centimeter of extract has

*Effect of Subcutaneous Injections of Concentrated Spleen Extract on
Mouse Sarcoma 180 — Richard Leisohn*

Fig. 1. Different stages of sarcoma 180 treated with concentrated spleen extract.

Tumors treated with concentrated spleen extract, show, after a few injections, palpatory findings entirely different from those in the controls. Whereas the control tumors spread and are broadly attached to the underlying tissues, the tumors treated with extract can be lifted up easily from fascia and muscles. This sign which was often observed before the tumor began to regress was one of the first indications that the tumor would disappear after prolonged treatment with spleen extract.

The time which elapses between the first injection and the complete disappearance of the tumor depends to a marked degree upon the size of the tumor. For instance in the earlier sets (724¹, 738, and 841) the tumors both in the injected and in the control animals were of moderate size. Two or three weeks of

¹Set 724 was treated with a less concentrated extract (.0 gm of spleen in 1 c cm). This set is not included in the statistics which deal only with the more concentrated extract (100 gm. of spleen in 1 c cm.).

injections were required to make the tumor in the injected mice disappear completely. On the other hand in the more recent sets (897, 898, and 899 [Tables III and IV], 990, 991, and 992, and later sets) which had developed very large tumors both in the animals which were selected for the injections and in the controls, 4 to 6 weeks elapsed before no trace of tumor was left.

The tumors have not recurred during an observation time of up to 5 months. A number of animals died recently of natural causes. Careful microscopic examination of the region where the tumor had been located failed to show any traces of tumor cells, except in one case in which a small remainder of tumor was found. We used to stop injections after the macroscopic disappearance of the tumor. We now continue injections for 2 to 3 weeks after inspection and palpation fail to show a trace of the tumor.

been maintained. The action of this concentrated spleen extract on sarcoma 180 is the basis of this report.

The extract is an aqueous product prepared by extracting with water, adsorption with activated carbon, triple extraction with alcohol and elution. It represents 100 grams of fresh spleen tissue per cubic centimeter.

Cultures of the extract are sterile both aerobically and anaerobically.

Healthy looking female mice of the Rock land farm strain weighing 18 to 20 grams were selected for the experiments. A strain of mouse sarcoma 180 originally received from the Crocker Laboratory was used for transplantation. Small tumor particles were introduced into the right axilla with a trocar. Every tumor was cultured before the transplantation. Before the experiments were started a certain percentage of animals were killed and cultures were taken in order to rule out infection. Furthermore whenever controls showed a percentage of regressions higher than the normal level, cultures were taken in order to exclude regression by infection.

REPORT OF EXPERIMENTS

Two hundred eighty-one animals with sarcoma 180 were treated with subcutaneous injections of 0.5 cubic centimeter of concentrated spleen extract. Two hundred ninety animals were used as controls. Eighty animals (20 in each series) were treated with other organ extracts (heart, liver, pancreas

and testis). Fifty nine animals were given smaller doses of spleen extract (0.1 c cm). Twenty animals were injected with chlorobutanol and 20 with merthiolate in the same percentage as used in the spleen extract and the other organ extracts (Table I). In order to prepare the charts for this presentation, the records were carried up to October 15, 1937.

The number of animals used in each set for injections with spleen extract and for controls is shown in Table II.

The injection (0.5 c cm) was given subcutaneously as far away as possible from the tumor. The tumor was situated near the right axilla, the injections were given into the subcutaneous tissue near the left hip joint. There was no sign of local irritation, inflammation, or infection found at the site of injection.

The first injection was given 7 to 9 days after the transplantation depending upon the size of the tumor (Fig 1a). In about 30 per cent of the tumors a marked hemorrhage was noted in less than 24 hours following the injection of the extract. In the majority of cases the hemorrhage did not occur until three or four subcutaneous injections had been given on 3 or 4 consecutive days (Fig 1b). However, in a number of animals this hemorrhage was observed within a few hours after the injection. This hemorrhage into the tumor gradually increased in size, when the injections were continued daily (Fig 1c). Ultimately the tumor consisted of a large hemorrhagic center (Fig 1d) surrounded by a narrow wall of tumor tissue. Subsequently a scab was noticed in the area which was formerly represented by the hemorrhage. When this stage was reached the tumor either stopped growing or began to diminish in size. Gradually the hemorrhagic scab was expelled, leaving a large cavity. This cavity eventually broke through the encircling tumor tissue, leaving a half moon like ring of tumor (Fig 1e). The cavity decreased in size in a few days the half moon like ring of tumor tissue was absorbed (Fig 1f) and after a few weeks the tumor not only disappeared completely, but the area where it had been located presented an absolutely normal appearance except for a slight alopecia (Figs 1g and 1h).

Table V Set 901 Controls for 897, 898, and 899

statement An inspection of the charts demonstrates very clearly that in spite of large ulcerations with secondary infections tumors in the controls continue to grow and ultimately cause the death of the animals. The process which is observed in the *treated* animals is entirely different. We do not notice the secondary infection, but we observe that the hemorrhagic area is excluded. The field appears completely dry contrary to the marked secretion which accompanies the ulcerative process in the controls.

In order to ascertain the specificity of concentrated spleen extract for the treatment of mouse sarcoma 180, four other organ extracts were tested, namely, liver, heart, pancreas, and testis. All these organs were obtained from the same animal as the spleen (beef). The extracts were identical in concentration and preparation with the spleen extract. It is of the greatest interest to know that none of these caused hemorrhages or retarded the growth of the tumors (Tables XII to XV).

Table III Set 897 Results in 10 treated animals

Control mice show a marked loss of weight in spite of the rapidly growing tumor whereas mice treated with spleen extract often begin to gain weight long before the tumor has actually disappeared (see charts). This gain in weight is sometimes the first indication that the tumor is about to regress. The weight gain continues after complete disappearance of the tumor.

Tables III to XI inclusive, present graphically the characteristic progress and final effect of some of the individual experiments. The full tabulation of the results is presented in Table II. It is evident from this table that of 281 animals treated with spleen extract the tumors disappeared in 170 cases (60 per cent). Of 290 animals used as controls only 23 (8 per cent) showed spontaneous regressions.

Sets of treated animals were not included in the statistics when the controls showed a high percentage of regressions. It is interesting to point out that the number of cures among the treated animals rises when the controls show a high percentage of regressions. For instance in one set in which the controls

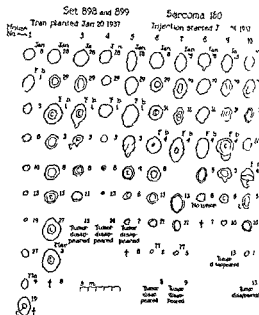

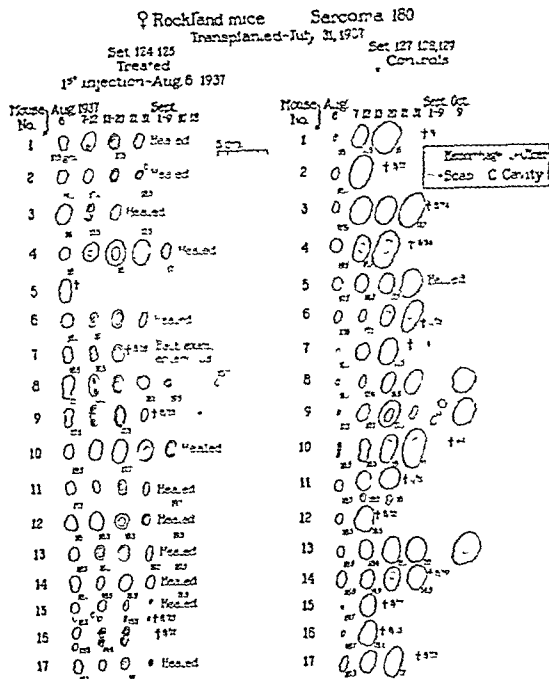

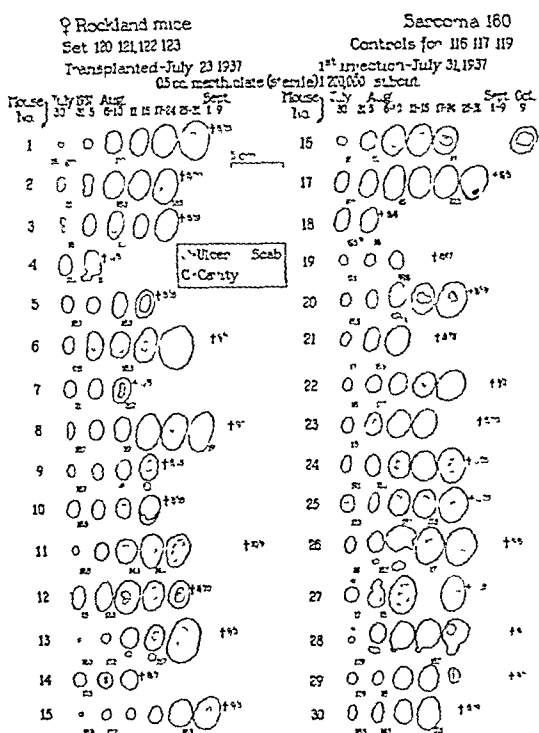

Table IV Sets 898 and 899 Results in 10 treated animals

showed 30 per cent regressions, the percentage of cures among the treated animals rose to 85 per cent.

We have confined our statistical survey to those animals whose tumors disappeared completely. We did not include a large group of mice (over 30 per cent) whose tumors showed regression or arrest of growth, but which died before the injections could be completed.

Two forms of spontaneous regressions were observed in the controls. First, early regression was observed in those tumors which showed an ulceration a short time after the transplantation namely on the sixth or seventh day. Some days later a few of these tumors showed a cavity. Their growth was arrested and they disappeared after the fourteenth day. Second, late regression was observed in a few animals which did not succumb to the rapidly growing tumor in 4 to 6 weeks. In this group an infection of the tumor could be observed which caused its disappearance.

It has been stated that any transplantable tumor is apt to disappear spontaneously in the presence of an ulceration. My experience with sarcoma 180 is at variance with this

Dr R Leuchtenberger has performed in this laboratory some very interesting experiments with histamine which have not yet been concluded. Therefore we shall report them in detail in a later publication. However, I may state now that, following subcutaneous injections of histamine, early hemorrhages occur in these tumors (sarcoma 180) which are identical in appearance with those observed following the subcutaneous injection of spleen extract. Histamine is Schwartzman-negative. Thus we find that two Schwartzman-negative substances (spleen extract and histamine) may effect hemorrhages into sarcoma 180.

Whereas small doses of spleen extract stimulate the growth of the tumors, large doses of histamine seem to have a stimulating effect upon sarcoma 180.

In its present form and application the extract does not cause disappearance of the tumor after a few injections. To effect a complete regression it usually requires injections

of 0.5 cubic centimeter extending over 3 to 6 weeks.

The mortality following the injection among animals injected with spleen extract depends to a large degree upon the proper gauging of the injections. If these are given routinely day after day without attention being paid to the state of health of the animal, the mortality is apt to be relatively high. However, if due care is taken to individualize the frequency of the injections according to the condition of the mouse, the mortality is reduced considerably.

Furthermore it should be pointed out that proper food and good care of the animals are of the utmost importance in reducing their mortality. In the earlier series we lost a considerable number of animals during the course of the treatments. Since proper attention was paid both to the frequency of the injections and the proper feeding, the mortality has been markedly lessened.

spleen extract might be due to the presence of a Schwartzman active substance

Through the courtesy of Dr Schwartzman the spleen extract was tested for the Schwartzman phenomenon The extract did not show the phenomenon This negative finding is of considerable importance as it proves that Schwartzman negative substances may cause hemorrhages into malignant tumors Apitz's statement that "all Schwartzman active substances and—according to experiences collected up to-date these substances only—cause hemorrhages into carcinoma" requires correction

Fig 2 Set 183, sarcoma 180, 4 hours after injection of spleen extract

Fig 3 Set 183, sarcoma 180, 24 hours after injection

Table XII Animals treated with liver extract

We expect to obtain a more rapid action and a higher percentage of cures by increasing the concentration of the extract and by further attempts to isolate the active principle

Microscopic examinations of the various phases during the treatment were performed by Dr Klemperer. Figure 2 represents the hemorrhagic phase as seen 4 hours after the first injection. Conspicuous dilatation of the blood vessels near the surface and superficial necrosis are noticed. In Figure 3, 24 hours after injection, extensive necrosis of the tumor is seen. The periphery still shows viable tumor. Figure 4, 48 hours after injection, shows almost complete necrosis and necrobiosis of the tumor with the exception of small nests of viable tumor cells at the periphery. The high power microphotogram (Fig 5) shows cytologic details of the same phase. Tumor cells are shrunken, the nuclei are pyknotic, the cytoplasm is eosinophilic and glassy compared with the untreated sarcoma 180 (Fig 6) which shows the cells basophilic

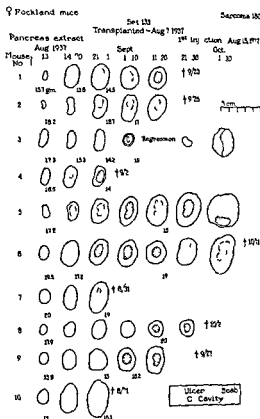

Table XIII Animals treated with pancreas extract

and finely granular. Figure 7, 11 days after the first injection, shows extensive and complete coagulation necrosis of the tumor. Cell ghosts are still present, chiefly at the periphery, mingled with these, occasional viable tumor cells are noted. Figure 8, control, 3 weeks old, shows also necrosis in the center. However, extensive areas of viable tumor cells are observed at the periphery. These microscopic studies are supplementary only to the much more striking gross observations of the fate of the tumor under treatment.

Of greatest interest is the observation that whereas the extract when administered in 0.5 cubic centimeter doses causes disappearance of the tumor in 60 per cent of the cases, the smaller dose of 0.1 cubic centimeter of the same extract has a markedly stimulating effect (Tables XVI and XVII). The tumors

Fig 4 Set 200, sarcoma 180, 48 hours after injection (low power)

grow very rapidly, in fact much more rapidly than the controls. The animals show a very acute loss of weight. After a few injections they change from healthy looking normal mice into completely emaciated and very sick looking animals. This most interesting obser-

vation may explain the contradictory reports given by other authors on the action of spleen extract on malignant tumors. Their failures to get results must have been caused by the fact that they used stimulating doses of spleen extract.

Fig 5 Set 200, same as Figure 4 (high power)

Fig 6 Microscopic section of untreated sarcoma 180

Fig 9 a and b, Spleen in animal treated with spleen extract, c, control

Fig 10 a and b, Spleen in animal treated with spleen extract, c, animal treated with pancreas extract

extracts (liver, pancreas, heart, and testis) is small, whereas after treatment with spleen extract the spleen is very large—often 4 to 5 times the normal size (Figs 9, 10, 11). The large size of the spleen following treatment with concentrated spleen extract suggests the possibility that the therapeutic effect of this extract is not caused by its direct action on the tumors, but by an indirect action via the spleen of the mouse. In other words, it is possible that by increasing the normal defense action of the spleen against malignancy we may retard the growth of the tumor and cause its disappearance. The marked enlargement of the spleen also suggests a possible application of the extract in the treatment of splenic diseases.

Experiments have been started to investigate whether spleen extract has a preventive action upon the growth of the tumor.

Before closing I wish to mention very briefly some recent experiments which I shall report in detail at a later date. They seem of sufficient importance to warrant a brief note. (1) When injections were started on the twelfth day after transplantation instead of on the seventh or eighth day, the process of healing was markedly accelerated and the percentage of cures increased. (2) When 0.1, 0.15, or 0.2 cubic centimeter of the extract is given intravenously, a hemorrhage does not occur. However the other stages (cavity and scab) are noted. We observed a marked regression or complete disappearance of the tumor. The

intravenous approach will now be tested on a large series of animals.

Sarcoma 180 is not supposed to cause metastases. However, we have noted intraperitoneal and other metastases following injections of 0.1 cubic centimeter of spleen extract, of pancreatic extract, and of histamine.

In the small percentage of refractory cases which do not show any response to treatment we have observed in practically every case the presence of intestinal parasites. Domagk has pointed out the possibility of a stimulating effect of these parasites on tumor growth.

Hemorrhages and regressions were noted in rat sarcoma 39 following treatment with spleen extract. However, as we had a fairly high incidence of regressions in the controls, and as the number of animals was small, we cannot at present draw any definite conclusions as to action of extract on sarcoma 39.

The extract will be tried in leucemic mice as it may be of value in some blood diseases.

Fig 11 a, Spleen in animal treated with spleen extract, b, animal treated with testicular extract, and c, control.

Fig 7 Set 193 sarcoma 180 11 days after injection

Fig 8 Set 196 control after 3 weeks

Injections of spleen extract at present on the market containing 5 grams of extract per cubic centimeter do not hinder the growth of the tumor. On the contrary they stimulate it

A possible lead to the action of the spleen extract upon the tumor may be found in the following observation. The spleen in the controls and in animals treated with other organ

MALIGNANT ADENOMA OF THE THYROID

Local Recurrences in the Veins of the Neck

ALLEN GRAHAM, M.D., F.A.C.S., Cleveland, Ohio

AN outstanding and well known peculiarity of carcinomas of the thyroid, especially carcinomas of the malignant adenomatous type, is the tendency of the tumor tissue to perforate into the small, thin walled veins in the tumor and the intraluminal propagation and extension of the tumor tissue to the capsular veins, the main thyroid veins, and thence to the jugular veins and even to the vena cava.

During the course of primary operations as usually practiced for the removal of such tumors, it is inevitable that many branches of the thyroid veins and the main trunks will be clamped, divided, and ligated. If perchance tumor tissue be present in the lumina of the veins between the site of ligation and the vena cava, it is obvious that not all the tumor tissue will be removed by the operation and it is more than probable that the patient will have recurrences or metastases which will be beyond further successful surgical intervention.

On the other hand, should tumor tissue be present in the lumina of the veins only distal to the site of ligation, that is, between the ligature and the peripheral distribution of the venous trunks, the very fact of ligation might tend to prevent or delay embolic dissemination of the tumor to the lungs and elsewhere, but would probably have little or no influence upon the further growth of tumor tissue which might remain in such an isolated venous segment. The growth of such a supposititious remnant of tumor tissue, confined to an isolated venous segment, might well account for the reappearance of nodules in the neck some months or even years after the original operation without evidence of distant metastases.

Failure to recognize or properly to interpret this postoperative sequel may lead to a pro-

longed struggle with repeated recurrences, repeated operations, dissemination of the tumor in the neck beyond the possibility of successful surgical removal, and termination of the struggle, after some years of hopeful expectancy, by death of the patient.

If, on the other hand, the possibility of such an occurrence be understood and kept in mind and appropriate surgical treatment be instituted in such cases, it will be possible to vouchsafe years of freedom from trouble for some patients and may perhaps result in a cure in a few instances. The following case reports are illustrative:

CASE REPORTS¹

CASE 1. An unmarried Jewish female, 18 years of age, was admitted to the hospital October 28, 1919, complaining of goiter and tonsillitis. The family history was irrelevant except that the mother had goiter. The patient had had frequent attacks of tonsillitis, the last terminating as a quinsy which ruptured spontaneously.

Two years before admission she noticed a gradual enlargement of the neck which had increased more rapidly during the last 8 months, following the taking of thyroid tablets. She had had some difficulty in swallowing, especially when she had a cold, but there was no history of tachycardia, palpitation, weakness, hyperhidrosis, unusual nervousness, or loss of weight. Her general health had been good.

On examination there were found no eye signs suggestive of hyperthyroidism. The tonsils were enlarged, congested, and protruded slightly. There was moderate bilateral enlargement of the thyroid which was more prominent on the left with numerous rounded, firm tumor masses scattered through the gland. The pulse was regular, rapid, and rhythmic. There was a slight tremor of the fingers.

The primary operation was performed October 30, 1919. Multiple discrete adenomas were found in the right lobe and these were removed by sharp dissection together with a small amount of adjacent thyroid tissue. The left lobe was not disturbed.

Macroscopical examination. The tissue sent to the laboratory consisted of four thinly encapsulated

¹Only positive or pertinent information is recorded, many negative findings being omitted from the case reports. The author will gladly furnish further details to those interested.

From the Department of Surgical Pathology of the Cleveland Clinic.

Read at the meeting of the American Association for the Study of Goiter, Detroit, Michigan, June 16, 1937.

Reports on experiments with trypanblue and on the action of spleen extract on splenectomized tumor animals will be presented in later publications

SUMMARY

1 Of 281 animals treated with subcutaneous injections of 0.5 cubic centimeter of concentrated spleen extract (100 gms of fresh spleen in 1 c cm) the tumor (sarcoma 180) disappeared completely in 170 animals (60 per cent)

2 Corresponding controls showed a spontaneous regression in 8 per cent of 290 animals

3 Injections extending usually over 2 to 6 weeks, depending upon the original size of the tumors, are required to cause disappearance of the tumors

4 Weight gain is an early sign indicating subsequent disappearance of the tumor

5 Small doses of the extract (0.1 c cm) have a stimulating effect upon the tumor

6 A marked increase in the size of the spleen is noted in the animals treated with

spleen extract. Animals treated with other organ extracts and controls do not show this enlargement

7 Extracts from the liver, heart, pancreas, and testis fail to cause hemorrhages into the tumor or to influence its growth

8 The spleen extract does not show the Schwartzman phenomenon

MALIGNANT ADENOMA OF THE THYROID

Local Recurrences in the Veins of the Neck

ALLEN GRAHAM, M D , F A C S , Cleveland, Ohio

AN outstanding and well known peculiarity of carcinomas of the thyroid, especially carcinomas of the malignant adenomatous type, is the tendency of the tumor tissue to perforate into the small, thin walled veins in the tumor and the intraluminal propagation and extension of the tumor tissue to the capsular veins, the main thyroid veins, and thence to the jugular veins and even to the vena cava

During the course of primary operations as usually practiced for the removal of such tumors, it is inevitable that many branches of the thyroid veins and the main trunks will be clamped, divided, and ligated. If perchance tumor tissue be present in the lumina of the veins between the site of ligation and the vena cava, it is obvious that not all the tumor tissue will be removed by the operation and it is more than probable that the patient will have recurrences or metastases which will be beyond further successful surgical intervention.

On the other hand, should tumor tissue be present in the lumina of the veins only distal to the site of ligation, that is, between the ligature and the peripheral distribution of the venous trunks, the very fact of ligation might tend to prevent or delay embolic dissemination of the tumor to the lungs and elsewhere, but would probably have little or no influence upon the further growth of tumor tissue which might remain in such an isolated venous segment. The growth of such a supposititious remnant of tumor tissue, confined to an isolated venous segment, might well account for the reappearance of nodules in the neck some months or even years after the original operation without evidence of distant metastases.

Failure to recognize or properly to interpret this postoperative sequel may lead to a pro-

longed struggle with repeated recurrences, repeated operations, dissemination of the tumor in the neck beyond the possibility of successful surgical removal, and termination of the struggle, after some years of hopeful expectancy, by death of the patient.

If, on the other hand, the possibility of such an occurrence be understood and kept in mind and appropriate surgical treatment be instituted in such cases, it will be possible to vouchsafe years of freedom from trouble for some patients and may perhaps result in a cure in a few instances. The following case reports are illustrative.

CASE REPORTS¹

CASE 1 An unmarried Jewish female, 18 years of age, was admitted to the hospital October 28, 1919, complaining of goiter and tonsillitis. The family history was irrelevant except that the mother had goiter. The patient had had frequent attacks of tonsillitis, the last terminating as a quinsy which ruptured spontaneously.

Two years before admission she noticed a gradual enlargement of the neck which had increased more rapidly during the last 8 months, following the taking of thyroid tablets. She had had some difficulty in swallowing, especially when she had a cold, but there was no history of tachycardia, palpitation, weakness, hyperhidrosis, unusual nervousness, or loss of weight. Her general health had been good.

On examination there were found no eye signs suggestive of hyperthyroidism. The tonsils were enlarged, congested, and protruded slightly. There was moderate bilateral enlargement of the thyroid which was more prominent on the left with numerous rounded, firm tumor masses scattered through the gland. The pulse was regular, rapid, and rhythmic. There was a slight tremor of the fingers.

The primary operation was performed October 30, 1919. Multiple discrete adenomas were found in the right lobe and these were removed by sharp dissection together with a small amount of adjacent thyroid tissue. The left lobe was not disturbed.

Macroscopic examination The tissue sent to the laboratory consisted of four thinly encapsulated

¹Only positive or pertinent information is recorded, many negative findings being omitted from the case reports. The author will gladly furnish further details to those interested.

From the Department of Surgical Pathology of the Cleveland Clinic.

Read at the meeting of the American Association for the Study of Goiter, Detroit, Michigan, June 16, 1937.

Fig 1 Case 1 a Primary tumor from the right lobe of the thyroid b Recurrence in the right lobe 1 year later $\times 250$

firm nodules having a very cellular grayish opaque cut surface and there was a moderate amount of hyperplastic non tumorous thyroid

Microscopical examination Sections from some of the nodules showed the absence of a definite lobular arrangement rather thick capsular zones and tumor tissue composed of acini of normal size or smaller which were closely packed together and were lined with a single layer of high cuboidal epithelial cells. There was no colloid material (Fig 1a). Sections from other nodules showed larger acini which were filled with dark pink staining colloidal material and were lined with low cuboidal cells.

A pathological diagnosis of multiple fetal adenomas was made.

The patient made an uneventful recovery and was discharged from the hospital 8 days after the operation.

Tonsillectomy was performed December 1, 1919. October 17, 1920, one year following the primary operation, the patient was readmitted to the hospital because of the recurrence of a nodule in the neck unassociated with symptoms. On examination the previous operative scar was scarcely visible. There was no lymphadenopathy. There was a small hard irregular painless tumor about the size of a walnut situated to the right of the thyroid cartilage and not attached to the skin.

The second operation was performed October 20, 1920. There were adhesions between the gland and the muscles but these were not dense. A small adenoma was situated directly over the larynx and there were thought to be multiple adenomas in the right lobe. The right lobe isthmus and part of the left lobe were removed.

Macroscopical examination The tissue removed consisted of the major portion of both lobes and isthmus of the thyroid. The weight of this tissue was 30 grams. The left lobe and isthmus consisted of colloid thyroid tissue without adenomatous nodules. The portion of right lobe was occupied by a non encapsulated infiltrating tumor mass with a fairly cellular somewhat granular periphery and a more fibrous center. Grossly the tumor appeared to be a carcinoma.

Microscopical examination Sections from the left lobe showed non tumorous colloid thyroid tissue. Sections from the tumorous portion of the right lobe showed strands and columns of atypical epithelial cells lying in a fairly dense connective tissue stroma and having no tendency to form acini. The epithelial cells varied considerably in

Fig 2 Case 1 a Recurrence in the left jugular vein b Thread passed through the lumen of the vein c The resected jugular vein showing tumor thrombus in the lumen c Cross section of the vein showing tumor thrombus attached to the wall low power photomicrograph $\times 4$

size and shape. Many of the nuclei were hyperchromatic, and mitotic figures were moderately abundant (Fig 1b). Sections from the non-tumorous part of the right lobe showed normal appearing thyroid tissue rich in colloid.

A pathological diagnosis of adenocarcinoma (malignant fetal adenoma) was made.

In view of the recurrence in the right lobe and the pathological diagnosis of carcinoma, radium treatment, 1500 milligram hours, was given while the patient was in the hospital. Mild symptoms of tetany developed and were controlled by means of calcium lactate and parathyroid extract. Otherwise the patient made an uncomplicated recovery and was discharged from the hospital 11 days following the second operation.

She was again seen April 25, 1921. There were one or two hard, firm, somewhat movable nodules about the size of hickory nuts in the left thyroid area. These were thought to be recurrences of the malignant tumor. On May 3 and 17, 1921, radium treatments of 900 and 950 milligram hours, respectively, were given over the left lobe of the thyroid.

In August, 1921, the mass in the left thyroid region was smaller. It was palpable but not visible.

During the ensuing 8 years the patient was under observation many times and was treated for various conditions unrelated to the goiter. In May, 1926, 6½ years after the second operation, she thought that the mass in the left thyroid region had become larger but examination at that time failed to confirm this. In March, 1927, she was married.

In September, 1929, 10 years after the primary operation and 9 years after the second operation, despite the fact that there had been no clinically detectable change in the nodule in the left thyroid area, the question of its removal came up for recon-

sideration. In view of the recurrence following the primary operation, the pathological diagnosis of carcinoma made at the time of the second operation, and the apparent recurrence and persistence of a mass following the second operation, it was deemed advisable to remove the mass.

The third operation was performed September 19, 1929. Under nitrous oxide-ether anesthesia, an incision was made along the border of the left sternomastoid muscle and the muscle was retracted mesially. A tumor mass was encountered in the region of the carotid sheath and appeared to be situated in the internal jugular vein. The vein together with the tumor mass was excised between clamps and the cut ends of the internal jugular vein were ligated.

Macroscopic examination. The weight of the tissue removed was 10 grams and it measured 4 by 2.5 by 2 centimeters. The anterior and lateral surfaces were covered by muscle, fascia, and fat. The mesial surface consisted of part of a vein wall and the capsule of the tumor (Fig 2a). The superior extremity of the mass consisted of a vein 7 millimeters in diameter (Fig 2b) which extended along the mesial surface of the mass for a distance of 3 centimeters. The entire venous segment was apparently filled with a solid, pseudolobulated, firm, white tissue containing very little colloid (Fig 2c). The inferior end of the venous segment appeared free from tumor thrombus and was 8 millimeters in diameter. Numerous other venous tributaries were filled with tumor tissue.

Microscopic examination. Sections revealed numerous large venous trunks filled with a tumor mass which consisted of an adenopapilliferous type of thyroid tissue (Fig 3a) showing a well marked tendency to form acini which contained varying

Fig. 4 Case 2 Site of local recurrence 5½ years after the primary operation

amounts of colloidal material. The epithelial cells lining the acini were cuboidal to high columnar in type and mitotic figures were not seen (Fig. 3b).

A pathological diagnosis of malignant adenoma, toxic thyroid tissue recurrent in the jugular vein was made.

The patient made an uneventful recovery and was discharged from the hospital on the seventh post-operative day.

The patient was last heard from in April 1936, 16½ years after the primary operation, 15½ years after the second operation, and 6½ years following the third operation at which time she was free of clinical evidence of malignant disease. Following the third operation (1929) symptoms of hypothyroidism developed and were controlled by means of thyroid extract.

In this case it is apparent from the record that, at the time of the primary operation, malignancy was not suspected before or during the operation, nor on gross and microscopic examination of the tissue removed. The operation consisted of shelling out four encapsulated nodules, presumably fetal adenomas from the right lobe and excision of a part of the lobe. One year later, the patient returned with a nodule in the right side of the neck, which was thought to be a regrowth of an incompletely removed adenoma or further growth of an adenoma which was not discovered during the primary operation. During the operation for the removal of the recurrence in the right lobe, malignancy was not

suspected. A large part of the right lobe with the tumor, the isthmus, and a part of the left lobe were removed. On gross and microscopic examination the pathologist suspected malignancy and made a diagnosis of adenocarcinoma involving the right lobe only. About 6 months after the second operation, the patient returned with a mass in the left side of the neck, which was interpreted as a contralateral recurrence or metastasis and was treated with radium. The mass decreased in size but persisted and after several years having gained experience in several other cases which strongly suggested the possibility, it was thought quite possible that this mass in the left side of the neck might be confined within veins and that operative removal might prevent dissemination. The operation was undertaken with this possibility in mind, under surgical anesthesia, with adequate exposure, every effort being made to keep beyond the limits of the growth and to remove involved veins if possible. This is the first case in which it was proved to the entire satisfaction of the writer that the local growth was in the jugular vein. The subsequent course apparently warrants the assumption that there was no other recurrence or metastasis.

CASE 2. A white male 55 years of age registered in the clinic September 26, 1925, complaining of goiter. The family history was essentially negative. The patient had had pneumonia and his appendix had been removed 11 years previously.

A goiter which had been present for 25 years had gradually increased in size and grown more rapidly during the last 2 years and was accompanied by definite symptoms of pressure such as difficulty in swallowing solid foods and difficulty in breathing when the head was in certain positions. He had been somewhat nervous for 4 to 5 years and slightly dyspneic on exertion for 2 or 3 years. He had had no palpitation or loss of weight.

On examination the pulse was found to be 100, blood pressure 125 systolic and 80 diastolic. There was a large adenomatous goiter. The right lobe was greatly enlarged and contained one nodule the size of an orange and another about the size of an egg. Both were quite hard, firmly fixed and did not move on swallowing. The left lobe was also enlarged and contained several small discrete nodules the size of a hickory nut or less. None of the cardinal symptoms or signs of hyperthyroidism were noted.

A clinical diagnosis of adenomatous goiter with possible malignancy was made.

The primary operation was performed September

Fig 5 Case 2 Recurrence in the jugular vein excised $5\frac{1}{2}$ years after the primary operation a, External surface. b, Mesial surface Note the tumor tissue filling the lumina of the divided veins

28, 1923, through a low collar incision The right lobe of the thyroid was found to contain two adenomas one of which was very large and was thought to be carcinomatous For this reason the entire right lobe was removed The left lobe was not disturbed

Macroscopical examination The weight of the small tumor from the region of the lower pole or isthmus was 42 grams, and it measured 5.5 by 4 centimeters It proved to be a benign encapsulated adenoma The weight of the large tumor was 345 grams and it measured 12 by 9 by 7.5 centimeters It consisted of a large encapsulated adenoma partially covered by a thin layer of compressed thyroid tissue The superior, inferior, and thyroidea ima veins were extensively plugged with tumor tissue Section through the tumor showed an old adenoma with areas of edema, some recent and old hemorrhage, and small areas of hyalinized scar tissue but no cystic or calcified areas

Microscopical examination¹ Sections taken from various portions of the tumor showed all manner of variations of histologically benign adenomatous tissue and transition of the adenomatous tissue into histologically carcinomatous tissue which invaded the capsule and grew into the branches of the thyroid veins

A pathological diagnosis of carcinoma of the malignant adenomatous type was made

The patient made an uneventful recovery and was discharged from the hospital on the sixth postoperative day Six days later roentgen treatments were given to the right and left thyroid areas, each field receiving approximately one erythema dose

In January 1929, more than 5 years after the primary operation, the patient returned to the

¹A photograph of the gross specimen and numerous photomicrographs illustrating the extremely varied histology of the primary tumor and the tumor thromboes in the thyroidal veins were published in Surg., Gynec. & Obst., 1924, 39 781-792 (Figs 3 to 22, inclusive) hence illustrations pertaining to the primary tumor are omitted from the present article

Fig 6 Case 2. A histologically benign type of recurrent tumor tissue in a branch of the jugular vein.

clinic because of the presence of a small lump on the right side of the neck which had been developing for about 1 year

On examination a small, hard, irregular mass which was somewhat fixed to the deep structures but was not adherent superficially was found in the right side of the neck (Fig. 4). This had caused no symptoms There was no other clinical or roentgenographic evidence of local recurrence or distant metastasis

The second operation was performed January 31, 1929 under nitrous oxide-ether analgesia A transverse incision was made over the tumor and, after dividing the muscles, we found a brownish friable mass just to the right of the larynx It was adherent to the overlying muscles and overlaid the carotid artery The tumor was removed by sharp dissection, the wound was packed open with gauze, and x-ray treatments of one-half erythema dose each were given into the open wound the day of operation and on the following day

Macroscopical examination. The weight of the mass of tissue removed (Fig 5a) was 11 grams, it measured 5 by 3 by 2 centimeters and included a tumor nodule, 3.5 by 2.5 by 2 centimeters Along one border there were several cord-like branching

Fig 7 Case 3 a Primary tumor not frankly malignant histologically b Tumor tissue in a vein in the tumor $\times 90$

structures suggestive of a vein wall. Along the opposite border there was a similar cord like structure 6 millimeters in diameter. At one end of this there were clamp marks indicating the site of division. When the sealed edges were opened a large venous trunk was found filled with red, soft friable tissue (Fig 5b).

Microscopical examination. A section through the mass showed a large vein presumably the internal jugular or one of its large branches filled with an adenomatous type of thyroid tissue of variable histological structure closely simulating the histological types noted in the primary tumor removed in 1923. It was not frankly carcinomatous histologically (Fig 6).

The wound was closed on the fifth postoperative day and the patient was discharged on the eighth postoperative day having made an uneventful recovery except for some induration in the wound after secondary closure. Two months after discharge from the hospital a second course of x ray treatment one erythema dose was given over the right thyroid area. The patient was last heard from on February 11, 1936 12 years after the primary operation and 7 years after the removal of the recurrence. He was free of clinical evidence of malignant disease.

In this case the possibility of malignancy was considered before the primary operation but a positive diagnosis was not made. During the primary operation one large adenoma in the right lobe was thought to be malignant hence the entire right lobe was removed. Gross examination of the tissue revealed many large veins around the adenoma filled with

tumor tissue. The histological characteristics of the tissue in the primary tumor and in the plugged veins has been illustrated in a previous publication (see footnote, preceding page).

This patient did not return for more than 5 years after the primary operation, at which time he had an apparently local growth situated at about the site of the upper pole of the right thyroid lobe (Fig 4). It was suspected that the recurrence might be confined to the veins, and the operation for its removal was undertaken with this in view, surgical anesthesia and adequate exposure being used. The subsequent course seems to indicate that this was the only recurrence or metastasis.

The writer is inclined to believe that the recurrence in this case was in the jugular vein or in large venous trunks immediately tributary thereto. The major interest was in completely removing the growth rather than in its precise anatomical location, and rightly so.

CASE 3. A white single female a school teacher 28 years of age registered in the clinic August 27 1928 complaining of goiter of 4 years duration. The family history was negative. The patient had had the usual diseases of childhood. Appendectomy had been performed 5 years previously and tonsillectomy 3 years previously.

The patient first noticed a goiter about 4 years prior to the first examination. It had grown slightly larger in the last 3 months causing a sense of pressure in the neck slight dysphagia and occasional

aching pains in the neck. She had always been nervous but was not increasingly so. There were no cardiac symptoms or loss of weight. She had been taking medicine, presumably some form of iodine, for several months.

On examination none of the cardinal symptoms or signs of hyperthyroidism were noted. There was a firm, discrete, oval nodule 5 by 3 centimeters in the right lobe of the thyroid partially concealed by the clavicle. The remainder of the examination was essentially negative.

A clinical diagnosis of adenoma of the thyroid without hyperthyroidism was made.

One year later the patient returned to the clinic stating that the goiter had increased in size but had caused no particular trouble.

The primary operation was performed September 19, 1929. The right lobe was found to contain two tumor nodules which were thought to be adenomas and a third adenoma was situated in the isthmus. The left lobe appeared to be normal. The right lobe with the two tumors was resected and the adenoma was excised from the isthmus.

Macroscopic examination The weight of the tissue removed was 40 grams. The right lobe measured 8.5 by 4 by 2.5 centimeters. In the lower pole there was an encapsulated tumor mass 2.5 centimeters in diameter which was very hard. The upper portion of the lobe appeared to be non-tumorous. The nodule from the isthmus was a small, encapsulated benign adenoma 1.5 centimeters in diameter.

Microscopic examination A section from the nodule in the lower pole of the right lobe showed a differentiated hyperplastic adenoma with areas of hyalinized scar tissue, old hemorrhage, and areas of calcification. At one end there was an area of rather cellular tissue arranged in solid cords and masses of closely packed epithelial cells not forming acini. The cell masses were separated by a delicate endothelialized vascular network. Mitotic figures were not observed. On account of the histological characteristics of the small area described (Fig. 7a) additional sections were taken which showed similar histological characteristics and the presence of tumor cells in the lumina of some of the capsular veins (Fig. 7b).

On the basis of these findings a pathological diagnosis of hyperplastic goiter with multiple adenomas, one of which was malignant, was made.

The patient made an uneventful recovery and was discharged from the hospital on the seventh postoperative day.

In December, 1933, the patient returned to the clinic because of the appearance of a small nodule in the suprasternal notch which was first discovered in March, 1932, about 2½ years after the primary operation. The nodule gradually increased in size but caused no particular symptoms and did not affect the general health. On examination a firm, elastic mass about the size of a lime was noted and palpable in the suprasternal notch. It was freely

Fig. 8 Case 3 a, above, External and cut surface of the first local recurrence removed more than 4 years after the primary operation. b, The wall of a vein and the histological characteristics of the tumor thrombus in the lumen $\times 135$.

movable under the skin but somewhat more firmly attached to the deeper structures. The mass was interpreted as a probable recurrence and its removal was advised.

The second operation was performed December 27, 1933, under local anesthesia. A transverse incision was made over the nodule and the latter, which was about 3 centimeters in diameter, was removed by sharp dissection. The nodule appeared to have developed in the scar where the pretracheal muscles had been divided at the first operation.

Macroscopic examination The weight of the tissue removed was 12 grams and it measured 3.5 by 3 by 3 centimeters. It consisted of a single, encapsulated nodule (Fig. 8a) of uniform, light yellowish-brown, homogeneous tissue with a small, irreg-

Fig 9 Case 3 a The second local recurrence in the suprasternal region removed 5 years after the primary operation. Note the tumor nodule in the center. At the lower end there is thymic tissue and a parathyroid. b The recurrent tumor nodule $\times 10$.

ular central area of edematous stroma and a more cellular periphery. The nodule was surrounded by fibrous tissue fat and muscle. It was suspected that the nodule was a growth of tumor tissue in a vein but this could not be demonstrated grossly.

Microscopical examination. Sections revealed a large vein filled with adenomatous thyroid tissue consisting of solid nests and cords of rather large cells showing very little tendency to form glands (Fig 8b). The cell masses were separated by a delicate highly vascularized stroma. There was no colloidal material or normal thyroid tissue. A pathological diagnosis of malignant adenomatous thyroid recurrent in the cervical vein was made.

The patient made an uneventful recovery and was discharged from the hospital on the fourth post operative day.

In August 1934, 8 months after excision of the first recurrence, the patient returned to the clinic because of a nodule in the suprasternal notch. This had been present for a few weeks and was increasing in size but caused no symptoms. It was interpreted as a probable recurrence.

The third operation was performed August 19, 1934, under gas anesthesia. A short incision was made in the line of the old scar and a nodule, about the size of an English walnut, was found embedded in the scar in the suprasternal notch and was completely excised, every effort being made to remain outside the capsule.

Macroscopical examination. The weight of the tissue removed was 12 grams and it measured 7 by 2.5 by 2 centimeters. The upper portion consisted of muscle and scar tissue and the lower portion con-

sisted of a mass of firm lobulated tissue somewhat suggestive of thymus. At the junction of the two portions or near the center of the specimen (Fig 9a) there was a small well circumscribed encapsulated nodule 2 centimeters in diameter consisting of light yellowish brown soft friable tissue in which no colloid or normal thyroid tissue could be recognized grossly.

Microscopical examination. Sections of the nodule revealed solid nests of uniform epithelial cells having round oval or irregular vesicular nuclei and considerable finely granular cytoplasm (Fig 9b). The cells showed no tendency to form glands and there was no colloidal material. The cell masses were separated by a delicate network of thin walled capillaries. A section from the lower portion of the specimen disclosed a small lymph node, a normal parathyroid and areas of lobulated thymic tissue with Hassel's corpuscles. A pathological diagnosis of recurrent malignant adenoma was made.

The patient made an uncomplicated recovery and was discharged from the hospital on the fifth post operative day.

The patient was last heard from May 11, 1937, 7½ years after the primary operation, 3½ years after excision of the first recurrence and more than 2½ years after excision of the second recurrence. She was free of clinical evidence of malignant disease and had been teaching school regularly for 2 years.

In this case malignancy was not suspected before or during the primary operation and after the most painstaking gross and micro-

Fig 10 Case 4 a, The primary tumor, histologically benign $\times 95$ b, Tumor cells and clumps of tumor tissue in an endothelial lined venous sinus, the only indication of possible malignancy. $\times 95$

scopical examination of the tissue removed and after making additional sections, it was by no means certain that the tumor was malignant. One of several nodules examined was suspicious on account of the presence of tumor cells in the capsular veins rather than by reason of its histological characteristics.

More than 4 years after the primary operation the patient returned with a small nodule in the suprasternal notch of about 18 months' duration. In view of the previous pathological diagnosis or uncertainty of diagnosis, the nodule was thought to be a recurrence, but it seemed small, superficially situated, and movable. These apparently favorable circumstances led to the decision, which was probably unwise, to remove the growth under local anesthesia. The risk of breaking into the mass or incompletely removing it is great enough at best and should not be further enhanced by inadequate exposure. One should consider not only the obvious mass but also the possible presence of clinically undetectable small masses in the immediate vicinity, and should ligate veins well beyond the mass.

Even though the operation for the removal of the first recurrence seemed to have been accomplished satisfactorily, at least in so far as the obvious nodule was concerned, the patient returned 8 months later with a second

recurrence in the suprasternal notch. At the third operation the patient was given surgical anesthesia, the field of operation was adequately exposed, and the excision was performed well beyond the limits of the growth, through healthy tissue. Three years later the patient was free of clinical evidence of malignant disease. (See note at end of paper.)

CASE 4 An adult white male, 45 years of age, registered in the clinic September 26, 1929, complaining of goiter, nervousness, and fatigue. The family history was negative. The patient had had the usual diseases of childhood and a nervous breakdown in 1917. He first noticed enlargement of the thyroid 3 years previously. The goiter had steadily increased in size since that time and was associated with nervousness, palpitation, tachycardia, fatigue, irritability, and headaches, all of which symptoms were increasing. He worried a great deal about his employment as a mail clerk which he stated was a nerve racking job which almost resulted in a nervous breakdown in June, 1929.

On examination the patient was found to be well nourished, weighing 172 pounds. The pulse rate was 112, blood pressure 134 systolic, 76 diastolic, the skin was warm and moist. There was no exophthalmos or other eye signs. The teeth showed many fillings and crowns. The tonsils were embedded, and there was no general lymphadenopathy. The right lobe of the thyroid was enlarged to about three times the normal size and contained elastic nodules. He had a fine digital tremor; otherwise examination was essentially negative. Clinical diagnosis was adenomatous goiter with hyperthyroidism.

The primary operation was performed October 2 1929 under nitrous oxide-oxygen analgesia and infiltration with novocain. The trachea was found to be displaced to the left. The right thyroid lobe was about four times the normal size and adenomatous in character. The left lobe was about twice the normal size and colloid in character. A subtotal thyroidectomy was performed and the wound was closed around a rubber drain.

Macroscopic examination. The tissue removed consisted of the major portions of the right and left lobes. The weight of these was 190 grams. The right lobe measured 12 by 6.5 by 3.5 centimeters and on section was found to contain a large encapsulated quite cellular finely granular soft tumor in which there were areas of hyaline scar tissue. There was only a small amount of non-tumorous thyroid around the adenoma. The left lobe measured 6 by 2.5 by 3 centimeters and contained one small adenoma 2 centimeters in diameter. Otherwise it consisted of lobulated translucent non-tumorous thyroid rich in colloid.

Microscopic examination. A section from the large tumor in the right lobe showed a partially differentiated adenoma with only a slight amount of colloid. There was considerable edema diffuse hemorrhage and in some areas the tumor was composed of solid cords and masses of cells separated by endothelial lined blood channels (Fig 10a). In these more cellular areas there was no colloid. The cells were of fairly uniform type somewhat variable in size but mitotic figures were not recognized. A few of the endothelial lined blood spaces contained islands of tumor tissue (Fig 10b). In view of this fact additional sections were taken. These showed larger areas of the more cellular type of adenomatous growth arranged in strands and solid masses of cells which were separated by a delicate vascularized stroma. The histological picture was very suggestive but not conclusive for malignancy. A tentative pathological diagnosis of malignant adenoma was made.

The patient made an uneventful recovery and was discharged from the hospital on the seventh postoperative day.

In September 1931 nearly 2 years after the primary operation he returned to the clinic because of a painless swelling in the right side of the neck which had been present for 3 months and was gradually increasing in size.

On examination the thyroidectomy scar was found to be in good condition and there was very little palpable thyroid tissue in front of the trachea. About midway between the episternal notch and the angle of the jaw on the right side of the neck there was a rounded non-tender freely movable mass about 1 3/4 by 3/4 inches in size. No other masses were palpable and there was no other evidence of recurrence or metastasis. The mass was interpreted as a probable recurrence and operation was advised.

The second operation was performed September 12 1931 under local anesthesia only. The tumor

nodule was exposed through a transverse incision and was removed by sharp dissection. The wound was closed.

Macroscopic examination. The tissue removed consisted of two small pieces. Their weight was 4 grams and they measured 2 by 1 by 0.5 centimeters and 1.5 by 1 by 1 centimeters respectively. They appeared to be composed of reddish grey, encapsulated colloid containing thyroid tissue.

Microscopic examination. Sections revealed actively growing hyperplastic adenomatous thyroid tissue consisting of large and small alveoli filled with closely packed epithelial cells of uniform size which were separated by well vascularized stroma and tended to form small acini which contained droplets of colloidal material. There was no normal thyroid tissue present. A pathological diagnosis of recurrent malignant adenoma was made.

The patient made an uneventful recovery and was discharged on the second postoperative day. A few days later approximately one erythema dose of roentgen irradiation was given over the right and left thyroid areas.

In September 1932 the patient came into the clinic for observation. There was no evidence of recurrence.

In April 1933 about 1 1/2 years after excision of the first recurrence the patient returned to the clinic because of the presence of two small nodules in the suprasternal notch which were discovered 2 months previously. These were firm and freely movable and were thought to be recurrences.

The third operation was performed April 26 1933 under full avertin anesthesia only. The previous collar scar was excised the trachea was exposed and the muscles on the right side of the neck were divided transversely for the exposure of the mass which occupied a position corresponding to the right thyroid lobe and extended to the carotid sheath but did not involve the carotid artery or internal jugular vein. The tumor appeared to be encapsulated. During the course of its removal the capsule of the tumor was ruptured and considerable soft tumor tissue was spilled into the neck. The tumor was found to be adherent to the thyroid cartilage but was thought to have been completely removed.

Macroscopic examination. Two pieces of tissue were received for examination. The weight of one which was removed from the upper right thyroid area was 2 grams; it measured 3.5 by 2 by 0.7 centimeters and consisted of fibrofatty and finely lobulated normal appearing thyroid tissue. The weight of the second piece of tissue removed from the lower right thyroid area was 17 grams and it measured 5.5 by 4 by 2.5 centimeters. It consisted of muscle scar tissue and two fairly well circumscribed nodules of firm friable tumor tissue, the capsule of one of the nodules having been ruptured.

Microscopic examination. Sections of the tissue from the upper thyroid area revealed no evidence of malignancy. Sections of tissue from the lower

thyroid area revealed actively growing adenomatous thyroid composed of solid strands and masses which were separated by highly vascularized stroma. The cell masses tended to form small and fairly large acini some of which contained droplets of colloid and an occasional mitotic figure was seen. Small blood vessels around the capsule contained clumps of tumor tissue. In general the tumor nodules appeared to be well circumscribed or encapsulated, and there was very little tendency to invade beyond the capsule.

A pathological diagnosis of recurrent malignant adenoma was made.

Following this operation there was hoarseness, a right abductor paralysis, and some induration but no discharge of serum from the wound. Otherwise the recovery was uneventful and the patient was discharged from the hospital on the tenth postoperative day.

In September, 1933, the patient was in the clinic with no evidence of recurrence, and he had regained his voice.

In March, 1934, he returned to the clinic having discovered two small nodules just above the scar on the right side of the neck, each about 1 centimeter in diameter.

The fourth operation was performed March 6, 1934, under analgesia and infiltration with novocain. One nodule was found embedded in the sternohyoid muscle and was removed. Immediately beneath the muscle there was a second, more deeply seated nodule in the space between the larynx and the carotid sheath. This nodule was attached to the laryngeal cartilage, a part of which was removed along with the tumor mass.

Macroscopical examination. The tissue received for examination consisted of a piece of muscle from the right side of the neck including a small well encapsulated mass of tumor tissue measuring 1 by 1 by 0.7 centimeter and a piece of tissue including a tumor nodule removed from the thyroid cartilage measuring 3 by 2.5 by 1.5 centimeters in which there was a circumscribed tumor nodule 1.3 centimeters in diameter, and several small fragments of muscle and scar tissue from the right thyroid area which were not grossly involved by tumor.

Microscopical examination. Sections of the various nodules showed actively growing adenomatous thyroid tissue similar in general characteristics to the recurrent nodules removed on previous occasions. It was not frankly carcinomatous histologically. Masses of tumor cells were present in venous channels.

A pathological diagnosis of recurrent malignant adenoma was made.

The patient made an uneventful recovery except for partial separation of the wound edges which were secondarily closed with clips. He was discharged from the hospital on the seventh postoperative day. There was continuance of the right abductor paralysis.

May 8, 1935 the patient was readmitted to the

hospital for removal of several small nodules in the incision and one at the level of the larynx. These were freely movable and had been present a few weeks.

The fifth operation was performed May 8, 1935, under nitrous oxide-oxygen anesthesia. One small, hard, fixed nodule was removed from the region of the thyroid isthmus. A second nodule was removed from the digastric triangle and a third nodule situated in the lower right cervical region was found to be quite extensive and infiltrating into the carotid sheath and a portion extended behind the sternum. As much as possible of this nodule was removed. On account of oozing, the neck was packed open and closed the following day. The three pieces of tissue received for examination proved to be recurrent adenomatous tumor tissue similar to that observed on previous occasions. The recovery was uneventful and the patient was discharged on the seventh postoperative day.

Following discharge from the hospital the patient was given roentgen irradiation, approximately one erythema dose over each lateral thyroid area.

In December, 1935, another similar course of roentgen irradiation was given over the right and left thyroid areas. The patient had been seen on several occasions and there was no evidence of recurrence.

In April, 1936, the patient came into the clinic with no evidence of recurrence.

The patient was last seen at the clinic October 8, 1936, 7 years after the primary operation and about 1½ years after excision of the fourth recurrence. His general condition was good, but there was one small shot-like nodule at the outer end of the incision.

This case further emphasizes what we believe to be a prime fallacy in the treatment of recurrences of this type. When the patient returned about 2 years after the primary operation, with a mass in the right side of his neck, various observers all agreed that it was rounded, appeared to be encapsulated, and was movable. Perhaps on account of the uncertainty of the original pathological diagnosis and the possibility that the mass might be a lymph node rather than a recurrence, its removal was attempted under local anesthesia. During the course of the operation the mass was ruptured but was thought to have been completely removed. One year later the patient was apparently free of recurrence but when seen 6 months afterward there were two small nodules in the suprasternal notch. The second and subsequent operations for removal of recurrences were more extensive and were conducted under full anesthesia, but the

Fig 11 A diagrammatic representation of the bilateral intercommunications between the thyroid plexus of veins and the external and internal jugular veins in the neck. A tumor which involves a lateral lobe of the thyroid might extend via one or more of the venous routes and might produce local growths in the distribution of the superior middle inferior or thyroidea ima veins

tumor became more widely disseminated and progressed beyond the possibility of complete surgical removal. When last seen, the patient still had recurrence and a cure is not to be expected. The duration of life, however, is difficult to predict. (See note at end of paper.)

EVALUATION OF STUDY

This paper is a preliminary report of our experiences with a selected group of thyroid neoplasms in which the primary operation for their removal has been followed by the development of local recurrences in the veins of the neck, without detectable evidence of distant metastases.

The primary operations upon the patients whose histories are submitted were performed before the appearance of the article entitled "Radical Operation for Malignant Tumors of the Thyroid Gland," recently published by Dr. George Crile and Dr. George Crile, Jr.¹ and which was designed, in part at least, to prevent or decrease the incidence of just such local recurrences as are illustrated by the cases here reported.

Local recurrences of this nature are probably more prevalent than one would suspect from a perusal of current literature. The writer is unaware of any publications dealing with this particular phase of malignant goiter.

An appreciation of the manifold opportunity for such local recurrences and their possible distribution may be gained from a study of the bilateral intercommunications between the venous networks of the lateral thyroid lobes and the internal, external, and anterior jugular systems and their convergence toward the innominate veins and the vena cava (Fig 11).

Naturally, anything in the way of a diffuse permeation of this venous maze would almost certainly preclude the possibility of successful surgical removal, and such cases do not come within the scope of the present discussion. We are concerned here with recurrent nodules of limited number and limited distribution, which on clinical examination, are found to be accessible and to have a degree of mobility such as to justify the expectation that they can be removed.

It is to be specifically understood that reckless and futile block dissections of the neck

¹Crile, George S. and Crile, George Jr. "Radical operation for malignant tumors of the thyroid gland." *Surg. Gynec. & Obst.* 1937 64 927-934.

obviously hopeless cases are not advocated. It is emphasized, however, that in certain instances the circumstances are favorable and for these we are asking special consideration.

The circumstances which, with few exceptions, are common to the cases here reported and which may be indicative of a possibly favorable outcome may be briefly summarized as follows:

Clinical findings. All the patients had adenomatous goiter. All were free of symptoms and signs of hyperthyroidism except Case 4, in which the syndrome was fairly definite. In no instance was a positive clinical diagnosis of malignancy made before the primary operation; such a condition was discussed as a possibility in Case 2. During the course of the primary operation, malignancy was not suspected in 3 cases, but was suspected in Case 2 in which the same question had been raised clinically.

Pathological findings at the primary operation. In all cases the thyroid tissue removed contained adenomas which appeared to be encapsulated; invasion of the capsule and gross plugging of the veins by tumor tissue were absent, except in Case 2. In none of the cases was the tumor as a whole frankly carcinomatous from a purely histological standpoint; in Case 2, however, there were areas which could be interpreted as histological cancer. The pathological diagnosis in Case 1 was multiple fetal adenomas; in Case 2, malignant adenoma; Case 3, hyperplastic goiter with multiple adenomas, one of which was malignant; Case 4, a tentative diagnosis of malignant adenoma was made. None of the tumors was cystic or distinctly papillary in character.¹ The pathologist as well as the clinician at the time of the primary operation had difficulty in making a positive diagnosis of malignancy. The one constant sign which might have suggested the possibility of future trouble was the presence of tumor cells or tumor tissue in the lumina of the capsular veins, and this sign was positive in the 4 cases reported. In these cases we were dealing with a previously benign adenoma which tended to become malignant and in which the histologically adenomatous char-

acteristics predominated over the carcinomatous. The intensity of the malignancy was of a low order.

Postoperative course. A striking feature of the postoperative course of the tumors under consideration is the relatively long latent period before the appearance of the local recurrences and their tendency to remain localized. This is consistent with the relatively low order of the malignancy of the primary tumors and the recurrences and is in striking contrast to the rapidity of recurrence and dissemination in the highly malignant undifferentiated or diffuse carcinoma of the thyroid. Hence, in the case of tumors of low grade malignancy in which tumor cells or tumor tissue are demonstrated in the veins at the time of the primary operation for adenomatous goiter, one would be justified in suspecting regrowth of the tumor in the veins in any patient returning 2, 3, or several years later with a localized, apparently encapsulated mass in the thyroid area. If, under such circumstances, there is no clinical evidence of distant metastases and if the mass is freely movable or has only limited fixation as has been the case in the instances here recorded, operative treatment is indicated.

Surgical treatment of local recurrence. The operation might be of an exploratory nature if deemed advisable but the operative procedure should be carried out in such a manner as not to lose the opportunity of completely removing the mass if it be removable, and with little or no curiosity about what is inside of it. Breaking into the mass, leaving remnants of it in the operative wound, and failure to remove tributary veins in which tumor tissue is present are almost certain to render a second successful surgical attack impossible. For these reasons it is probably inadvisable to attempt to remove these apparently innocuous, freely movable recurrent nodules under local anesthesia, especially if they are deeply situated in the neck. The more prudent course would seem to be to employ surgical anesthesia, to expose adequately the tissue to be removed, and to pay particular attention to the condition of the venous tributaries around the mass.

The peculiar nature of the pathological process involved should be well understood

¹Tumors of the thyroglossal tract and tumors of lateral aberrant thyroid origin do not come within the scope of this discussion.

before institution of the *first surgical procedure for the removal of the recurrence* in order that the surgical attack may be directed against the vascular apparatus which harbors the growth, and that the details of the operation may be designed to accomplish its purpose, namely, complete removal of the lesion. Biopsies, inadequately conceived, and illy executed surgical procedures are not in the best interests of the patients now under consideration. *The first operation for the removal of the recurrence offers the best and, perhaps, the only opportunity for a cure.*

Irradiation. Radium and roentgen therapy, at least within the limitations of the irradiation dosage employed in the cases reported, was ineffectual in preventing recurrences or curing recurrences. In Case 1, radium treatment was given over the right thyroid area immediately following the operation for removal of the recurrence in the right lobe. Seven months later 2 radium treatments were given over the recurrence in the left jugular vein. The mass persisted for the succeeding 8 years, at the end of which time it was removed surgically, and no irradiation was employed after this third operation. More than 6 years later the patient was free of recurrence. In Case 2, Coolidge tube treatment was given over the right and left thyroid areas shortly after the primary operation. Recurrence in the right cervical veins appeared 4 years later and was removed about $1\frac{1}{2}$ years

afterward. Following removal of the recurrence, roentgen irradiation was given into the open wound and 2 months later a second course was given. More than 7 years after this last treatment the patient was free of recurrence. In Case 3 no irradiation was employed. In Case 4 roentgen irradiation was given over the right and left thyroid areas shortly after removal of the first recurrence. Within the next $3\frac{1}{4}$ years recurrences were excised on 3 occasions, following the last of which roentgen irradiation was given and repeated 7 months later. When last seen the patient had a recurrent nodule in the scar.

The most effective treatment of local recurrences of the type reported has been surgical removal, and there would seem to be no reason for withholding it in favorable cases of this apparently radioresistant type of growth.

NOTE.—Since the completion of this paper 2 of the patients have returned to the clinic for removal of recurrent nodules in the neck. In Case 3 there were two small nodules, one of which was situated in the dermis near the right external end of the thyroidectomy wound and the other was situated in the suprasternal notch mesial to the right sternomastoid. These two nodules were removed under general anesthesia July 27, 1937 and proved to be similar histologically to the previously removed recurrent nodules. In Case 4 there was a small nodule immediately beneath the skin near the right end of the old operative wound and a second larger deeply situated mass near the trachea on the right side which apparently extended posterior to the right sternoclavicular joint but there was no evidence of distant metastases. The small superficial nodule was excised under nitrous oxide and novocain anesthesia on June 29, 1937 and proved to be similar histologically to the recurrent nodules removed on previous occasions.

STUDIES ON THE CIRCULATION IN PREGNANCY

II. Vital Capacity Observations in Normal Pregnant Women

K. JEFFERSON THOMSON, M D., Mount McGregor, New York, and
MANDEL E. COHEN, M.D., Boston, Massachusetts

EVEN though numerous reports concerning the vital capacity (by definition, the maximum amount of air that can be exhaled after the deepest possible inspiration) in pregnancy have appeared in the literature (Table I) since the introduction of spirometry into clinical medicine by Jonathan Hutchinson in 1846, there is no conclusive evidence as to what influence normal pregnancy has on vital capacity. A review of the literature (3, 4, 7, 14, 16, 17, 23, 29, 30, 35, 36, 40, 41, 42) and most of the modern American text books on obstetrics (6, 11, 12, 13, 37) gives vague and conflicting information concerning the vital capacity in normal pregnancy and little information concerning the vital capacity in pregnant cardiac women, in the pregnancy "toxemias" and other abnormal obstetrical conditions.

For the evaluation of certain physiological phenomena that occur in normal pregnancy such as dyspnea and orthopnea, knowledge of the effect of pregnancy on the vital capacity is important. Also, in a search for an early sign of heart failure in pregnant cardiac patients, one naturally turns to tests of clinical value in the non-pregnant. Of these, the vital capacity determination is the simplest and probably most valuable. In order to evaluate such observations in abnormal situations in pregnancy, an accurate knowledge of what happens in the normal pregnant woman is necessary.

For this reason, vital capacity determinations were made in conjunction with other circulatory studies as a part of a general study on the circulation in pregnancy. The complete data of the circulatory studies on 19 of

the subjects under study were presented in a previous report (10).

This report presents observations on the vital capacity in a group of 31 normal pregnant women.

PROCEDURE

The subjects for this study were obtained from the prenatal clinic of The Boston Lying-in Hospital. Those included presented no evidence of serious medical or obstetrical disorder. Individual patients were excluded from the group only when, through lack of co-operation or inability to perform the tests, satisfactory observations could not be made.

In addition, a small control group of 9 normal non-pregnant women in the same age group was observed over a 14 month period, usually at monthly intervals.

Of the pregnant group, vital capacity observations were usually made at monthly intervals before delivery, at 2 and 6 weeks postpartum and in some instances as long as a year or more after delivery.

All determinations were made after at least 12 hours of fasting. Early in the study observations were made with patients in the lying, sitting, and standing positions. Determinations taken with patient in the sitting position were especially adaptable to study of all pregnant women, since observations could be made on postpartum and sick subjects under practically the same conditions as on ambulatory patients, the only difference being that the ambulatory and convalescent patients were allowed to dangle their legs over edge of bed while the others were required to sit erect in bed. For reasons discussed later, it soon appeared that the lying and standing determinations added nothing to make their continuance an important part of the study.

The subjects were required to sit quietly at least 30 minutes before readings were initiated

From the Department of Obstetrics Harvard University Medical School and the Cardiac Clinic and Research Laboratory, Boston Lying-in Hospital, Boston

The complete data on which this report is based will appear in tabular form in the reprints

and a 5 minute rest interval was required between determinations. When the lying and standing observations were made, a 30 minute rest period was required in each position before the test was started, and readings were then made in the manner described.

Each subject was given a demonstration of precisely how the test was performed and its proper execution was demanded on each attempt. The patient was instructed to exhale slowly first, then to make a maximum rapid inspiration after which the mouthpiece of the spirometer was inserted in the mouth promptly and without loss of air to the exterior, then to exhale forcibly into the spirometer and to continue expiration until the lungs were emptied as completely as possible. At each attempt the subject was urged to make a maximum effort. At the first visit several trials were often necessary before the patient could perform the test properly. If vital capacity determinations are made under these conditions and in the manner described, its constancy on any day is remarkable. A series of at least 3 determinations which checked within 50 cubic centimeters of each other and were satisfactory attempts (patient cooperative, maximum inspiration complete expiration, no extra breaths, no leakage) was considered a test and the highest reading of the group was taken as the vital capacity for that day.

The importance of adhering to the conditions under which the test is carried out and the exact method of actually performing the test can not be overemphasized. If these conditions are followed rigorously, the variations observed in the vital capacity from month to month are likely to be due to actual changes in the vital capacity and not to variations in technique.

As a means of comparing the vital capacities of different non pregnant individuals, it has been shown by West and by Christie and Beams that correction for body surface area is the most accurate. Accordingly such correction was made in this study. The surface area was calculated from the height weight tables based on the formula of DuBois and DuBois. Since no accurate method of determining the surface area of pregnant women is available, it was calculated on the basis of the

patient's "normal" non pregnant weight and height.

For normal non pregnant women the vital capacity is, according to Christie and Beams, approximately 2000 cubic centimeters per square meter body surface area. They showed that although it may normally rise above this figure, a decrease of 15 per cent or more is usually considered as abnormal. These figures have been used as a basis for comparison between non pregnant women and pregnant women.

In addition, correction was also attempted for "corrected" surface area, this being computed from the patient's height and actual weight (15) as observed at varying times during pregnancy and the puerperium.

METHODS

The vital capacity was measured with a plain water spirometer (Collins). The subcostal angle was measured with a protractor, the 3 determining points being the xyphoid process and points 7 centimeters from it on the border of each costal margin.

Seven foot x ray photographs of the heart and lungs were taken on some of the patients and in a few at monthly intervals throughout pregnancy and at the various observation periods in the puerperium.

Either subjective or objective evidence of shortness of breath was interpreted as dyspnea.

The duration of pregnancy in weeks which represents the time during pregnancy at which any observation was made has been calculated from the actual date of delivery. The duration of a normal full term pregnancy being taken as 40 weeks.

RESULTS

Vital capacity and related observations on 31 normal pregnant women (21 primiparae, 10 multiparae) comprise the material for this report.¹ All the patients in this series were observed at least once antepartum and at least once postpartum. Unless otherwise specified, the vital capacity determinations

¹In addition to 34 observations on 1 to 4 observations per case were made on 59 additional normal pregnant women since no postpartum observations were made on these data are not included. The antepartum course was however similar to that of the cases reported in this paper.

presented will be those which were measured with the patients in the sitting position.

COMPARISON OF VITAL CAPACITIES TAKEN IN LYING (SUPINE), SITTING, AND STANDING POSITIONS

In 10 cases vital capacity determinations were made on the same date with the patients in the lying, sitting, and standing positions. In general the changes during pregnancy and the puerperium were similar regardless of the position of the patient in which determinations were made (Fig 1). The vital capacity was usually higher when taken with the patient standing than in the other positions and higher sitting than lying. This is similar to the studies on the non-pregnant cases of Hasselbalch (22) and of Christie and Beams. There is a rather small difference between the sitting and standing determinations while the lying determinations are about 5 per cent less than either the sitting or standing vital capacities. Because of the similarity in the trend of vital capacity change in pregnancy and the puerperium and because of the similar value of the sitting and standing observations, the sitting position was chosen because of its applicability to this study as well as that of patients unable to stand, particularly decompensated cardiacs.¹

Regardless of which of the above positions was used in taking observations, it is evident that the vital capacity either remains the same or rises slightly in most of the cases as

¹Studies on the vital capacity in pregnant cardiac patients will appear in a subsequent paper

TABLE I.—VITAL CAPACITY IN NORMAL PREGNANT WOMEN—SUMMARY OF THE LITERATURE

Observer	Year	Number of cases	Vital capacity			Number of cases with post-partum observations
			Increase	Decrease	No change

The average observed vital capacity, vital capacity per square meter body surface area, vital capacity per square meter body surface area "corrected" and the average weight, body surface area and subcostal angle for the various periods of observation during pregnancy and the puerperium in 31 normal pregnant women.

Fig 1 The average vital capacity lying sitting, standing in cubic centimeters per square meter body surface area (uncorrected) in 10 normal pregnant women. The horizontal line represents the average normal vital capacity for non pregnant women. The heavy perpendicular line represents delivery and separates the antepartum and postpartum periods. Note that the lying vital capacity is about 5 per cent less than sitting and standing the general trend in all positions is however the same.

women (117 antepartum, 52 postpartum), the number of antepartum observations varied between 1 and 6, the postpartum observations varied between 1 and 3. Four patients were observed once antepartum 5 twice 2 three times, 10 four times, 3 five times, and 7 six times. These antepartum observations were distributed as follows during the 9 to 12 week period, 2 cases, during the 13 to 16 week period, 10 cases, during the 17 to 20 week period, 11 cases, during the 21 to 24 week period, 17 cases, during the 25 to 28 week period, 19 cases, during the 29 to 32 week period, 20 cases, during the 33 to 36 week period 20 cases, during the 37 to 40 week period, 18 cases.

Fifteen cases had 1 postpartum observation, 11 had 2 postpartum observations, 5 had 3 postpartum observations. The postpartum observations were made during the 1 to 2 week period in 27 cases, in the 3 to 6 week period in 10 cases, and in the 7 weeks or later period in 15 cases.

For the most part, the values were within the normal range for non pregnant women.

The smallest observed vital capacity value antepartum was 2,150 cubic centimeters, the largest 4,100 cubic centimeters. Postpartum the range was from a minimum of 2,510 cubic centimeters to a maximum of 4,050 cubic centimeters. The average of all antepartum observed vital capacity observations was 3,346 cubic centimeters, the postpartum average of all the observed values was 3,284 cubic centimeters.

Although not present in every case or at every observation there was a tendency for the vital capacity to increase during pregnancy and decrease after delivery. In 22 of 31 cases the last antepartum vital capacity was higher than the first in 4 it was less, in 1 there was no change and in 4 there was only one antepartum observation so that such a comparison was impossible. Further, in 24 of the 31 cases the highest antepartum vital capacity was higher than the highest postpartum observation, in 6 the reverse was true. In only 1 case was there evidence of neither antepartum increase nor postpartum decrease. The average of the vital capacities of

Fig 2 The average observed vital capacity, weight, and surface area (based on weight change in pregnancy) in normal pregnant women. The heavy perpendicular line represents delivery and separates the antepartum and postpartum periods

the entire group showed a progressive increase from the twenty-first to twenty-fourth week value of 3,300 cubic centimeters throughout the remainder of the pregnancy, reaching its highest value of 3,455 cubic centimeters in the thirty-seventh to fortieth week period (Fig. 2)

The average observed antepartum vital capacity values were as follows. for the 13 to 16 week period, 3,264 cubic centimeters; for the 17 to 20 week period, 3,224 cubic centimeters; for the 21 to 24 week period, 3,300 cubic centimeters; for the 25 to 28 week period, 3,314 cubic centimeters; for the 29 to 32 week period, 3,346 cubic centimeters; for the 33 to 36 week period, 3,385 cubic centimeters, for the 37 to 40 week period, 3,455 cubic centimeters. The average postpartum values were: for the 1 to 2 week period, 3,204 cubic centimeters, for the 3 to 6 week period, 3,153 cubic centimeters, for the 7 plus week period 3,248 cubic centimeters

After delivery there was a sharp drop in the average vital capacity from the thirty-seventh to fortieth week value of 3,455 cubic centimeters to 3,204 cubic centimeters in the first to second week postpartum period. It

remained at essentially the same level throughout the postpartum observation period which in some patients extended over a year period (6 cases) or longer (the longest postpartum observation being 81 weeks)

It can be seen from both individual cases and the average values that the observed vital capacity increases slightly or remains constant as pregnancy progresses, decreases abruptly following delivery (2 weeks postpartum) to its lowest level in the study, and then returns to a level similar to that observed in early pregnancy. This is presumably equal to the "normal" non-pregnant level, although there are no data on that point.

The maximum increase in the prepartum vital capacity with the first observation taken as 100 per cent amounted to approximately 12 per cent (Case 31).

The maximum decrease in the vital capacity observed during the course of pregnancy with the first observation taken as 100 per cent amounted to approximately 7 per cent (Case 40).

For purposes of comparison the changes in body weight and approximate surface area

Fig 3 The vital capacity in cubic centimeters per square meter body surface area (uncorrected) in normal pregnant women. The horizontal line represents the average normal vital capacity for non pregnant women. The curves of individual cases are plotted separately the curve of average values being plotted with a heavier line. The heavy perpendicular line represents delivery and separates the antepartum and postpartum periods.

computed from the changes in weight are charted with the observed vital capacity (Fig 2)

VITAL CAPACITY, CORRECTED

A On basis of "normal surface area. In order to compare the vital capacities of different pregnant individuals with each other and with non pregnant women, the vital capacity per square meter body surface was calculated from the observed vital capacity and the surface area of the patient. For reasons pointed out previously, the surface area was that determined from the patients measured height and the "normal" non pregnant weight i.e. the "normal" non pregnant surface area.

Each value for observed vital capacity during pregnancy and the puerperium was divided by this "normal" surface area value

with the resulting value being termed vital capacity in cubic centimeters per square meter body surface area.

On this basis the average values antepartum were for the 13 to 16 week period, 2,103 cubic centimeters, for the 17 to 20 week period 2,112 cubic centimeters, for the 21 to 24 week period, 2,116 cubic centimeters, for the 25 to 28 week period, 2,156 cubic centimeters, for the 29 to 32 week period, 2,168 cubic centimeters, for the 33 to 36 week period, 2,179 cubic centimeters for the 37 to 40 week period 2,203 cubic centimeters. The postpartum averages were for the 1 to 2 week period, 2,067 cubic centimeters, for the 3 to 6 week period, 2,030 cubic centimeters for the 7 plus week period 2,112 cubic centimeters. The minimum value antepartum was 1,470 cubic centimeters the maximum value was 2,555 cubic centimeters the average of all the antepartum observations was 2,158 cubic centimeters. The postpartum minimum value was 1,605 cubic centimeters, the maximum was 2,500 cubic centimeters, the average of all the postpartum observations was 2,077 cubic centimeters.

Since for each patient the correction factor remains constant the changes observed in the vital capacity during the course of pregnancy and the puerperium for the individual cases will be similar to those noted under the observed vital capacity.

The curve of average values differs but slightly from the average curve of the observed vital capacity (Fig 3).

On the basis of comparing the last antepartum observation with the first, 22 cases showed an increase in vital capacity as pregnancy progressed, 4, a decrease, 1 no change, and in 4 single observations antepartum prevented such a comparison. Twenty four of the 31 cases showed the highest antepartum observation to be higher than the highest postpartum observation while 6 showed the opposite and 1 showed no change.

The values of the vital capacity in most instances approximated the value set as normal for non pregnant women i.e. 2,000 cubic centimeters per square meter body surface area (8). Nineteen had vital capacity above 100 per cent of normal, 21 of the 31 had vital capacity of at least 90 per cent of normal, 29

Fig. 4 The average vital capacity in cubic centimeters per square meter body surface area (uncorrected) and corrected for weight change in pregnancy. The horizontal line represents the average normal vital capacity for non-pregnant women. The heavy perpendicular line represents delivery and separates the antepartum and postpartum periods.

had vital capacity of at least 85 per cent of normal; only 1 of the entire group (Case 31) falling below 80 per cent. In this patient the vital capacity was 74 per cent of normal at its lowest level in the twenty-fourth week of pregnancy and 88 per cent of normal at its highest level in the thirty-sixth week of pregnancy. The postpartum vital capacity observations on this patient made at 2, 6, 26, and 65 weeks after delivery never exceeded the highest pregnancy value of 88 per cent of normal.

B. On basis of surface area corrected for weight changes during pregnancy. An attempt was made to adjust the vital capacity for surface area changes during pregnancy. Since no accurate method was known for determining the surface area during pregnancy, the usual height-weight tables (15) calibrated really for non-pregnant individuals, was used which probably approximates the actual surface area in pregnancy. It seemed of interest to carry out this calculation, inexact as it is, to get some idea of how the vital capacity was changing with respect to the changes in surface area that occur as pregnancy progresses.

When this was done it was found that the adjusted vital capacity decreased between the 17 to 20 and the 25 to 29 week periods, increased to a maximum at the 33 to 36 week period, decreased at the 37 to 40 week period, remained constant at the 2 week postpartum period then increased again (Fig. 4). It will be seen from this that the vital capacity did not increase proportionate to the surface area increase, hence there was, in the adjusted vital capacity, a decrease. For instance, the observed vital capacity increased in the 37 to 40 week period, but since the weight and the adjusted surface area, which reflects this change, increased proportionately more, there is an apparent decrease in the vital capacity when corrected for this factor.

The average values of the vital capacity "corrected" for surface area changes in pregnancy were: for the 13 to 16 week period, 2,064 cubic centimeters; for the 17 to 20 week period, 2,135 cubic centimeters; for the 21 to 24 week period, 2,023 cubic centimeters; for the 25 to 28 week period, 1,989 cubic centimeters, for the 29 to 32 week period, 2,039 cubic centimeters, for the 33 to 36 week

Fig 5 The relationship between the average observed vital capacity and the average curve of subcostal angle values. The heavy perpendicular line represents delivery and separates the antepartum and postpartum periods. Note the close correspondence between the two curves.

period, 2,055 cubic centimeters, for the 37 to 40 week period, 2,004 cubic centimeters. Postpartum the average values were for the 1 to 2 week period, 2,007 cubic centimeters, for the 3 to 6 week period, 1,979 cubic centimeters, for the 7 plus week period, 2,090 cubic centimeters. The minimum value antepartum was 1,396 cubic centimeters, the maximum 2,475 cubic centimeters, the average of all the antepartum observations was 2,043 cubic centimeters. The minimum value postpartum was 1,586 cubic centimeters, the maximum was 2,457 cubic centimeters, the average for all the postpartum values was 2,030 cubic centimeters.

Subcostal angle The subcostal angle was measured 126 times on 25 patients, 86 times antepartum and 40 times postpartum. There is a progressive increase in the subcostal angle as pregnancy progresses, seen in 18 of 25 cases and in the curve of average values (Fig 5), in 4 cases there were single antepartum observations and in 3 of the cases no change was noted. In no instance did the subcostal angle decrease in size during the antepartum period.

By the second week postpartum there is a sharp decrease in the subcostal angle which in the group averaged 28.7 degrees. By the seventh week postpartum or later the subcostal angle had returned to its early pregnancy level (Fig 5).

The average values for the antepartum subcostal angle were for the 13 to 16 week period, 68.5 degrees, for the 21 to 24 week period, 80.0 degrees, for the 25 to 28 week period, 83.5 degrees, for the 29 to 32 week period, 88.7 degrees, for the 33 to 36 week period, 93.1 degrees, for the 37 to 40 week period, 103.5 degrees. Postpartum the average values were, for the 1 to 2 week period, 74.8 degrees, for the 3 to 6 week period, 62.0 degrees, for the 7 plus week period, 68.0 degrees.

X ray studies The lung markings were increased without exception in x ray photographs of the chest taken during pregnancy. Postpartum x ray photographs of the chest resembled those of non pregnant women except for variations interpreted as due to shadows of the enlarged lactating breasts.

The diaphragms were elevated during pregnancy. In 3 cases studied at frequent inter-

vals with x-ray photographs of the chest, the diaphragms maintained their position relative to the ribs, yet the distance from a fixed point (the transverse process of the first thoracic vertebra) to the dome of the diaphragm (the vertical or long diameter of the chest) decreased as pregnancy progressed and increased postpartum. The maximum antepartum decrease was 4 centimeters, the maximum increase postpartum as compared with the minimum antepartum value was 3.5 centimeters. Also, the transverse diameter of the chest increased antepartum and decreased postpartum. The maximum increase in the transverse diameter of the chest during pregnancy was 2.1 centimeters.

As the transverse diameter of the chest increased and the long diameter diminished during pregnancy the vital capacity increased. Postpartum, when the chest configuration returned to normal, changes in the diameters of the chest occurred which were the reverse of those just described and, concomitant with them, the vital capacity diminished.

During fluoroscopic examination of the thorax, the diaphragms, although elevated during quiet respiration, were seen to be capable of moving with apparently normal excursion during forced inspiration and expiration, although at a somewhat higher level than in the non-pregnant state.

Dyspnea. Dyspnea occurred in 18 of the 31 patients, i.e., in approximately 60 per cent. It appeared as early as the third month in 1 patient (Case 45) and in 1 patient continued into the puerperium (Case 31). It was noted in every month of pregnancy. It was noted in the second week postpartum (Case 31). In some patients it was present one month, absent the next, and later recurred; in others it persisted over a several months' period irrespective of how the vital capacity was changing. However, it tended to be present somewhat more frequently in the latter months of pregnancy.

Dyspnea, therefore, bore no constant relationship to vital capacity; in this group it occurred in some cases in which the vital capacity was highest and in others it was found to be absent when the vital capacity was at its lowest.

EVALUATION OF STUDY

Irrespective of the mode of presentation of the data, except on the basis of "corrected" surface area, the vital capacity increases slightly or remains constant as pregnancy progresses and decreases postpartum. Since the accuracy of computing the surface area of pregnant women is questionable, the significance of the changes in vital capacity corrected for this factor is doubtful.

In a review of the literature on vital capacity in pregnancy, it is significant that every careful study based on *repeated observations* on the same patients showed an increase in the observed vital capacity during the course of pregnancy and a decrease postpartum, although the number of cases observed was small (Hasselbalch (23), 1 case; Root and Root, 1 case; Enright, Cole and Hitchcock (16), 7 cases). Rowe who studied 26 cases in the same manner found similar changes antepartum but his studies were incomplete since no postpartum observations were recorded. In addition, 30 compensated cardiacs studied in a similar fashion showed a similar increase in vital capacity during pregnancy (38).

It should be stated that most of the authors reporting a diminished vital capacity antepartum (Zhurakovski, Wintrich, Alward) made observations during the period immediately before delivery (usually within 1 week). In some of the cases of Root and Root and Enright, Cole, and Hitchcock most of which show a definite increase in vital capacity during pregnancy, there is evidence of a slight drop just before delivery. Unfortunately, no special study of that period was made here. However, it is highly possible that this factor may be responsible for the discrepancy in the literature. Other possibilities to explain the conflicting reports (Table I) may be one or more of the following sources of error:

1. Observations on different patients at different periods in pregnancy and the puerperium.
2. Insufficient period of time spent in observation.
3. Poor performance of the test by the patients studied.

Fig 6 The vital capacity in cubic centimeters per square meter body surface area in 9 normal non pregnant women. The horizontal line represents the average normal vital capacity for women. The curves suggest a seasonal trend.

4 Presence of unrecognized intercurrent disease which may have influenced the vital capacity.

5 Failure to adhere to standard conditions for performing the tests.

These possible errors have been eliminated in this study.

Since the increase observed in the vital capacity in pregnancy is relatively small and not always constant the question of its significance arises.

In a group of normal non pregnant women (Fig 6) there is some fluctuation from observation to observation both above and below the mean while in pregnant women there is a slight but usually progressive increase before delivery with a sharp decrease by the second week postpartum (Fig 3).

The standard deviation of the normal non pregnant group when the variation around the mean of each individual patient is considered, is 58 cubic centimeters with a probable error of ± 30 cubic centimeters.

The total increase in average vital capacity in the pregnant women from the sixteenth to the fortieth week is $+102$ cubic

centimeters which is 2.6 times the probable error above.

The decrease in the vital capacity from the last average antepartum to the first average postpartum value is -138 cubic centimeters which is 3.5 times the probable error, the final postpartum value which is presumably the normal non pregnant value is -93 cubic centimeters which is 2.4 times the probable error.

Further when one compares the last antepartum value with the first, it is found that in 22 of 27 cases where data for comparison were present, the vital capacity is higher at the end of pregnancy. Thus plus the fact that in 24 of 31 cases the highest antepartum value is higher than the highest postpartum value, is additional evidence that there is an antepartum increase in the vital capacity with a postpartum decrease.

From the data presented it appears that the vital capacity certainly does not often decrease during pregnancy; it remains constant or increases reaching a maximum during the tenth month of pregnancy and diminishes postpartum.

The possible factors which might effect changes in the vital capacity during pregnancy should be discussed. These are: (1) training, (2) increase in body weight, (3) changes in chest volume, (4) changes in position and movement of the diaphragm, (5) changes in the residual air, (6) mobility of the thoracic cage, (7) changes in intrapleural and intra-abdominal pressures, (8) changes in the accessory muscles of respiration, (9) mechanical effect of the enlarged breasts and physiological effects of lactation.

Since the patients in this study had repeated observations made on them, the possibility of *training* being a causal factor was considered. This seemed unlikely since the last, i.e., the postpartum observations were not usually the highest ones. To exclude further this possibility, 9 normal non-pregnant women from 20 to 38 years of age (average, 28.6 years) who were followed at frequent intervals over a 14 month period failed to show a progressive increase in their vital capacities (Fig. 6).¹

Although there is a progressive *increase in body weight* during pregnancy, its increase is out of proportion to the increase in vital capacity. The effect of weight gain on the vital capacity of a normal individual is not known and data on this point could not be found in the literature. The similar increase and decrease in both during the course of pregnancy and the puerperium (Fig. 2) although disproportionate suggests a possible relationship.

It has been shown by Zhurakovski, MacKenzie, and others that the *circumference of the chest* increases in pregnancy about 5 to 7 centimeters which finding has been substantiated in this study. It has also been demonstrated by Klawns and Palugay that the anteroposterior and transverse diameters of the chest are increased while the long diameter is usually decreased which was also true of those measured in this study. The subcostal angle increases during pregnancy. *The correlation between the increase in vital capacity and the increase in subcostal angle is striking (Fig. 5)*

¹These observations on the normal non-pregnant group suggest the possibility of a seasonal variation in vital capacity. The data on the normal pregnant women presented here were analyzed to determine if the increase noted during pregnancy was caused by seasonal trend. Such was not the case.

and indicates that the change in vital capacity is linked with change in chest configuration.

It has been shown by Kountz and Alexander that the vital capacity in patients with emphysema can be increased by elevating the diaphragm by means of a specially designed abdominal belt. Thus it can be seen that an elevated diaphragm does not invariably mean reduced vital capacity, as commonly supposed, but may actually tend to increase it. Such a factor may operate in pregnancy. The mechanism by which this increase is brought about is not known but may be associated with reduction in the volume of *residual air* and hence an increase in vital capacity. This explanation of the increase in vital capacity in pregnancy has been suggested by Hasselbalch (23).

The relative *mobility of the thoracic cage* has been shown by Peabody and Wentworth to be a factor in vital capacity value. A study now being conducted by Gorman and Thomson indicates that there is more mobility in the sternomanubrial joint during pregnancy than in the puerperium. That this may be due to "relaxin," the hormonal substance shown first by Hisaw to affect the symphysis pubis of the pocket gopher, later purified by Fevold, Hisaw and Meyer, and recently demonstrated by Abramson (1) in the blood of women as early as the tenth week of pregnancy, is a possibility. Further evidence that the change in the chest configuration is possibly under hormonal control is the observation that the subcostal angle begins to widen, as did the symphysis pubis in the studies of Abramson, Roberts and Wilson (2) earlier in pregnancy than could be accounted for satisfactorily by mechanical pressure of an enlarging uterus.

Changes in both the absolute *intrapleural and intra-abdominal pressures* or in a ratio of one to the other might be a factor in producing vital capacity changes in pregnancy and puerperium, but there are insufficient observations on this point.

The influence of pregnancy on the *accessory muscles of respiration* is not known. It is conceivable, however, that one of the important factors in the rather marked decrease in vital capacity immediately postpartum is a change

in tone and lack of efficiency of the accessory muscles of respiration, particularly those of the abdomen following delivery. That this decrease is not due to effect of anesthesia and general operative manipulation is shown by the work of Churchill and McNeil who demonstrated that vital capacity decreases only in postoperative patients with abdominal incisions.

The mechanical effect of the enlarged breasts during pregnancy, particularly postpartum, and the actual physiological changes associated with lactation may be important factors in the postpartum decrease in vital capacity. Further understanding of the physiology of lactation is necessary to clarify this point.

One might expect, from the foregoing consideration of the factors which tend to increase the vital capacity during pregnancy, a greater increase in vital capacity than is actually observed. This relatively small increase, however, may well be the net resultant of forces. On the one hand most of the factors discussed would tend to increase the vital capacity. On the other hand the effect of the increase in volume of the pulmonary vascular bed in pregnancy would tend to diminish the vital capacity. That there is an increase in volume of the pulmonary vascular bed in pregnancy is evidenced by x ray and fluoroscopic examination of the lungs (34) and by histological examinations of Hofbauer who described around the branches of the fine bronchioles marked congestion of the vessels and peribronchial infiltration, chiefly with lymphocytes. In most cases, the first set of factors must predominate.

This study suggests

1 Since the vital capacity does not as commonly supposed, decrease spontaneously during normal pregnancy, a significant decrease during pregnancy must be explained by some pathological state.

2 The "dyspnea of pregnancy" can not be explained as it commonly is by a decrease in vital capacity. Dyspnea depends, as has been demonstrated by Peabody (32) and Harrison (20) largely on the ratio between vital capacity and pulmonary ventilation. A large increase in pulmonary ventilation with

only a slight increase in vital capacity to accompany it would lead to the development of dyspnea. This is precisely what happens in pregnancy. The pulmonary ventilation increases considerably, as is shown by several observers among whom are Anthony and Hansen (5) who demonstrated an average 57 per cent increase.

That the irritability of the "respiratory center" is heightened, as shown by Hasselbalch (23), is of further interest in a consideration of the "dyspnea of pregnancy." And finally it is reasonable to speculate that the altered lungs of pregnancy (25) may through the mechanism of reflex dyspnea from the congested lungs, described by Harrison, Calhoun, Cullen, Wilkins, and Pilcher lead to increased ventilation and dyspnea.

CONCLUSIONS

1 The vital capacity in normal pregnant women is within the limits set as normal for non pregnant women.

2 During the course of normal pregnancy the observed vital capacity usually remains constant or shows a slight increase.

3 The observed vital capacity decreases after delivery in most cases.

4 There is an increase in the subcostal angle during pregnancy, with a postpartum decrease.

5 The increase in vital capacity during pregnancy parallels closely the increase in subcostal angle value, as does the postpartum decrease.

6 The change in vital capacity in pregnancy is associated with alterations in the size and shape of the chest.

7 The increase in the observed vital capacity in pregnancy is not proportionately as great as the increase in body weight and approximate surface area.

8 The vital capacity in the lying position during pregnancy is approximately 5 per cent less than in the sitting and standing positions, but changes in a similar way.

9 The vital capacity in the standing position during pregnancy is slightly higher than that in the sitting position.

10 Age and parity have no apparent effect on the vital capacity in pregnancy.

The authors are indebted to Drs George P. Robb and Duncan E Reid for assistance in part of this work and to Dr E B Wilson, statistician, for reviewing the charts and data

BILIARY DISEASE IN YOUNG SUBJECTS

ALFRED H. POTTER, M.D., F.A.C.S., Springfield, Ohio

THE increased consideration being shown gall bladder disease in children as evidenced by the many papers and case reports that have appeared in the literature since the publication of my original article¹ is indeed gratifying. While some writers still claim the occurrence to be exceedingly rare a greater number have conceded it to be far more prevalent than was formerly thought.

It is not my intention to infer that the disease is as common in childhood as in adult life, yet I do contend that had gastrointestinal disturbances, icterus, and other symptoms in children received the same consideration that like symptoms would have received in adults, many cases of gall bladder disease would not have escaped recognition.

In my estimation early recognition and early treatment are not only essential for the patient's immediate relief, but more particularly to avoid the possibility of disease of the liver in later life. I am firmly convinced that at the present time, gall bladder surgery in children is several years in arrears of the symptoms. This is emphasized by the fact that a large majority of cases of gall bladder disease in the third and fourth decades give histories of symptoms dating back to the first or second decade.

It is interesting to note that the more recent textbooks on pediatrics do not show this condition in children to be a pathological curiosity of little or no importance. The subject deserves and is receiving more intensive study. It is my belief that in the future with the application of advanced methods, a greater number of diagnoses will be made pre-operatively and a lesser number at necropsy.

The writer has since his previous report, personally observed 6 verified cases of gall bladder infections in children not over the age of 15 years, the case reports of which are included herewith. Case 1 is typical of many to

be found in the literature supporting the theory that very often biliary disease originates in the early years of childhood.

Bearing in mind the fact, established by clinical study and observation, that the best results in gall bladder surgery are effected in young subjects, and that postoperative complications are most apt to occur and postoperative indigestion and pain are most apt to continue in patients who have surgery in later life, every effort should be exerted toward a correct pre-operative diagnosis. This should not be difficult. The history and classical findings are usually typical. In reviewing the numerous cases on record, one gains the impression that had the possibility of a biliary tract disease been entertained the diagnosis could have been, in most instances, correctly made.

In 1928, based on personal observations and collected data, I succeeded in establishing gall bladder disease in young subjects as a possibility not to be ignored. This was wholly inconsistent with the tenor of the textbooks and general medical opinion, but was supported by a tabulated list of 228 cases, including 4 of my own taken from the literature between 1722 and August 1927. The upper age limit was placed at 15 years. Beahm also in 1928 published a list of 60 cases, 17 of which were not included in my report. I have been able to collect an additional 25 cases from the literature of the years prior to 1928.

A search of the literature from August, 1927 through July, 1937 and personal communications and observations have revealed 162 cases, which when added to the 42 prior to 1928 and not included in my previous report bring a grand total of 432 cases.

Surely this large number of cases proves that gall bladder disease in children is by no means uncommon. Were all observed cases reported and added to the incalculable number diagnosed and treated as other pathological conditions the incidence would be greatly increased. Biliary tract disease in young children is therefore an entity which should be

¹Gall bladder disease in young subjects. Surg. Gynec. & Obst. 1928 46: 795-803.

suspected when clinical symptoms consistent with it are present and cannot be satisfactorily accounted for by other pathological conditions. After such elimination, special tests for biliary tract disease should be applied.

There is little to be added to what has already been said regarding the incidence of gall-bladder disease in children. However, certain aspects of the etiology, symptomatology, and diagnosis might be stressed.

ETIOLOGICAL CONSIDERATIONS

There can, I think, be little doubt that infectious disease of some part of the digestive tract is one of the principal causes of gall-bladder disease in children. Typhoid fever has been mainly incriminated. Since the incidence of typhoid in the United States has greatly diminished with no relative change in the incidence of gall-bladder disease, one must look for other contributory factors such as infections of the upper respiratory tract, including influenza and pneumonia, scarlet fever, appendicitis, intestinal parasites, and sometimes a history of abdominal trauma (Table I).

Cholecystitis may also be a complication of the systemic infections of childhood. A moderately large number of cases have been observed in the convalescent stage of scarlatina: Schottmueller details 5, Saxl and Gross and Ssawrimowitsch report similar instances. Schottmueller associates hepatitis with the cholecystitis in his cases, and believes that the toxin of the hemolytic streptococcus and not the microbe itself affects the liver and gives rise to the complication.

We must not overlook the possibility of a congenital origin of biliary tract disease, as illustrated in the cases of Melchior, of Brooks, and of Dotti.

Zelditch, et al. in some of the cases observed by them, associated cholecystitis with lambdasis, the latter being the etiological factor of the former.

SYMPTOMS

When biliary tract disease exists in children, the symptoms, in most cases, are the same as in adults. Young children, unable to describe their symptoms accurately, are inclined to complain only of abdominal pain not

TABLE I.—BUREAU OF CENSUS REPORT* ON ETIOLOGY, AGE, SEX, RACE

A. Deaths in children under 15 years of age from causes considered etiological factors in biliary tract disease, in white, negro, and other races

	Males	Females	Total
Infectious and parasitic diseases	13,201	12,807	26,008
Appendicitis	1,767	1,427	3,194
Influenza, respiratory complications specified	1,277	997	2,274
Scarlet fever	949	843	1,792
Typhoid fever	248	280	528

B. Deaths from biliary calculi in children not over 15 years of age, including males and females, white and others, none

C. Deaths from other diseases of gall-bladder and biliary passages in children not over 15 years of age

		Under 1 yr	1 yr	2 yrs	3 yrs	4 yrs	5 to 9 yrs	10 to 14 yrs	Total
Males—	white	4	0	4	2	2	4	2	18
	negro	0	1	0	0	1	1	1	4

localized, rather than to describe the classical symptoms. Thus, unless the physician has some suspicion of gall-bladder disease he is likely to err in diagnosis.

Zelditch and his associates made a thorough clinical investigation of 34 cases of mild cholecystitis in children, and state that in the majority, abdominal tenderness found in the subcostal region was more accurately localized either midway between the right costal margin and the umbilicus, or at the very edge of the ribs between the right mammillary zone and the scaphoid process. In about half their cases, the liver was found to have become enlarged.

Localized pain at the umbilicus is a predominant symptom in a vast number of cases.

DIAGNOSIS

The diagnosis of biliary tract disease in children is not difficult if the condition is suspected and the customary clinical and laboratory tests are applied.

TABLE II—STATISTICAL ANALYSIS—COMPARISON OF COLLECTED CASES OF 1928 AND 1937

Age incidence	No. of cases		Percentage	
	1928	1937	1928	1937

Usually when a child complains of persistent abdominal pain found on investigation to be localized in the right subcostal or epigastric region, even in the absence of clear-cut symptoms, the condition is diagnosed as appendicitis, indeed, if such pains are noted as atypical, they are considered as referred.

Many of the cases reported in the literature were diagnosed as appendicitis and the patients operated upon before the true condition was revealed. However, other conditions in children may give rise to abdominal pain. Before diagnosis is made, tuberculous peritonitis, intestinal parasites, and other gastro intestinal diseases should be taken into consideration.

All the children in the cases studied by Zelditch, et al., with persistent abdominal pain were subjected to duodenal intubation routinely, as well as examination of bile, of gastric contents of feces, and to x ray examination of the tract. The examination of bile was very helpful in diagnosing biliary tract disease. In most cases changes were observed in bile A, B, or C, the bile containing flakes of mucus, fine or coarse the latter usually containing many leucocytes. The bile was apt to contain cholesterol when there was a tendency to cholelithiasis. Simultaneous changes in bile A and bile B denoted simultaneous changes in the gall bladder and biliary passages. When bile C was changed, there was usually an affection of the liver. Inflammatory changes in bile C suggested cholangitis.

In cholecystitis the blood examination usually revealed slight leucocytosis and when intestinal parasites were present their ova were usually found in the feces, also in bile A and bile B occasionally when lamblia was associated with cholecystitis.

The most effective means of arriving at a correct diagnosis of biliary tract disease when it is suspected in children appears to be cholecystography. Graham states that in the St. Louis Children's Hospital, since the development of this diagnostic method, several cases in children under 15 years of age, some of them infants, have been confirmed by operation, some with stones, some with icterus, and some with catarrhal icterus. There were also a considerable number of cases diagnosed as chronic cholecystitis which were not sub

mitted to operation. Besides Graham, Velo, Beals, Rudisill, Montgomery, Shawan and Long, McClendon, and Holbrook were able to make correct pre-operative diagnoses by means of the cholecystograph

TREATMENT

A word should be said regarding treatment. While in advanced cases the classical cholecystostomy or cholecystectomy must be the method of choice, Zelditch and associates state that in mild cholecystitis cases the patients usually recovered following duodenal intubation and rest, and that only a few of such patients had to return to the clinic owing to recrudescence of the abdominal pains. Medicinal and dietary measures and rest are often effective in the more mild cases, but if symptoms persist surgical intervention is indicated.

I wish to report the following 6 cases of interest which have come under my personal observation during the past 10 years:

CASE 1. A poorly developed white boy aged $7\frac{1}{2}$ years entered the hospital December 20, 1930, appearing to be acutely ill. He was lying in bed, knees flexed, and suffering with a generalized pain over the entire abdomen. The skin was markedly jaundiced. Patient was dehydrated. The tongue was red and dry, the skin hot to the touch. He had had many attacks of gastro-intestinal upsets with abdominal pain, nausea, vomiting, and jaundice at irregular intervals since 2 months old. It was my privilege to see this boy when he was $2\frac{1}{2}$ months old during such an attack, but the symptoms were of a milder type, and were seemingly confined to the gall bladder. I have seen him many times since. The present upset is more severe, and points not only to the gall bladder but to the appendix as well. The patient has been ill for the past 5 days with colic-like pains in the abdomen, diarrhea, constipation, acholic stools, anorexia, nausea, and vomiting. Examination reveals chest negative, abdomen, distended with rigidity of muscles and very tender on palpation over McBurney's point and gall-bladder areas. Temperature was 102 degrees, pulse, 120, respiration, 28. Blood count showed hemoglobin, 67 per cent (Dare), leucocytes, 12,450, polymorphonuclears, 76 per cent. Urinalysis revealed: specific gravity, 1022, albumin, +, acetone, slight trace, heavy trace of bile. Wassermann and Kahn tests were negative, van den Bergh, immediate direct reaction positive. A cholecystograph revealed a shadow indicative of the gall bladder, accepting the Graham dye very well. Gall bladder not enlarged, outline was regular, with evidence of the presence of calculi within the shadow. A diagnosis of chronic cholecystitis, cholelithiasis, and acute appendicitis was made.

Operation was performed December 21, 1930. A right paramedian incision was made extending from 2 inches above to 2 inches below the umbilicus. The peritoneal cavity contained a small amount of serous fluid. The gall bladder was distended, with thickened wall and a marked degree of inflammation. Calculi were easily palpated. With the history of many previous attacks, a cholecystectomy was considered advisable. The appendix was rather high, surrounded by the omentum, and revealed a very acute inflammation. An appendectomy was also done. One drainage tube was inserted through the upper angle of the incision to the former bed of the gall bladder. Another drain was inserted through the lower angle of the incision to the pelvis. The patient's convalescence was a bit stormy, although he made a complete recovery. Final diagnosis acute cholecystitis, cholelithiasis, and acute suppurative appendicitis.

The pathological findings showed an acute cholecystitis and an acute suppurative appendicitis. The gall bladder contained 20 small faceted calculi. A bile culture showed mixed infection.

Patient was discharged January 10, 1931. On January 3, 1937, he was enjoying very good health, and has had no disturbance since his discharge from the hospital.

CASE 2 (This patient was seen in consultation with the late Dr. J. H. Poulton.) A fairly well developed white boy, aged 8 years, entered the hospital November 17, 1930. He appeared to be ill, but not seriously, suffering with diffused pains over the entire abdomen, although there was more tenderness on palpation in the right hypochondriac region. The abdomen was slightly distended, no rigidity of abdominal muscles, but some spasticity of right rectus below the right costal arch. The sclera and skin were icteric. The onset of present illness began 1 week ago, with abdominal pain, nausea, and vomiting. The boy was ill for 2 days, then was permitted to get up and play for 2 days, after which his condition became worse and he was put to bed. He was constipated at first, but at this time the bowels were loose and the stools acholic.

His general health had been good. Patient had had the usual diseases of childhood, but no serious illness. The tonsils were hypertrophied. There were no other symptoms than the abdominal pain, nausea, and tenderness on palpation over the gall-bladder area. The skin and sclera were icteric. Physical examination was essentially negative.

Temperature was 99.8 degrees, pulse, 88, respiration, 20. The Widal test was negative, Wassermann and Kahn, negative. Blood count revealed hemoglobin, 75 per cent; red blood cells, 3,750,000; white blood cells, 8,960, small lymphocytes, 36; large lymphocytes, 2; coagulation time, 2 minutes; polymorphonuclears, 62 per cent. Urinalysis revealed: color, dark amber; appearance, cloudy; specific gravity, 1022, reaction, acid, albumin, +, sugar, 0; acetone, slight trace, diacetic acid, slight trace; bile, heavy trace, casts, 0, cylindroids, occasional; leu-

cocytes few, mucus moderate amount Fouchet positive, van den Bergh immediate direct reaction positive

Cholecystography revealed a shadow indicative of gall bladder accepting Graham dye very poorly. The gall bladder was evidently much larger than normal size but of regular outline, with no signs of the presence of a foreign body. Its appearance suggested a possible hydrops of the gall bladder.

The patient remained in the hospital for a week under medical treatment and improved. He was discharged November 24 1930. Diagnosis acute cholecystitis and cholangitis, hydrops of gall bladder.

CASE 3 (This case was seen in consultation with Dr. H. H. Hildred.)

Patient entered the hospital January 10 1930. A white male, aged 8 years, well developed and nourished, lying quietly in bed but complaining of some pain in the head and abdomen with maximum tenderness above and to the right of the umbilicus. The skin and sclera were jaundiced. Patient had complained of pain around the umbilicus for the past 3 or 4 days; the pain at first being severe enough to make him double up. This was continuous for several days and was accompanied with nausea and vomiting. Jaundice appeared after the first 2 days. The bowels were at first constipated but became more free. The stools were of a very light yellowish color. For the past several days, any fluids even water would induce nausea and vomiting. Pain in the abdomen was subsiding when patient entered the hospital. Patient had anorexia for 4 or 5 days but stated he was hungry.

Patient had had measles, mumps, scarlet fever, varicella and pneumonia twice. Tonsillectomy and adenectomy were done 2 years ago.

With the exception of jaundice, brownish red urine, several carious teeth, abdominal pain and slight distention, and a palpable mass the size of a hen's egg in upper right quadrant, there were no outstanding signs or symptoms. General physical examination did not reveal any disturbances of heart or lungs. As a matter of fact, examination was essentially negative.

Temperature was 99.4 degrees, pulse 82, respiration 20. Throat culture revealed Greening streptococcus and staphylococcus, no diphtheria forms. Blood count showed hemoglobin 82 per cent, red blood cells, 4,120,000, white blood cells 6,300, color index 1.0, coagulation time 13½ minutes. Urinalysis revealed color brown, specific gravity 1.025, reaction, acid, albumin 0, sugar 0, acetone, 0, bile slightly positive, epithelia small amount, mucus present, bacteria present, Wassermann and Kahn tests were negative, Fouchet positive, van den Bergh immediate direct reaction, positive.

Radiographic examination showed no evidence of obstruction of the intestines, large or small. The gall bladder did not take Graham dye but its shadow seemed larger than normal.

Diagnosis cholecystitis, acute catarrhal jaundice, cholangitis (?).

Patient remained in the hospital 11 days under treatment and was discharged January 21 1930 with a promise to return should any other disturbance arise. Patient's condition improved. He had one attack since leaving the hospital with very pronounced gall bladder symptoms. Will eventually be operated upon.

CASE 4. Patient a white female, aged 11 years, entered the hospital January 25 1930. When first seen, she was lying quietly in bed in no apparent distress. She was a well developed and well nourished child but deeply jaundiced. Temperature was 99 degrees, pulse, 72, respiration 20.

One week ago the patient began to have anorexia and became drowsy and sleepy. She complained of pain in the upper right quadrant (costal margin) anteriorly, also of pain in the lumbar region of the back. She had epigastric pain which seemed to be worse in the evening, dull and present at intervals. She was jaundiced from the beginning. The stools were clay colored, the urine yellow, but there was no pruritus.

Patient had had measles and mumps but no serious illness. She had had occasional frontal head aches and nose bleeding. She had recently recovered from a mild attack of influenza.

Head, eyes, nose, ears, and neck revealed nothing remarkable. Oral hygiene was poor and she had several carious teeth. Her heart had a soft, systolic murmur. There was no increased cardiac dullness. Lungs showed equal expansion on both sides. A few râles could be heard on deep inspiration anterior and posterior over both lungs, both lobes otherwise negative. The abdomen showed some slight distention. There was tenderness on palpation at the right costal margin anteriorly. The liver was not palpable. There were no palpable tumors or masses, no other tenderness. Reflexes were present and equal. No glandular adenopathy was noted. The skin was deeply jaundiced. Menstrual periods were regular of 28 day type and of 5 to 6 days' duration.

Throat culture revealed Greening streptococcus, no diphtheria forms. Urinalysis revealed color amber, specific gravity 1.012, reaction acid, specific gravity hazy, albumin 0, sugar 0, acetone 0, bile present, casts 0, leucocytes small number, epithelia small amount, bacteria, loaded. Blood examination revealed hemoglobin 76 per cent, red blood cells 4,300,000, white blood cells 9,000, no leucocytosis, 40 per cent with shift to left of 12 per cent. Kahn and Wassermann test gave negative reaction for syphilis, van den Bergh immediate direct reaction positive, Fouchet positive.

Diagnosis acute cholecystitis with jaundice. CASE 5 (This case seen in consultation with Dr. H. H. Hildred.)

A fairly well developed and nourished white female, aged 9 years, was admitted to the hospital January 15 1930. Five days previously she complained of pain in the upper right quadrant of the abdomen, anteriorly, anorexia, vomiting and con-

stipation. The patient had a temperature, the skin and sclera were deeply icteric, and the stools were clay colored. She had on previous occasions had similar symptoms. Past history revealed that patient had had measles, mumps, pneumonia, and more recently influenza. The patient's parents state that the child has been jaundiced with upset stomach quite a number of times; and in fact, that she first became jaundiced 2 weeks after birth.

Examination revealed tenderness over the entire abdomen, more marked in the upper right quadrant, and especially to the right of, and above, the umbilicus, with some distention. There was marked rigidity of the right rectus muscle in the upper right quadrant with some spasticity. The skin and sclera showed marked icterus. The temperature was 100 degrees, pulse, 100; respiration, 32. The blood count showed hemoglobin, 75 per cent; red blood cells, 4,300,000, white blood cells, 8,900, polymorphonuclears, 78 per cent, lymphocytosis, 40 per cent with shift to the left of 12 per cent. Urinalysis showed specific gravity, 1022; color, dark amber, albumin, 0, sugar, 0, acetone, trace; bile, present. Throat cultures revealed Greening streptococcus, no diphtheria forms. Kahn and Wassermann tests were negative; Fouchet, negative, van den Bergh test, immediate direct reaction, positive 37.5 milligrams. Roentgenological examination of chest did not reveal any pathological condition.

Cholecystography revealed a shadow indicative of a gall bladder accepting Graham dye fairly well, very much larger than normal, outline regular. No signs of a foreign body were noted within the shadow. The appearance was that of a hydrops of the gall bladder. Oral hygiene was very poor. Other than the foregoing, the physical examination was essentially negative.

Diagnosis of acute cholecystitis (hydrops), with jaundice.

The patient's parents steadfastly refused to have any surgical intervention, and the patient remained in the hospital under treatment for 11 days when she was discharged improved, with the understanding that she was to return at some future date.

Information has come to us that subsequent to the family's moving away from the city, the patient had a recurrence with similar symptoms at which time she was operated upon. The diagnosis was chronic cholecystitis with hydrops and subacute appendicitis.

CASE 6. (This case was seen in consultation with Dr. H. B. Martin. The writer was also present at the autopsy.)

Patient was a white male, a 7½ months premature infant, weighing 4 pounds 10½ ounces. He was born March 12, 1932, 4:25 p.m.—delivery was uncomplicated.

Patient was undernourished with skin and sclera deeply jaundiced. The abdomen was somewhat distended. Pulse was rather feeble; temperature, 97. There was some slight difficulty in breathing at irregular intervals. Patient was put in an incubator

and at first seemed to improve, but gradually lost ground and died March 13, 1932, at 6:50 p.m., when 26 hours old. It was believed the patient had some congenital abnormalities which caused the condition.

Autopsy on March 14, 1932, 9:30 a.m. revealed the following: The body is that of a premature white male child, 26 hours old. The hair is light and the body is deeply jaundiced. The child measures 42 centimeters in length and weighs 4 pounds 5 ounces. There are no malformations or special marks of identification. The child is 6 weeks premature.

Abdominal cavity. When the abdomen was opened, the peritoneal cavity was found to contain a small amount of yellowish fluid. The liver was large as was also the spleen, but the enlargement did not exceed the normal limits for baby of this age. Upon cut section, the liver was found to be soft, somewhat yellowish, but otherwise not remarkable. The gall bladder was distended, quite tense, and larger than normal. The wall was thin and appeared edematous, and did not empty under pressure. The gall bladder was opened and found to contain a quantity of thick, white bile. The cystic duct was distended and a probe was easily passed into the common duct, where an obstruction was met. The duct was opened at this point and there was seen an atresia with the wall thickened. The stomach and pylorus were normal as was the entire gastro-intestinal tract. The spleen was normal on cut section. The left kidney was of the usual size and the ureter was somewhat enlarged. The kidney was opened and the pelvis was found dilated and filled with urine under pressure. The right kidney was entirely similar and the right ureter was enlarged. The adrenals were normal. The bladder was normal and no gross evidence of obstruction was to be found.

Thoracic cavity. The thymus was of normal size. The cardiac area was not enlarged and the lungs showed a nearly complete exhaustion with a few scattered areas of petechiae. There was no obstruction to the trachea or bronchi. Upon examination of the heart, the coronary arteries especially those of the right descending branch, were found to be thickened in an irregular manner, but this thickening appeared grossly to be of the adventitial type. The heart was not enlarged and presented no abnormalities.

Cranial cavity. There was an extensive edema of the brain with a yellowish accumulation of fluid beneath the dura. The brain itself was not remarkable, however, and the meningeal vessels were somewhat congested.

Anatomical diagnosis: (1) Prematurity. (2) Bilateral congenital hydronephrosis. (3) Hydrops of gall bladder. (4) Atresia of common duct. (5) Thickened coronary arteries. (6) Edema of the brain.

Microscopical sections. (1) Sections of the heart show a normal myocardium and an adventitial thickening of the coronary arteries. (2) Section of the lungs shows partial atelectasis, but no other noteworthy pathology. (3) Sections of the spleen show

an abnormal amount of blood pigment indicating an excess hemolysis of blood cells. The endothelial and lymphoid structures are not remarkable. (4) Sections of the gall bladder and common duct do not show any remarkable pathological condition excepting a hemorrhagic infiltration of duct. (5) Section of the kidneys shows some hemorrhage into a few of the glomeruli but no evidence of infection. (6) Sections of the liver are remarkable showing a marked central necrosis with small accumulation of pus cells and hemorrhage and degenerated blood cells around the periphery of the lobules which process has practically destroyed the liver structure so that the usual arrangement of liver cells is obscured. (7) Sections of the bladder are not remarkable. Final diagnosis—causes of death: (1) hydrops of the gall bladder, (2) stenosis of the common duct, (3) acute necrosis of the liver, (4) marked hemolysis of blood in the spleen, (5) bilateral hydronephrosis, (6) partially expanded lungs, (7) inflammatory sclerosis of the coronary arteries, (8) edema of the brain, (9) prematurity, (10) jaundice.

CONCLUSIONS

Beginning with a report by Gibson, in 1722, we have been able to collect a total of 270 cases in the 205 years ending in 1927—an average of approximately $1\frac{1}{2}$ cases per year. In the following 10 years we were able to collect 162 cases, or an average of 16 per year, an increase of 12 to 1. If the next 10 years show a corresponding increase, as is highly probable with the application of improved diagnostic measures biliary disease will have become firmly fixed as a pathological condition existing in young subjects.

It is interesting to note an increase of 500 per cent in the number of cases diagnosed by symptoms, and a decrease of 71 per cent in the number diagnosed at necropsy. As in adults, females are in slight excess of males.

Suffice it to say that the statistical summary verifies the fact that great progress is being made and that fewer and fewer cases of gall bladder disease in children will escape recognition.

VISCERAL METASTASIS FROM RECTAL CARCINOMA

CLARK E. BROWN, M.D., and SHIELDS WARREN, M.D., Boston, Massachusetts

ONE disturbing feature in the end-results of radical resections for carcinoma of the rectum has been the all too frequent development of visceral metastases. This is no reflection upon the present types of resections designed to remove adequately the local tumor within the limits of anatomical feasibility. Pre-operative x-ray examination of the lungs and careful inspection and palpation of the liver at laparotomy may sometimes demonstrate already existing visceral metastases. Enlarged local lymph nodes may be hyperplastic or neoplastic, and differentiation must often wait on microscopic examination.

Attempts to anticipate metastasis and recurrence by examination of the surgical specimen have been based largely on involvement of lymph nodes and on histological tumor grading. In rectal carcinomas the nodes have been disappointing indicators because visceral metastases often occur independently of neoplastic lymph nodes. The local growth, however, offers another harbinger of organ metastasis, namely invasion of the veins and capillaries by tumor.

The present study of 170 rectal carcinomas with complete postmortem findings attempts to evaluate the importance of local blood vessel invasion as compared with neoplastic lymph nodes in predicting the occurrence of visceral metastases. Incidental to this, we have noted the influence of such factors as the histological type, extent, and location of the primary growth, duration of disease, age, and sex, upon the development of visceral metastases.

The files of the New England Deaconess, the New England Baptist, the Pondville Hospitals, and the House of the Good Samaritan have furnished our material. This group of 170 cases, covering a period of nearly 10 years, was selected because it had detailed postmortem protocols and numerous microscopic slides of the local lesion. Constituting the series are cases of patients dying immediately after resection or colostomy, survivals after operation, and those cases in which no operation interrupted the natural course of the disease.

This series represents only a small portion of patients with rectal carcinoma treated in the above hospitals over the stated time period, and includes only a moderate number of the rectal cancer deaths during that period. Because of the selection imposed by the necessity of having postmortem examinations for this study, generalizations from the facts forthcoming should be made with some caution.

METHOD

Autopsy protocols of patients with carcinomas occurring within 15 centimeters of the anus, or having been removed from that site, were assembled. From the case records information on symptoms, operative procedures, surgical specimens, and postoperative course was tabulated. Data pertaining to location, size, and extent of the primary tumor, and lymph node metastases were recorded from the description of the surgical specimen. Slides were reviewed to confirm the diagnosis and to search for tumor growth into blood and lymphatic vessels.

The chances of error in vessel identification were slight, as nearly all tissues were both paraffin and celloidin imbedded, and after being sectioned, were stained with hematoxylin-eosin, phloxine-methylene blue, and phosphotungstic acid hematoxylin. As would be expected, difficulty was encountered in determining whether intravascular tumor foci present were in capillaries or lymphatics. The finding of erythrocytes in the lumen was of great aid in differentiation. In cases of doubt, decision was made against intravascular invasion. Careful examination of the perirectal fat frequently disclosed involved capillaries and venules. In patients unoperated upon the local findings were tabulated from the postmortem protocols and slides. Visceral metastases were checked and the causes of death noted (Figs 1 to 5).

DATA

The nomenclature employed to designate the various types of rectal cancer carries significance from the standpoint of tumor grading. The term malignant adenoma is used to designate those well differentiated glandular growths classed by many as grade I adenocarcinoma. Those classified as adenocarcinomas are tumors with moderate gland formation as well as solid cell masses

and invasiveness analogous to grade II. Carcinoma simplex is used to indicate tumors with scant or no alveolar formation, solid cell masses, marked invasion, many mitoses, and is consistent with grades III and IV. The colloid or more properly mucinous, carcinomas have in this site the clinical behavior of grades III and IV carcinomas. The epidermoid carcinomas included are those occurring about the sphincter. Seventy one of the primary growths were obtained as surgical specimens and 99 as autopsy specimens. In Table I all cases are arranged according to treatment.

The untreated cases are seen to constitute only 13.5 per cent of the total, and the resections comprise 42 per cent. This is a fair proportion con-

sidering that some patients were referred to these hospitals for terminal care. Dixon has reported that over 50 per cent of rectal growths are inoperable when first observed. By chance all the 9 patients with carcinoma simplex received some form of treatment. The anal location of the epidermoid cancers accounts, no doubt, for their general treatment. Comprising the radical operations are 46 one stage abdominoperineal resections, 9 two stage, and 16 posterior excisions.

The causes of death in the patients in the aforementioned treatment groups are tabulated in Table II. Four fifths of the resection deaths can be accounted for by conditions precipitated locally by radical removal of the growth, such as peritonitis, obstruction, shock, or hemorrhage. The causes of death from colostomy, on the other hand, seem concerned more with the general debility of the patient. Here pneumonia and pulmonary embolism account for 40 per cent of the colostomy deaths following operation. The relatively high incidence of pulmonary embolism from a simple procedure like colostomy suggests that systemic factors, such as debility, poor nutrition, poor aeration, and sluggish circulation are of etiological importance. Of the 26 resection survivors, 10 died without evidence of recurrence or metastasis. Late postoperative complications like obstruction and sepsis accounted for 6 of these deaths. In the table the patients not operated upon and the colostomy survivors were grouped together. About half of this group died of cachexia or exhaustion from widespread metastasis or local recurrence. A large portion of the remainder died of pneumonia occasioned, no doubt, by cachexia.

Single or multiple adenomatous polyps of the colon were associated with 18 or 11 per cent of the 165 glandular or adenoid carcinomas. This coincidence, although smaller than the 40 per cent reported by Westhues and nearly 50 per cent

TABLE I—SUMMARY OF TYPES OF CARCINOMA AND TREATMENT

Types	Resections		Colostomy	Non-operative	Total	Percent of total type resected
	Acute deaths	Survivals				
Malignant adenoma	9	3	2	6	4	3
Adenocarcinoma	31	4	4	4	100	45
Mucinous carcinoma	3	4	6	3	16	44
Carcinoma simplex	0	4	5	0	9	41
Epidermoid carcinoma	7	1	2	0	8	60
Total	45	6	19	3	170	47

Note: Acute resection deaths includes those deaths occurring with the first metastasis postoperatively. Recurrence survival includes those patients surviving the operation by colostomy.

TABLE II—CAUSES OF DEATH

	Shock	Hemorrhage	Peritonitis	Sepsis	Obstruction	Ileus	Pulmonary embolism	Pneumonia	Cachexia	Cardiac	Renal insufficiency	Pulmonary tuberculosis	Miscellaneous	Undetermined	Total
Deaths from resection	5	3	16	5	5	2	1	5	1	1	1	0	0	0	45

Total	5	7	25	14	10	2	8	27	42	4	16	2	5	3	170

reported by Susman is still significantly higher than the incidence of adenomatous polyps of the large intestine in general. Susman reported a 6 per cent incidence of polyps in 1100 consecutive postmortems, and Stewart reported 4.19 per cent in 1815 autopsies in which the colon was carefully scrutinized. In his series the latter also reported 10,985 previous autopsies in which no special search was made for polyps, and here the incidence was only 0.47 per cent. Faulty observation may account partially for the lower incidence of polyps with carcinoma in our series, although the colon was examined with moderate care in all cases.

The situation existing between colonic polyps and cancer is summarized by Karsner and Clark, who, after a brief but informative review, conclude that colonic polyps must be regarded as potentially malignant.

The number of visceral metastases with the number of cases occurring in each treatment group is tabulated in Table III.

The total visceral metastases for each type of growth is summarized next to the cases showing positive lymph nodes in the latter columns of the table. The 70 cases of lymph node metastases are not identical with those showing visceral metastases although there is some overlapping.

A total of 70 cases with visceral metastases among 170 seems small until it is realized that 45 deaths occurred within 1 month of resection, and 33 followed colostomy within a similar period. Inasmuch as the treatment accorded the various adenoid types (malignant adenoma, adenocarcinoma, mucinous carcinoma, and carcinoma simplex) was proportionately similar, the relative malignancy of the different types is reflected in the percentage visceral metastases in each. This is in accord with Rankin and Broders, and Stewart and Spies. Mucinous carcinoma, however, shows only 31 per cent visceral metastases. Expression of its malignant tendency must be sought in diffuse, local growth and in extensive lymphatic permeation due probably to mechanical pressure by the mucinous material. Support for this contention is at hand in the highest percentage lymph node involvement for all types—69 per cent. Even though fewer malignant adenomas were resected the occurrence of metastases to viscera and to lymph nodes was well below that for any of the other types of malignant growth.

The 6 patients with visceral metastases in the group of 45 resection deaths merit some comment. In 2 of these, metastases to the liver were noted at operation. In the 4 remaining, no metastases

TABLE III—VISCERAL METASTASES OCCURRING IN EACH TREATMENT GROUP

vertebrae The inference from this heterogeneous group is that local extension may account for some, but not most of the bone metastases from carcinoma of the rectum. The fact that the vertebrae are the chief sites of skeletal metastasis for primary cancers in general supports this conclusion. Aufses in 1930 added 8 cases of skeletal metastasis from rectal cancer to 16 reported in the literature. His series totaled 117 cases, with 29 autopsies. Five of his 8 cases of skeletal metastasis were proved at autopsy.

Before discussing the conditions in the local growth which help to bring about visceral metastasis, we would like to consider briefly three general factors, namely: duration of symptoms of the disease, age, and sex.

The total symptom duration has been calculated for each case as the sum of the pre-operative symptom duration and postoperative survival period in months. The effect of disease duration on the incidence of visceral metastases in 86 cases of adenocarcinoma is shown in Chart 1. The 14 resection survivals were omitted because they represented duration without the primary focus.

Chart 2. Symptom duration and percentage of visceral metastasis.

Here the percentage visceral metastasis is plotted against the average duration in months. The average duration for the 32 cases of adenocarcinoma dying at resection was 10 months, and 16 per cent of these showed visceral metastasis. Forty-seven per cent of the 17 colostomy deaths with an average duration of 13 months, and 74 per cent of the 38 colostomy survivals or non-operated upon patients averaging 27 months total duration showed visceral metastases.

Another method of summary has been applied to the adenocarcinomas, the malignant adenomas and to the total adenoid group (Chart 2). Arbitrary time periods of 6, 12, 24, and 48 months were adopted, and the visceral metastases in cases falling into these duration groups were tabulated for each type of growth. Resection survivals were omitted as above.

The duration in months is plotted against the percentage visceral metastases. This method of computation puts rather rigorous demands upon duration as influencing visceral metastasis since each duration period is non-cumulative. The type of surgical intervention here is of little moment because the primary tumor was present throughout the disease. Since colloid carcinoma and carcinoma simplex constitute only 17 cases eligible for consideration here, they were included in the adenoid group without being given special consideration. In the method mentioned an obvious source of error is the date set for the origin of the growth. Miles has estimated definite time periods as determined by the progress of the growth around the bowel wall, but so many of our cases were already annular that we have judged the duration onset arbi-

Chart 1 Symptom duration and percentage of visceral metastases

were noted in the liver. Thus 9 per cent of resected cases had no discernible visceral metastases at the time of operation. Two of these patients had occult liver metastases and 2 had lung metastases. In 3 of these 4 cases the local tumor was found at operation to have extended to a pelvic viscus.

There seems to be very little doubt that the broader the criteria for operability, the greater will be the number of cases with hidden metastases included. This inevitable handicap to surgical treatment, however, is relatively small and should in no way be construed to discourage an attempt at cure or palliation through wide resection.

TABLE IV—LOCATION OF METASTASES IN 70 CASES WITH VISCERAL INVOLVEMENT

Intestine 4	Brain 1
Spleen 4	Appendix 1
Pancreas 3	Pleura 1

Fig. 2 Small focus of adenocarcinoma adherent to the wall of a capillary. Note the erythrocyte within the lumen. $\times 425$

The chief sites of visceral metastasis in the 70 cases are as follows: liver, 57 times; lung, 38 times; and adrenal, 19 times (Table IV). Eighty-one per cent of the patients with metastasis to an organ showed liver involvement. Metastasis to the liver alone occurred 23 times and to the lung alone 6 times. In all patients with lung metastases alone, the local lesion was in the lower 9 centimeters of the rectum. Dissemination by systemic or portal circulation from the lower rectum must depend somewhat upon chance, however, since in 11 of the 23 patients with metastasis to the liver alone the local lesion was in the lower 6 centimeters of the rectum. In only 3 patients did blood borne metastasis take place without tumor deposits in the liver or lung. One occurred in a 68 year old woman complaining of convulsions 1 month previous to operation. A cerebral lesion was localized and at operation a nodule in the Rolandic region of the right cerebral cortex near the midline was found. Frozen section diagnosis of metastatic adenocarcinoma, probably of lower gastro-intestinal origin, was made. The following day postmortem examination disclosed 10 centimeters above the anus a fungating adenocarcinoma only 0.7 centimeters in diameter showing slight invasion of the muscularis. The 2 other cases involved bone. In 1 discrete nodules were present in lumbar and thoracic vertebrae. In the other tumor was present in a lumbar vertebra but local extension could not be ruled out. The 13 cases of bone metastasis included deserve some comment. In 2 metastases were present in the ribs and in 1 in the humerus. In the remainder the vertebrae were involved. In 2 of these the primary growth had been removed. In an additional 3 the thoracic vertebrae showed foci of growth. Five other tumors were adherent to and involved the sacrum or lower lumbar

TABLE VI—ALL CASES—INFLUENCE OF DEGREE OF INVASION ON VISCERAL METASTASIS

Resection deaths—45 cases	Number surgical specimens	Visceral metastasis on immediate autopsy	Percentage
Growth within musculature	17	1	6
Growth through musculature	21	2	10
Growth into adjacent organs	7	3	43
Resection survivals—26 cases	Number surgical specimens	Visceral metastasis in subsequent autopsy	Percentage
Growth within musculature	9	4	44
Growth through musculature	14	6	43
Growth into adjacent organs	3	2	67
Non-resection—99 cases	Autopsy specimens	Visceral metastasis at autopsy	Percentage
Growth within musculature	16	5	31
Growth through musculature	41	27	66
Growth into adjacent organs	22	20	48

Fig 4 Venule distended with mucinous secretion, debris, and cells of mucinous carcinoma. Tumor cells appear to be growing along the surface of the intima as well as beneath it. An accompanying arteriole is included. $\times 425$

assume to curability. Therefore we classified the lesions somewhat after the method of Lockhart-Mummery as (1) those remaining within the rectal musculature, (2) those perforating the muscular coat, and (3) those involving an adjacent organ by permeation. Each lesion was so classified and the visceral metastases occurring with it were noted. A summary of these when grouped according to treatment is shown in Table VI.

In the resection survival group, of the 12 cases with visceral metastasis found at autopsy, there had been local recurrence in 9, and involvement of an adjacent pelvic organ in 8. The 44 per cent organ metastasis of the growths within the muscularis as against the 43 per cent for those perforating the wall cannot be explained on the basis of the more malignant types falling into the former group, for on check-up such was not the case. The amount of perirectal tissue removed might be operative here since 7 of the 9 growths limited to the muscularis grossly were removed by posterior resection, and 3 of the 4 showing organ metastasis were removed by this method. This does not attain the significance one might be inclined to give it when one considers the 14 resection survivors with growths perforating the muscularis. Six of these showed visceral metastasis subsequently although only 2 were posterior resections. In the 8 without visceral metastasis,

2 were posterior resections. However, the fallacy of assuming, because there is no grossly visible extension of the growth through the bowel wall, that no such extension has taken place should be emphasized and the adoption of less radical procedures on this account must result inevitably in a certain number of recurrences and subsequent visceral metastases. The analysis by Dukes of 100 surgical specimens in which he finds as a rule that lymphatic spread does not play a part in dissemination until the growth has spread by contiguity through the rectal wall cannot explain the metastases following the removal of intramural growths in our series.

The location of the lesion in the rectum has been thought by some to condition the chances of visceral metastasis. Alleged variations in the abundance of lymphatics and veins in the anterior and posterior walls of the rectum has been assumed to account for supposed differences in the frequency of metastasis from this site. Unfortunately, the tumors in over half of our series are bulky and annular. The group of cases in which there is mention of anterior, posterior, or lateral position of the tumor is too small to merit any conclusions.

Regarding the effect of the tumor position in the longitudinal axis of the bowel upon visceral metastasis, certain obstacles are at hand. It is necessary first to select carcinomas of the same

Chart 3 Age distribution

transly by the appearance of pertinent symptoms. Only such symptoms as rectal bleeding, progressive pain, or persistent change in bowel function have been utilized.

With due consideration of the shortcomings of the method, two features appear significant in Chart 2. In the period between 12 and 24 months all types show an increase in visceral metastases. After this period malignant adenomas show a surprising drop. The possibility of error in diagnosis between benign polyp and malignant adenoma cannot be entertained because these patients at death exhibited evidence of recurrent or spreading disease. Our only explanation for this phenomenon is the presence of tumors whose local exophytic tendency and obstructive effect far overshadow their power of vascular invasion. Morphologically we should expect such cases in the malignant adenoma group. In adenocarcinomas the tendency to visceral metastasis increases with the duration of the disease.

Pre-operative symptom duration merits only passing comment. Table V shows the average pre-admission symptom duration in patients after resection to be well below that in those in whom resection has not been done. Brindley found the symptom duration of 76 operable rectal

TABLE V — AVERAGE DURATION OF SYMPTOMS IN MONTHS ON ADMISSION

	Resected	ns	N	resected	s

Group average	10	6	16	4	

cancers to be 9.4 months. These averages have little application in determining operability because many of the patients with inoperable growths had a pre-admission duration of less than 11 months and some of those subjected to the resection had a pre-operative symptom duration of longer than 16 months. Four of the 6 patients with visceral metastasis who died following resection had a pre-operative symptom duration of less than 11 months; the average for the resection group. The pre-admission symptom duration has little utility in the determination of whether a patient with rectal carcinoma is operable.

The maximum age incidence of rectal cancer has been reported in the sixth decade (Hasden and Shedden and Miles 13). In our series 52 patients developed symptoms of rectal cancer in the sixth decade and 53 in the seventh. The sixth to eighth decades inclusive account for 80 per cent of the series. In Chart 3 the number of cases of each type is plotted against the decades into which they fall. It is seen that malignant adenoma reaches its maximum incidence in the seventh decade while adenocarcinoma, colloid carcinoma, and carcinoma simplex reach theirs a decade earlier. This slight support for the thesis that more malignant forms of carcinoma appear in the younger age groups is in agreement with other reports of a similar nature (Brindley, Fowler and Shedden).

The influence of sex upon the incidence or curability of rectal carcinoma is no different in this series than in others. Of the 170 patients 104 were males and 66 were females, a predominance frequently mentioned (Harding and Hankins, and Daland, Welch and Nathanson).

The size of the local lesion and its invasiveness are thought to have an effect upon the frequency of vascular metastases. It is often difficult to calculate accurately the size of an infiltrative growth in a tubular structure.

In some of the postmortem protocols one dimension of the tumor was omitted and the term annular was applied frequently to denote size. McVay has found that the size of the local growth apparently bears little relation to the extent of lymph node involvement, and we

TABLE VI.—ALL CASES—INFLUENCE OF DEGREE OF INVASION ON VISCERAL METASTASIS

Resection deaths—45 cases	Number surgical specimens	Visceral metastasis on immediate autopsy	Percentage
Growth within musculature	17	1	6
Growth through musculature	21	2	10
Growth into adjacent organs	7	3	43
Resection survivals—26 cases	Number surgical specimens	Visceral metastasis in subsequent autopsy	Percentage
Growth within musculature	9	4	44
Growth through musculature	14	6	43
Growth into adjacent organs	3	2	67
Non-resection—99 cases	Autopsy specimens	Visceral metastasis at autopsy	Percentage
Growth within musculature	16	5	31
Growth through musculature	41	27	66
Growth into adjacent organs	42	20	48

assume to curability. Therefore we classified the lesions somewhat after the method of Lockhart-Mummery as (1) those remaining within the rectal musculature, (2) those perforating the muscular coat, and (3) those involving an adjacent organ by permeation. Each lesion was so classified and the visceral metastases occurring with it were noted. A summary of these when grouped according to treatment is shown in Table VI.

In the resection survival group, of the 12 cases with visceral metastasis found at autopsy, there had been local recurrence in 9, and involvement of an adjacent pelvic organ in 8. The 44 per cent organ metastasis of the growths within the muscularis as against the 43 per cent for those perforating the wall cannot be explained on the basis of the more malignant types falling into the former group, for on check-up such was not the case. The amount of perirectal tissue removed might be operative here since 7 of the 9 growths limited to the muscularis grossly were removed by posterior resection, and 3 of the 4 showing organ metastasis were removed by this method. This does not attain the significance one might be inclined to give it when one considers the 14 resection survivors with growths perforating the muscularis. Six of these showed visceral metastasis subsequently although only 2 were posterior resections. In the 8 without visceral metastasis,

Fig. 4. Venule distended with mucinous secretion, debris, and cells of mucinous carcinoma. Tumor cells appear to be growing along the surface of the intima as well as beneath it. An accompanying arteriole is included. $\times 425$.

2 were posterior resections. However, the fallacy of assuming, because there is no grossly visible extension of the growth through the bowel wall, that no such extension has taken place should be emphasized and the adoption of less radical procedures on this account must result inevitably in a certain number of recurrences and subsequent visceral metastases. The analysis by Dukes of 100 surgical specimens in which he finds as a rule that lymphatic spread does not play a part in dissemination until the growth has spread by contiguity through the rectal wall cannot explain the metastases following the removal of intra-muscular growths in our series.

The location of the lesion in the rectum has been thought by some to condition the chances of visceral metastasis. Alleged variations in the abundance of lymphatics and veins in the anterior and posterior walls of the rectum has been assumed to account for supposed differences in the frequency of metastasis from this site. Unfortunately, the tumors in over half of our series are bulky and annular. The group of cases in which there is mention of anterior, posterior, or lateral position of the tumor is too small to merit any conclusions.

Regarding the effect of the tumor position in the longitudinal axis of the bowel upon visceral metastasis, certain obstacles are at hand. It is necessary first to select carcinomas of the same

Fig 5. Tumor cells of adenocarcinoma growing in the lumen of a small artery within the bowel wall. This is a rare finding especially in surgical material. $\times 250$

kind and approximate duration. Many of the larger growths overlap any such arbitrary limits as 5, 10, or 15 centimeters above the anus. With these difficulties in mind we have chosen 33 adenocarcinomas with a maximum diameter of less than 5 centimeters located either in the first 5 centimeters of the rectum or between 10 and 15 centimeters above the anus. Twenty of these were located in the lower range, and 13 in the upper. Six of the lower growths and 9 of the upper growths had blood borne metastases. Results similar to these were found in larger less well controlled series. It appears, therefore from these limited data that there is a slightly greater tendency for the high rectal growths to yield visceral metastases. This apparent tendency does not extend to the sigmoid for Harding and Hankins have found metastasis to viscera more likely from rectal than sigmoidal growths.

The approximate agreement between the number of visceral metastases and the lymph node metastases for each type of growth is coincidence only. The fallacy of considering it valid in the individual case is apparent in the subsequent

tables which compare the percentage associations of neoplastic nodes and of local intravascular invasions with visceral metastases. Each case has been considered individually with regard to the lymph node metastases, and intravascular invasions present in the local lesion. These have been checked against the presence of coexistent distant visceral metastases. The lymph nodes listed as positive are those neoplastic nodes present in the surgical specimen or discovered subsequently in the abdomen at autopsy. The assumption is made that the surgeon might discover all intra abdominal neoplastic lymph nodes in the resection cases and that the 26 resection survivors without nodes at laparotomy did not develop them subsequently.

In Table VII we have divided the 100 cases of adenocarcinoma into those cases in which neoplastic nodes and visceral metastasis occurred together, into those in which one occurred and not the other, and into those in which neither occurred. The same has been done with growths showing local intravascular invasion. It appears that lymph nodes were positive in 45 cases and that in 32, or 71 per cent, of these visceral metastases were coexistent or developed subsequently.

The nodes were negative in the 55 remaining cases, but in 17, or 31 per cent, of these, visceral metastases were found. Analyzed according to the invasion of vessels by tumor in the primary growth we find this to have occurred in 70 cases; and that in 49, or 70 per cent, of these, visceral metastases were present or developed subsequently. And in the 30 remaining which showed no intravascular growth locally, none had visceral metastases. A similar situation was found to exist in the 40 cases of malignant adenoma, and in the 165 cases comprising the entire adenoid group. Tables VIII and IX summarize these.

In only one instance did visceral metastases occur in the absence of local intravascular invasion. The groups of carcinoma simplex and mucinous carcinoma are too small for analysis separately and both have been included with the adenoid group.

The three foregoing tables make no correction for the varying methods of treatment. An attempt to do this has been made in Table X.

In general, the same trends are present as noted in Tables VII, VIII, and IX. The percentage showing visceral metastases associated with neoplastic lymph nodes is approximately the same as that in the case of local intravascular invasions and visceral metastases. It is interesting

to note that these percentages increase as the duration of the disease increases. In the case of the lymph nodes going from 38 per cent in the acute resection deaths to 82 per cent in the non-resection cases, and in the case of intravascular growth from 38 per cent to 74 per cent. On the other hand, visceral metastases were present in 6 per cent of the cases of acute resection death which had negative lymph nodes, and in 46 per cent of the resection survivals with negative nodes. In contrast, visceral metastases were unheralded by local intravascular tumor in only one instance. In the 25 cases of resection survival, where prognosis attains some practical significance, the 11 cases of visceral metastasis all showed local vascular invasion. Only 5 of the 11 cases of visceral metastasis fell in the group of 12 cases showing neoplastic nodes.

It should be kept in mind that the foregoing discussion deals with the prediction of blood-borne metastases to viscera, and applies to individual and group prognosis only indirectly, since all deaths from rectal cancer are not concerned with visceral metastasis. Many result from massive local recurrence or postoperative complication.

The spread of rectal carcinoma through blood vascular channels is at least as important as

TABLE X—TOTAL GROUP 170 CASES—ASSOCIATION BETWEEN LYMPH NODES AND INTRA VASCULAR INVASION WITH VISCERAL METASTASES IN CASES DIVIDED INTO VARIOUS TREATMENT GROUPS

Note: The 5 cases of epidermoid carcinoma are included. Twelve divided into metastases and both of these showed intravascular invasion. Because of overlapping of cases under different headings the total cases given in the table add to more than 170.

through the lymphatic route. Evidence of this vascular spread is usually available in the primary growth. The relatively large number of cases (33 per cent) with tumor growth within vessels locally and with no coexistent visceral metastasis detracts from the value of this factor in a positive sense. It serves to emphasize a fact determined experimentally by Warren and Gates that only a small proportion of tumor cells entering the circulation survive and grow in distant foci. Likewise this circumstance in rectal carcinoma is similar to that found by Clute and Warren in carcinomas and potentially malignant adenomas of the thyroid where the local intravascular invasions are many but the distant metastases relatively few. Nevertheless as far as the prediction of visceral metastases in rectal carcinoma from the local growth and nodes is concerned, the presence of intravascular tumor means as much from the prognostic standpoint as neoplastic nodes and their absence means much more.

Detailed methods of statistical analysis have been applied to the data concerning lymph node involvement and visceral metastases though omitted here to conserve space. The conclusions may be regarded as sound so far as the primary data warrant them.

SUMMARY AND CONCLUSIONS

1 The tendency of rectal carcinoma to metastasize via the blood stream varies in general with the degree of differentiation. Malignant adenoma produced visceral metastases in 23 per cent of our cases, adenocarcinoma in 49 per cent and carcinoma simplex in 56 per cent.

2 Mucinous carcinoma has a marked tendency to metastasize by way of the lymphatics.

3 In general the longer the duration of rectal carcinoma the greater are the number of visceral metastases.

4 Metastasis of rectal carcinoma to bone is not rare. 5 per cent in this series.

5 The more the primary growth penetrates the bowel wall the greater are the chances of blood borne metastasis.

6 The reliability of prognosis of visceral metastases by observation of local intravascular invasion and to a less extent by lymph node metastasis, increases with the duration of the disease.

7 Forty-one per cent of the cases showed visceral metastases.

8 Sixty-one per cent of the cases showed local intravascular invasion.

9 Sixty-seven per cent of those with local intravascular invasion showed visceral metastases closely paralleling the 66 per cent of visceral metastases with positive lymph nodes.

10 Only 1 case of the 70 showing visceral metastases failed to show local intravascular invasion, whereas 24 cases (34 per cent) of these failed to show positive lymph nodes, or, expressed in a different way, 24 per cent of the cases with negative nodes had visceral metastases.

11 Sections of the primary growth in rectal carcinoma should be scrutinized carefully for invasion of capillaries or veins by tumor, because intravascular tumor invasion frequently means visceral metastases and its absence, provided at least three sections from different parts of the growth are examined, nearly always rules out visceral metastasis. Its efficiency in predicting visceral or bone metastasis outranks that of neoplastic lymph nodes.

We are indebted to the members of the staffs of the hospitals mentioned for use of the cases and for helpful suggestions particularly Drs. Ernest M. Daland, Frank H. Lahey and Leland S. McKinnick. We thank Dr. Tracy B. Mallory for data on seven surgical specimens from the laboratory of the Massachusetts General Hospital.

VITAMIN OILS IN THE TREATMENT OF BURNS

An Experimental Study

CHARLES B PUESTOW M D, F A C S, HENRY G PONCHER M D and
HAROLD HAMMATT B M Chicago, Illinois

THE therapeutic value of fish liver oils and of vitamins in the healing of burns and other wounds has been discussed frequently in recent medical literature. Most observers are enthusiastic over the results obtained, but all do not agree as to the factors responsible for them. This study was undertaken to obtain some knowledge of the comparative values of several oils and other commonly used agents in the healing of burns.

Stimulation of tissue growth has been noted following the administration of cod liver oil and of vitamin preparations by various routes. Wuttig, in 1905, produced considerable endothelial proliferations in the liver by injecting cod liver oil into the mesenteric veins of rabbits whereas olive oil was inert. Bond applied irradiated ergosterol dissolved to saturation in liquid petrolatum as a dressing for ulcers and granulating wounds. He believed that it reduced infection, promoted healthy granulations and stimulated epithelization, possibly due to a further continued irradiation effect on the wound tissues after the primary irradiation of the sterol by the ultraviolet rays from the mercury vapor lamp had ceased. Loehr has used cod liver oil dressings extensively in the treatment of burns and other wounds. He obtained excellent results in a large series of patients with second and third degree burns. Cod liver oil was mixed with inert materials to form a paste, which was applied freely to the burned areas. If these were on the extremities, plaster casts were applied over the dressings. The dressings were changed as infrequently as possible but could be removed painlessly. He states that cod liver oil is self sterilizing and found that it diminished the

incidence of infection of burns and controlled secondary infection when present. The wounds were rapidly cleansed and epithelization was stimulated to a degree not seen in any other form of treatment. Skin grafting was not found necessary in wounds treated by this method. Loehr further states that the treatment did not prevent early fatalities from burns more than other forms of therapy, but the number of late fatalities, due to secondary infections, was markedly reduced more so than with tannic acid. He attributes the effect of cod liver oil therapy to the action of vitamins A and D on the tissues of the wound. Its chief disadvantage is the odor.

Other observers have been favorably impressed by results obtained with cod liver oil dressings applied to burns and wounds. Steel reports that indolent ulcers were rapidly healed by it. Marked relief of pain followed its application, more so than with other dressings (11, 12). Skin wounds in guinea pigs (3) healed better after application of cod liver oil ointment than after vitamin free ointment. Vitamin A ointments have been used by Horn and Sandor and by Sandor, who believe it inhibits infection and stimulates healing. Lauber and Rocholl found that small and medium amounts of vitamin A added to a cholesterol base accelerated the healing of experimental wounds by 50 per cent but larger amounts inhibited recovery as did other vitamins with various bases.

The influence of vitamin deficiencies on wound healing and the effect of the administration of various vitamins by mouth has been studied. Lauber produced wounds on the backs of rats and noted the time of healing while on an ordinary diet. Addition to the diet of 4 units daily of vitamin A shortened the healing time by one half. Large quantities had no effect and massive doses (40,000 units

From the Departments of Surgery and Pediatrics, University of Illinois College of Medicine.
This study aided by a grant from Mead Johnson & Co.

Fig 1 Twelve day old control burn This burn has not been treated

Fig 2 Twelve day old burn treated with 5 per cent fresh tannic acid solution

Fig 3 Twelve day old burn treated with ointment No 5, high vitamin A to D ratio

daily) more than doubled the healing period. He found that administration of vitamins B and D had no effect on healing time, but that avitaminosis definitely retarded it. In treating severe and infected burns Franzetti administered orally 20 to 30 drops of a solution containing 12,000 units per cubic centimeter each of vitamins A and D. He applied camphor in oil containing vitamins A and D to the burned areas. Under this form of therapy he observed that the local infections responded well and the general intoxication, edema, fever, and albuminuria rapidly diminished.

Davson does not believe vitamin A to be the responsible agent for tissue regeneration. He injected subcutaneously cod liver oil and halibut liver oil into the ears of rabbits and at a later date made histological sections. Although he states that vitamin A is 100 times greater in amount in halibut liver oil than in cod liver oil, both preparations produced the same degree of tissue response, a marked stimulation of phagocytes, fibroblasts, and young capillaries. Liquid paraffin and olive oil proved relatively inert when employed in similar experiments.

METHOD

Pigs and rabbits were employed in the experiments here presented. The former were used because their size and the thickness of the skin permits the production of sufficiently large lesions for more accurate study. The reaction of the skin of pigs to heat appears similar to that of human skin, except that

vesicles do not form. Burns were produced in shaved areas of the back with the animals under general anesthesia. Lesions were produced by the use of an electrocautery applied to a given area at a constant temperature for a definite period of time. By careful regulation of the degree of heat and the time of application an attempt was made to produce a number of wounds of the same depth in a given experiment, so that a more accurate evaluation of the effects of various therapeutic agents could be made. On a given date a number of uniformly deep lesions were produced and each treated with a different therapeutic agent, generally one lesion being left untreated as a control.

On a later date another experiment was started by producing a series of burns which were all of equal depth but all deeper than those of the previous experiment. Each of these likewise was treated with a different therapeutic agent. Thus the burns in each given experiment were of uniform depth although the depths of lesions varied in different experiments. Care was taken to use areas of skin of similar location and thickness. Applications of the ointments were made twice daily to assure the constant presence of the medication. The size of the burns was measured when produced, and subsequent measurements were made to determine the rate of healing. The character of the crust and the presence or absence of secondary infection was noted. After complete healing biopsy specimens of the entire epidermis were studied his-

tologically to determine the amount, thickness, and type of epithelium and the amount and degree of fibrosis and hyalinization of the scars. Adequate and uniform diets were fed throughout the experiments.

Each therapeutic ointment consisted of 6-1/2 per cent by weight of the specific oil compounded with a base consisting of yellow bees wax, 15 per cent, hydrous wool fat, 12.5 per cent, and spermaceti, 10 per cent. The oils employed and their identification numbers are as follows:

- 1 Olive oil free of vitamins
- 2 Cod liver oil containing 1800 units of vitamin A and 175 units of vitamin D per gram
- 3 Irradiated ergosterol in oil containing 1 million units of vitamin D per gram
- 4 Fish liver oil containing 45,000 units of vitamin A and 75,000 units of vitamin D per gram
- 5 Fish liver oil containing 380,000 units of vitamin A and 2,000 units of vitamin D per gram

Five per cent tannic acid solution was applied to other lesions, and control lesions were left untreated.

VITAMIN CONTENT OF THERAPEUTIC OINTMENTS

Ointment number	Units per gram of ointment	
	Vitamin A	Vitamin D
1	0	0
2	1.5	100
3	0	625,000
4	28.5	46,875
5	37,500	50

RESULTS

From Table I a graph (Fig. 6) was made showing the average size of the burns treated with each therapeutic agent and the average number of days required for complete healing to occur. A review of this graph permits certain conclusions. The application of fresh 5 per cent tannic acid solution did not appreciably diminish the time required for complete healing of burns in pigs as compared with similar lesions untreated. Lesions treated with a vitamin free olive oil ointment healed in approximately the same length of time as the control burns but averaged about 25 per

cent larger in area. The average size of burns to which cod liver oil ointment was applied was equal to that of the controls but the period of healing was more than 25 per cent shorter than that of the controls or of tannic acid treated lesions. The three high vitamin ointments, No 3 very high in vitamin D, No 4 with a low vitamin A to vitamin D ratio, and No 5 with a high vitamin A to vitamin D ratio, were applied to burns averaging nearly 50 per cent larger in size than the controls or those treated with tannic acid or standardized cod liver oil ointment. The time of healing of lesions treated with these high vitamin ointments was approximately the same as that required to heal the smaller lesions treated with cod liver oil ointment. Thus lesions 50 per cent larger than the controls were completely epithelized in approximately three-quarters of the time required to produce the same degree of repair in the controls or in the lesions treated with tannic acid. The results of the three high vitamin ointments were so nearly alike that none can be considered superior to any other in the stimulation of wound healing. As vitamin A was entirely absent from ointment No 3 it seems fair to assume that this vitamin is not the important factor in wound healing. However, high concentrations of vitamin A did not retard healing in these experiments. In cod liver oil ointment in

which the concentration of both vitamins A and D was comparatively low healing was definitely stimulated but not to the same degree as was noted with the use of ointments containing a high concentration of either A or D.

Table II shows the results obtained in the treatment of burns on rabbits. Here the results compared quite favorably with those

obtained from pigs except that the degree of acceleration of healing was perhaps less marked. Fifteen rabbits had burns treated with ointment No. 3 which was very high in vitamin D. All but two died in less than a week, suggesting a very toxic effect of this ointment. The two which lived had sustained very small lesions.

Careful histological studies were made of all lesions. An attempt was made to compare the thickness and type of epithelium and the amount and degree of fibrosis and hyaliniza-

tion. The epithelium everywhere was fairly well developed. There were well developed connective tissue changes of moderate hyaline and fibrous character, with no areas of keloid density. The microscopic variations were so slight that they could well be accounted for by differences in age, size and sex of the animal and variations in thickness of the skin in different parts of the body. It was concluded that there were no characteristic microscopic differences in the scars of lesions treated by the various agents (Figs. 4 and 5).

No attempt has been made in this study to compare the systemic effects of burns under the various treatments employed. The pigs had no obvious general effects from the burns, as the lesions, in comparison to their total skin surface area were small. However in rabbits the very high mortality when burns were treated with high vitamin D ointment was striking.

SUMMARY

Controlled burns were produced upon pigs and rabbits and were treated with ointments containing varying amounts of vitamin A and vitamin D. The time and character of local wound healing was determined and compared with untreated controls and burns treated with tannic acid.

Burns treated with 5 per cent fresh tannic acid solution healed in the same length of time as untreated controls of similar average size.

The application of vitamin free olive oil ointment to slightly larger burns was followed by complete healing in the same length of time as the controls.

Cod liver oil ointment shortened by 23 per cent the healing period of burns equal in size to the controls.

Burns which averaged 50 per cent larger than the controls were treated with three high vitamin ointments. No. 3 containing no vitamin A but very high in vitamin D, No. 4 having a low vitamin A to vitamin D ratio and No. 5 with a high vitamin A to vitamin D ratio. The time of healing was approximately 25 per cent shorter than in the smaller control lesions and those treated with tannic acid. It was no longer than in the smaller lesions treated with cod liver oil ointment of low vitamin content. The response to the various high

vitamin ointments employed was approximately the same

Histological studies of the scars of all healed burns revealed no characteristic difference for the various therapeutic agents employed

THE RELATION OF CATGUT SENSITIVITY TO WOUND HEALING

CORNELIUS J. KRAISSL, M.D., BEATRICE M. KESTEN, M.D., and
J. GRIER CIMIOTTI, B.S., New York, New York

IN a previous article (6) entitled "Intrinsic Factors Altering the Absorption of Catgut" evidence was presented which seemed to indicate that the sensitivity of an individual to one or more of the specific constituents of this suture material was one of the causes of its premature absorption.

The possibility of a relationship between sensitivity to suture material and post-operative wound complications has been appreciated by many observers. Gratia and Gilson were impressed with the frequency with which postoperative adhesions and even intestinal obstruction occurred along the line of catgut suture in patients having been operated on previously or to whom serum or protein therapy had been given. They came to the conclusion that these complications were manifestations of a localized allergic reaction to catgut which was due to the introduction of this antigen in a previously sensitized individual.

They first sensitized three groups of guinea pigs, one to sheep serum, one to horse serum and one to both sera, while another group served as controls. They then introduced a suspension of powdered catgut into the abdominal cavity of these animals. After 8 days the sensitized guinea pigs showed an intensely hemorrhagic inflammatory intraperitoneal reaction with adhesions of the intestinal loops, and some of those not immediately sacrificed developed intestinal obstruction. It was found that the greatest reaction occurred in those guinea pigs which had been sensitized to sheep serum, a less intense reaction occurred in the others, while none occurred in the controls. They also sensitized three groups of rabbits to catgut, horse, and sheep sera respectively, and then introduced powdered catgut, desiccated horse serum, and desiccated sheep

serum respectively into the peritoneal cavities as well as into a group of non sensitized rabbits. The greatest reaction was found to have occurred in the animals sensitized to catgut and to a less degree in those sensitized to horse and sheep sera, but it was not stated what reactions occurred when animals previously sensitized to sheep serum or horse serum were tested with catgut. These reactions were said to be similar to the necrotic nodule produced in the subcutaneous tissue by repeated inoculations of antigen as described by Arthus. Efforts were made to desensitize the animals by the introduction of various substances, but this was entirely unsuccessful. One thing was demonstrated, however, that if catgut was immersed for a time in anti sheep rabbits serum, it failed to produce the reactions in the sensitized animals.

In an attempt to disprove the theories of Gratia and Gilson, Frugoni in a series of experiments was unable to find precipitins in the sera of rabbits which were supposedly sensitized to catgut and failed to produce anaphylactic shock in a group of guinea pigs. He also introduced catgut into the peritoneal cavities of another group of animals and after 3 months introduced more. Many of the animals developed no adhesions and those reactions which did occur were thought to have resulted from foreign body reaction or from infection. No skin tests were made to indicate whether or not sensitivity had been produced.

Catgut used in most parts of Europe is chemically sterilized and frequently hardened with formaldehyde, resulting in an almost non absorbable material. Frugoni's negative results may have been due to the use of this type of catgut.

Marchesani was not entirely successful in demonstrating the relationship of the specificity between catgut and sheep serum. How

ever, in animals which were sensitized with catgut extract, the introduction of catgut beneath the skin caused a marked reaction. This was studied microscopically and consisted of hyperemia, edema, increased leucocytic response, and even local necrosis was occasionally produced. Allergic reactions were also demonstrated in animals sensitized to catgut by introduction of catgut extract in the conjunctival sac. No evidence of either type of reaction could be seen in the non-sensitized animals.

Babcock pointed out that faulty wound healing is frequently observed following thyroidectomy where catgut is used. He suggested that the edema, serosanguineous discharge, and slight separation of wound margins was due to sensitivity to the catgut, but he did not demonstrate sensitivity in these cases. However, when he substituted silk these reactions were entirely eliminated in 80 consecutive thyroidectomies. Babcock's method of testing normal individuals for sensitivity to catgut is open to question, for he found reactions in all of the 120 individuals in which he buried small strands of catgut beneath the skin.

Hinton suggested the possibility of a relationship between catgut sensitivity and wound dehiscence as well as postoperative incisional hernia. He considered this possibility in 3 of 19 cases of wound disruption in which there seemed to be no other adequate cause. He did not demonstrate sensitivity by appropriate skin reactions in these cases but in a group of 112 normal patients without previous contact with catgut he found 9 which gave a positive reaction to the intradermal injection of an extract of fresh sheep intestine. He assumed, therefore, that a certain percentage of all operative patients are sensitive to catgut.

Another interesting but rather speculative observation was a case reported by Tripp. The patient suffered from asthma following a second operation and the symptoms subsided after it was assumed that the catgut had been absorbed. Tripp believed that the individual had been sensitized by the suture material of her previous operation but no skin test confirmed this impression.

*No. 551 was sensitized to chronic catgut and laparotomy performed with plain catgut.

Jenkins has also considered the possibility of catgut sensitivity as a cause of premature absorption in a discussion of the whole problem of wound disruption.

In a previous clinical and experimental report (6), a study of wound healing was made

*No. 582 was sensitized to plain catgut and the laparotomy performed with chromic catgut.

in a small group of sensitized and non sensitized guinea pigs. It was found that 6 of the 19 sensitized animals disrupted their laparotomy wounds while this did not occur in the 6 control animals. In the present report this study has been continued on a larger scale to include 84 guinea pigs. Of these 28 were sensitized to plain catgut, 16 were sensitized to chromic catgut, 8 to chromic acid while 20 were used as controls. The 6 remaining died of intercurrent infection.

DETAILS OF EXPERIMENTS

Sensitization to plain catgut. The first group of 28 animals was sensitized to plain catgut by several methods and by a combination of these methods (Table I). Eight animals received 0.1 gram of powdered catgut introduced into the peritoneal cavity through a 1 centimeter incision which was closed with 1 bolt suture of the same suture material. These animals were tested at 2 week intervals with

an intradermal injection of catgut extract but after 1 month as there was no evidence that they were sensitive, 4 of them then received an additional 2 strands of catgut about 2 centimeters long introduced beneath the prepared skin of the back while the remaining 4 had a laparotomy incision closed with 3 bolt sutures of the same suture material. These guinea pigs were tested for sensitivity at 2 week intervals and at the end of 3 months all showed a positive skin reaction.

Four animals received an intraperitoneal injection of 2 cubic centimeters of the plain catgut extract and these were skin tested every 2 weeks. Sensitivity was manifest after 1 month. In 13 animals 3 double strands of catgut about 4 centimeters long were introduced subcutaneously. After a 2 month interval they gave a positive response to an intradermal test. The 3 remaining animals

TABLE V—INTRADERMAL TESTS TO SUTURE MATERIAL

*Control (saline)—Negative reactions

were sensitized as follows: 1 by laparotomy using 3 sutures of plain catgut to close the incision; 1 by 3 intradermal injections of 0.1 cubic centimeter of plain catgut extract, and 1 by 1 intracardiac injection of 0.5 cubic centimeter of the same material which resulted in a positive skin reaction after 19 days.

Sensitization to chromic catgut. Sixteen guinea pigs survived sensitization to chromic catgut (Table II). Of these 6 were sensitized by the subcutaneous suture method, 6 were sensitized by a combination of intraperitoneal injection of powdered catgut and subcutaneous suture, 3 by intraperitoneal injection of 2 cubic centimeters of chromic catgut extract, and 1 by laparotomy, chromic catgut being used to close the incision.

It was found that the animals receiving the powdered catgut intraperitoneally were not sensitive after more than 5 weeks had elapsed and they received an additional 2 strands of catgut subcutaneously. After another month elapsed they were then found to be sensitive by the skin test.

The average time required to sensitize the animals by repeated injections of extract intraperitoneally was 1½ months. The average time for sensitization by the subcutaneous suture method was 3 weeks, although 2 animals gave a positive skin reaction at the end of 17 days, which was the shortest time recorded.

Sensitization to chromic acid. Believing that the chrome radical might prove to be of inter-

est in this connection, a group of 8 guinea pigs received 2 cubic centimeters of a 1 to 10,000 solution of chromic acid subcutaneously. It was found that the animals required 2 or 3 injections at 5 week intervals to produce evidence of sensitivity as determined by intradermal skin tests of the same material (Table III).

Control group. Twenty-six guinea pigs reserved for the control group were skin tested for sensitivity to the material to be used. There were 23 negative and 3 gave a doubtful reaction.

Evidence of sensitivity. As has been indicated in the previous paragraphs animals were skin tested for evidence of their sensitivity. This was done by the injection of a dilute solution of catgut extract or chromic acid into the shaved skin of the abdominal wall. A positive reaction consisted of redness, flare, and wheal. A doubtful reaction consisted of a mild area of redness, while a negative reaction showed no apparent response of any type.

Preparation of catgut extract and chromic acid solution. The catgut extract was prepared by grinding a large amount of the dried material to a powder. This was sterilized in an oven for 1 hour as described by Rappaport, and 5 grams were extracted for 24 hours in an agitator, in 100 cubic centimeters of one-hundredth normal sodium hydroxide. The suspension was filtered through a Chamberlain filter and then through a Berkefeldt filter. Nitrogen determinations were made by the

micro Kjeldahl method. What portion of this nitrogen represented dissolved protein was not determined. In the case of the chromic catgut, the result was 0.14 milligrams of total nitrogen per cubic centimeter and of the plain catgut the result was 0.13 milligrams per cubic centimeter. These extracts were diluted to 100 cubic centimeters with saline for the final concentrations. Cultures were made of the solutions and no growth was obtained.

Chromic acid solution was also prepared in saline in a concentration of 1:10,000 and autoclaved before using.

Laparotomy procedure. After a positive skin test had been obtained, laparotomies were performed on all animals in the following manner. The animal was anesthetized with ether, the abdomen was shaved, and the skin was prepared with iodine and alcohol. A paramedian incision was made approximately 2.5 centimeters in length. This was extended down to the muscle which was usually separated by blunt dissection. The peritoneum was incised thus exposing the viscera. Then those sensitized to plain catgut were sutured with No. 00 plain catgut taken through all the layers of the abdominal wall. Those sensitized to chromic catgut were similarly sutured with chromic catgut, except No. 551 which was sensitized to chromic catgut and had a laparotomy performed with plain catgut and animal No. 582 which was sensitized to plain

catgut and had a laparotomy performed with chromic catgut. Half the controls were closed with plain catgut and the other half with chromic catgut. Following closure a dressing of collodion and cotton was applied and the animal was protected during the immediate postoperative period. The animals were observed at frequent intervals and a record made of the progress of wound healing. The results are shown in Table IV.

Results. It will be observed that of the 28 animals sensitized to plain catgut, 10 disrupted their abdominal wounds, 9 showed definite abnormal wound healing, while 9 healed normally. In the group of 16 sensitized to chromic catgut, 5 disrupted, 4 healed abnormally, and 7 healed normally. Of the animals sensitized to chromic acid 2 disrupted, while 3 showed abnormal wound healing and 3 healed normally. These results are in marked contrast to the 26 control animals of which only 1 showed evidence of abnormal wound healing and none disrupted. Abnormal wound healing was considered to take place when there was marked redness and edema about the sutures which extended to the wound margins causing thickening and eversion. The time of healing was invariably prolonged.

CLINICAL INVESTIGATION

Definite conclusions can be drawn only from unquestionable results. The factors in human

wound disruption are manifold and cannot be applied to controlled animal experimentation, nor is it possible to control these numerous factors so as to evaluate any one of them properly in a study of clinical cases. Presumptive evidence, however, may be obtained from a large series of cases if there is only one variable factor. The general observation that in disrupted wounds sutured with catgut, the catgut has largely disappeared suggests that it has been too rapidly absorbed. The same observation has been made in the wounds which disrupted in the guinea pig series. If every case on a surgical service were skin tested for catgut sensitivity and if it were found that a much higher incidence of wound disruption occurred in sensitive individuals and their results could not be explained by a consideration of the other causative factors one might consider the results presumptive evidence of the importance of this factor. We propose to make this study and present it in a subsequent paper.

However, suggestive facts are revealed by a study of the following groups: (1) pre-operative patients, (2) patients who had been operated upon and (3) patients surviving wound disruption.

Each of these groups was further subdivided into those which gave a history of some allergic manifestation and those which did not. There were 227 individuals in the first group, 75 in the second, and 30 in the third. All were subjected to the intradermal injection of the four solutions used in the skin tests in the guinea pigs except that they were diluted 1:10. This dilution made the irritation less marked but did not affect the interpretation of the reaction. Tests were made by introducing 0.1 cubic centimeter of the four solutions in the skin of the volar aspect of the forearm. They were recorded after 15 to 20 minutes and the criteria of a positive reaction consisted in erythema, enlargement of the wheal, and pseudopods from the wheal.

The results are shown in Tables V and VI. It will be observed that the allergic patients exhibited evidences of sensitivity more than twice as frequently as normal individuals. A history of an operation also increased the incidence of positive tests and when both of

these elements were combined the incidence rose still higher.

Table VI is an analysis of 30 cases which survived wound disruption at the Presbyterian Hospital since 1930.

All 5 cases which gave a history of allergy showed a positive skin test to one or more of the extracts. Twelve of the whole group had a previous operation and 7 of these gave a positive reaction. Of the 18 which gave no history of operation, 12 had a positive skin test indicating that this factor was of little importance in this group. However, it may be possible that the reaction to the catgut causing the disruption may have desensitized the individual resulting in a negative response to the skin test.

It is felt, therefore, that a history of allergy or a previous operation increases the likelihood of an individual being sensitive to catgut.

The reason for this relationship seems to be that allergic individuals are very frequently sensitive to a number of foreign proteins as shown by the various tests given in the allergy clinic. Catgut, being derived from sheep is a foreign protein but may undergo certain chemical changes in manufacture, particularly when it is chromicized. This process may alter the specificity so that we felt it important to use catgut extract itself rather than an extract of the fresh material. It was also considered possible that acquired sensitivity may be produced by an operation in which catgut is used, particularly if the individual has allergic tendencies.

SUMMARY

A. Laparotomies were performed on a group of 84 guinea pigs. 52 of these were previously sensitized to plain catgut, chromic catgut, or chromic acid. Twenty six were used as controls and the remaining 6 died of intercurrent infection.

1. Of those sensitized to plain catgut 33.7 per cent disrupted their abdominal wounds, 32.1 per cent of them healed abnormally, and 34.1 per cent healed normally.

2. Of the animals sensitized to chromic catgut 31.2 per cent disrupted, 25 per cent healed abnormally, and 43.7 per cent healed normally.

3. Those sensitized to chromic acid re

sulted in 25 per cent of disruption, 37.5 per cent abnormal healing, and 37.5 per cent normal healing

4 All of the 26 non-sensitized control animals healed normally except 1 which healed abnormally.

B. Three hundred and thirty-two patients were tested for sensitivity to plain catgut extract, chromic catgut extract, and chromic acid.

1. Fourteen and fifteen hundredths per cent of them gave a positive reaction to one or more of the solutions

2. Fifteen per cent of those patients with both a history of allergy and a previous operation were sensitive, while a positive reaction was obtained in 9.5 per cent of those with a history of operation alone

3. Seventeen and three tenths per cent of the patients with a history of allergy alone showed evidence of sensitivity while 2.3 per cent of the individuals without a history of either condition gave a positive response.

4 All 5 of the patients who disrupted their abdominal wounds and who had a history of allergy showed evidence of sensitivity, while 52 per cent of those without a history of allergy gave a positive response

CONCLUSION

Laboratory experimentation has demonstrated that guinea pigs may be sensitized to catgut. When this material is again introduced into such an animal a marked local reaction usually occurs at the site of its introduction. This frequently results in a rapid absorption of the catgut and often disruption of the wound.

Clinical investigation reveals a definite incidence of sensitivity to this suture material as determined by skin tests done with appropriate solutions. This incidence greatly increases with a history of allergy or a previous operation.

It is felt, that when catgut is to be used, the individual should be tested for sensitivity, particularly if he falls in the latter two groups.

By this procedure one of the factors relating to disruption of wounds may be eliminated and in this way the incidence of this catastrophe may be reduced

The authors wish to express their appreciation to Dr. Frank L. Meleney and Dr. J. Gardner Hopkins for their kind assistance and helpful suggestions in the preparation of this paper, and to Mrs. Rhoda H. Bower for assisting with the chemical analyses.

The Surgical Procedures for Biliary Calculi—Elliott C. Cutler and Robert Zollinger

CLINICAL SURGERY

FROM THE SURGICAL CLINIC OF THE PETER BENT BRIGHAM HOSPITAL

THE SURGICAL PROCEDURES FOR BILIARY CALCULI

ELLIOTT C. CUTLER, M.D., F.A.C.S., and ROBERT ZOLLINGER, M.D., F.A.C.S.,
Boston, Massachusetts

IT IS our purpose to describe techniques for cholecystectomy, choledochostomy, and cholecystostomy in order to assist the young surgeon to avoid his mistakes of commission, most of which are the result of awkward or incomplete exposure of the operative field, and include such potential catastrophes as insecure ligation of the cystic duct or artery, angulation, or even ligation of the common duct and failure to recognize relatively common congenital abnormalities. Even more serious, and certainly more frequent, are the mistakes of omission, which usually are the result of the surgeon's failure to recognize and remove calculi in the biliary system beyond the cystic duct

CHOLECYSTECTOMY (FIGS 1-13)

General indications and pre-operative preparation The diagnosis of a diseased gall bladder can usually be confirmed by the oral administration of tetraiodophthalein sodium dye. When the gall bladder cannot be visualized, and no calculi are visible by this method, the test is repeated by the intravenous administration of the dye before cholecystectomy is recommended. Sosman has found that approximately 30 per cent of the gall bladders which appear to be abnormal after oral dye administration can be visualized by giving the dye intravenously. However, when the diagnosis is obvious, this procedure can justifiably be omitted, and in the presence of jaundice cholecystography is not indicated.

A history of at least one attack of biliary colic was obtained in more than 90 per cent of our cases, and in general the shorter the interval between the last attack of colic and the operation, the better the result of cholecystectomy. We have found biliary calculi in a high percentage of cases. In the patients who present only "gas" or vague indigestion as the major complaint, cholecystectomy should be advised with caution, for, as Graham has shown, the results are not good.

Approximately one-third of the patients at the Peter Bent Brigham Hospital with abnormal gall bladders by cholecystogram are submitted to surgery, although a much higher percentage had been recommended for surgery

Anesthesia. The choice of anesthesia is governed by the desires of the surgeon as well as the condition of the patient. Adequate relaxation of muscles by general anesthetics simplifies the operation. In elderly or debilitated patients, local anesthesia (novocain, 1 per cent, without adrenalin) can be used with satisfaction. Deeply jaundiced patients or those in whom there probably is liver damage should not be given large amounts of ether or chloroform as both are injurious to the liver parenchyma. Spinal anesthesia alone or a combination of nitrous oxide-oxygen and novocain may be used in such instances with a small amount of vinyl ether for the few moments whenever complete relaxation is necessary.

Position. The placing of the patient in the proper position on the operating table is of first importance in securing adequate exposure. Figure 1 depicts the value of breaking the table at the costal margin and having the body as a whole semi-erect, so that the weight of the liver tends to lower the gall bladder below the costal margin. Such a position acts as a natural retractor because the intestines have a tendency to fall away from the site of operation. The surgeon must remember to level the operating table before attempting to close or he will find that there is unnecessary tension placed on the structures of the abdominal wall

Incision and exposure. The high right rectus incision, as shown in Figure 2, is the one preferred. The skin incision must be a little longer than the peritoneal incision at the upper end, and therefore as a rule should begin above the costal margin. After deepening the incision to the rectus sheath the bleeding points should be tied to do away with unnecessary hemostatic forceps

7

13

Figs 7 to 13 Cholecystectomy

in the wound Pads or towels moistened in salt solution should then be placed over the fat to protect it from contamination. The rectus sheath is next incised, and the fibers split in a parallel fashion, picking up the blood vessels at each tendinous interruption. If care is used the majority of the underlying motor nerves can be preserved by retracting them to the upper and lower ends of the wound. The peritoneum should be opened just to the right of the xyphoid and continued to the umbilicus or below, depending upon the thickness of the abdominal wall and the length between the xyphoid and umbilicus. The peritoneum is then attached to the gauze or towels which already cover the subcutaneous fatty tissue. In our experience the transverse incision is not as simple in performance by junior surgeons as is the right rectus incision which we have described in detail. This may be due to the fact that the position of the gall bladder cannot be definitely determined beforehand and because, in our opinion, abdominal exploration and incidental appendectomy are not easily performed through this incision. However, we make no effort to remove the appendix routinely unless it can easily be brought into the field of operation. When the patient's position on the table is proper and the high incision made, the liver will drop down and the break in the table will tend to thrust the deep structures forward. A general abdominal exploration is now carried out. Following this, the site for cholecystectomy is prepared. Occasionally, when assistance is limited, the use of the main part of a Balfour self-retaining retractor may be used advantageously. With the right rectus incision described, however, a self-retaining retractor usually does not give adequate exposure to the right side, and as a rule we have found it better to use a single flat retractor at the right costal margin. Retraction of the mesial side is made by the left hand of the first assistant, which placed on a moist pad goes upward and inward to the upper border of the duodenum and holds downward and toward the midline all the structures below this. If the hand is correctly placed, the hepatoduodenal ligament, which contains the common duct, portal vein, and hepatic artery, the only anatomical structures endangered in this operation, is exposed. A deep, wide retractor may be substituted at the lower angle of the wound for the assistant's hand.

Figure 3 shows the wound opened, a retractor laterally, and the first assistant's left hand over a wet pad holding the intestines from the operative field. The fundus of the gall bladder is seized in a hemostat of the broad-nosed type. This is

applied only after the decision is made to remove the gall bladder, since to apply such a hemostat and then not remove the gall bladder would leave a devitalized point. A better exposure of the undersurface of the liver may be obtained if the operator places his right hand up over the dome of the liver and tilts it downward. Also, to aid in the exposure of the under surface of the liver, the round ligament may be divided between clamps (Fig. 3). The assistant, by maintaining traction on the round ligament, further aids in the exposure.

In the presence of jaundice of unknown etiology the hemostat should not be applied to the fundus of the gall bladder until the operator has determined whether this area is to be used for cholecystgastrostomy, or that cholecystectomy is necessary.

Details of the procedure Figure 4 shows the palpation of the common duct with the left hand of the operator. An effort is made to determine the consistency of the common duct, the presence of calculi and the condition of the head of the pancreas. Regardless of whether or not the common duct is to be explored, the region of the ampulla and cystic duct should now be accurately exposed. This is accomplished by exerting tension on the fundus of the gall bladder. The peritoneal attachment of the ampulla which is continuous with the structures about the common duct are visualized and incised (Fig. 5), thus liberating the ampulla of the gall bladder from its position against the common duct and cystic duct. A hemostat blindly applied to this region may result in extensive injury to the common duct because the ampulla may be lying parallel to it for a considerable distance. Better visualization of these structures is then obtained by applying a second hemostat to the ampulla and exerting gentle traction upon this at the same time that one pulls upward the clamp on the fundus. This puts the cystic duct under tension so that it can easily be identified. The cystic duct is followed down to the common duct. When this structure is visualized and the operator is certain (1) that the common duct need not be opened and (2) that cholecystectomy is to be performed, a thin-bladed right angle clamp (Mixer) is placed across the cystic duct (Fig. 6) about 1 centimeter from the common duct. Just above this a curved half-length clamp (Kelley) (Fig. 7) is placed on the cystic duct and the duct is divided between these clamps. The utilization of the exact type of clamps described simplifies both the division of the duct and the subsequent ligation of the proximal end of the duct. As the cystic duct is

cut across, the operator visualizes its size and consistency deriving further information as to the likelihood that stones have passed through its lumen. Traction is then exerted upon the clamp on the distal end of the cystic duct and the ampulla. This further exposes the deeper structures. The cystic artery should then be visualized and divided between the same type of clamps used in the division of the duct. Following the division of these structures (Fig. 8), the traction should be very gentle, lest the gall bladder be torn from the liver bed. The cystic artery and cystic duct are now separately ligated (Fig. 9) before the gall bladder is removed. We prefer to use a silk ligature but, if chromic catgut is used, a small size is preferable. The peritoneal surface of the gall bladder close to the liver should now be incised on both sides either with a knife or scissors following which, by careful dissection in the loose fatty tissue between the gall bladder and the liver, the gall bladder can be separated from its bed and drawn out of the wound without injury to the liver and without dividing any sizable vessels (Fig. 10). Before the gall bladder is finally removed from its cleft in the liver, advantage may be taken of the traction which can be exercised upon it, fine sutures are placed to close the peritoneal opening about the common duct, the area of the cystic duct and artery, and the open bed of the gall bladder in the undersurface of the liver (Figs. 11 and 12). The round ligament is reapproximated in the cases in which it has been divided, and the rent in the falciform ligament likewise is repaired. The omentum may be placed up into the region of the gall bladder bed to aid in walling off this area.

It has now become a frequent practice in simple uncomplicated cases to close such a wound without drainage. If gross infection has been present or if the wound is not absolutely dry and hemostasis or closure of the liver bed is incomplete it is wiser to leave a small cigarette drain which should extend to the renal fossa and lie against the cleft in the liver from which the gall bladder has been removed.

Closure then proceeds after the accustomed method of each operator. If the transverse incision or the oblique Kocher incision is used tension sutures, even in the face of infection, are not necessary. We prefer to close the wound with silk, using a continuous suture for the peritoneum and transversalis fascia, and interrupted mattress sutures for the rectus fascia, subcutaneous fat and skin. A chromic catgut suture, size No. 1 or 2 is frequently used for the peritoneum and fascia layers. If the common rectus muscle splitting

incision is utilized, particularly if the patient is elderly, obese, or if there be much infection it is always wise to use several silk worm gut or steel wire tension sutures.

CHOLEDOCHOSTOMY AND CHOLECYSTECTOMY (FIGS. 14-21)

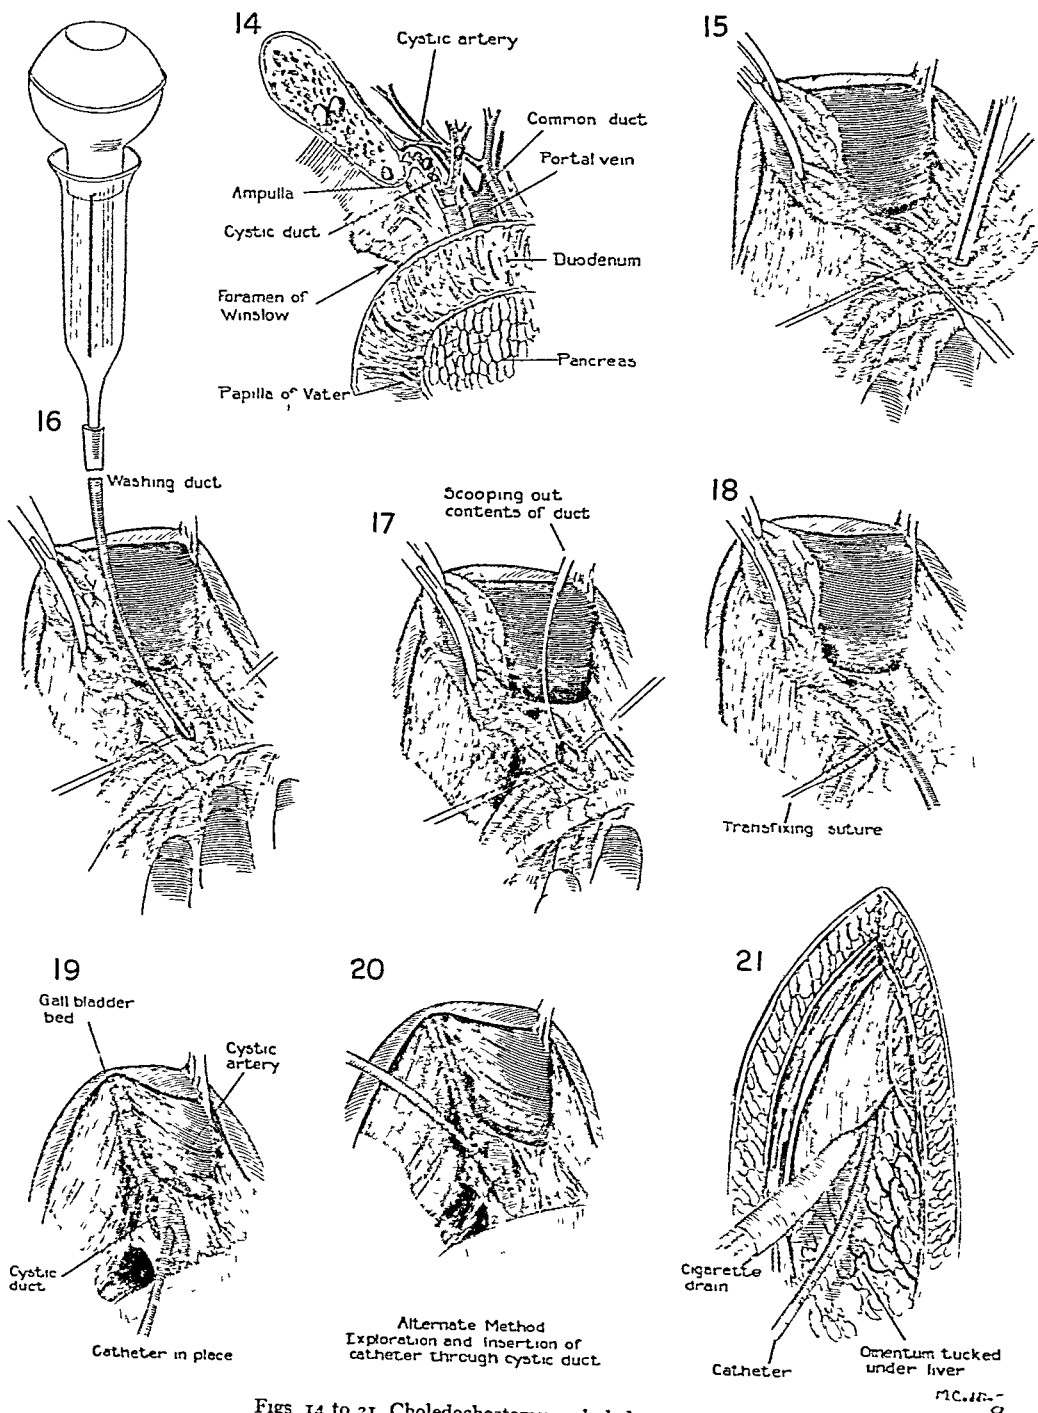

General indications and pre operative preparation. The decision to explore the common duct depends not only upon the history and the symptoms but upon the anatomical findings presented to the surgeon by palpation and visualization at operation. We have used the following criteria as indications for exploring the common duct:

- 1 History or presence of jaundice
- 2 Cholangitis associated with cholelithiasis.
- 3 Recurrent symptoms after cholecystectomy
- 4 Frequent attacks of gall stone colic
- 5 Irreversible involuntary vomiting
- 6 Suggestion of stone by palpation.
- 7 Dilated or thickened common duct
- 8 Contracted thickened gall bladder
- 9 Dilated cystic duct
- 10 Thickening of head of pancreas
- 11 Many small stones in gall bladder and cystic duct.

The first five indications are obtained from the history. Indications 6 to 11 are obtained by observation and palpation. By following these indications we have found that it is necessary to explore the common duct in about 40 per cent of our cases. Over a period of several years at the Peter Bent Brigham Hospital the incidence of common duct stone was as high as 22.8 per cent of all patients operated upon for cholelithiasis. This would indicate that almost one fourth of the patients undergoing cholecystectomy should have the common duct explored and the young surgeon therefore must be as familiar with the technique of exploring the common duct as he is with the technique of cholecystectomy. Figure 14 depicts, schematically, the common locations of calculi.

In the presence of increased or severe jaundice, it is usually desirable to delay operation for a few days to see if general improvement will follow. Unless the icterus is of very long duration with a prolonged bleeding and clotting time we have not been particularly impressed with the dangers of hemorrhage when the tissues are handled carefully and meticulous hematemesis is carried out. High carbohydrate intake, either orally or parenterally is advised in all cases for a time before operation.

Exposure. Figure 15 depicts the exposure and the stage at which the common duct is exposed. The surgeon should note the size of the duct the

Figs 14 to 21 Choledochostomy and cholecystectomy.

M.C. 11-10

thickness of the wall, the presence of inflammation and any other pathological findings, together with the factors mentioned previously, to determine whether exploration of the common duct is necessary. In doubtful situations the common duct is identified by its position in the hepatoduodenal ligament, by its direct relation to the cystic duct, by the presence of a vein running over its wall, and by aspiration of bile through a fine needle.

Details of the procedure To explore the common duct, two silk sutures are placed a few millimeters apart in its wall at a point, as a rule just below the entrance of the cystic duct into the common duct (Fig 15). By traction on these sutures and by traction on the gall bladder, which is never disconnected from the duct system until after the procedures upon the common duct have been completed, an excellent exposure of the field is provided. The common duct is then opened between these sutures over a distance of at least 1 centimeter (Fig 16). A variation of this procedure suggested by Halsted has been utilized in certain cases, i. e., in cases in which the cystic duct is sufficiently large, it may be possible to explore the common duct through it. If this is to be done, the cystic duct is opened between the same type of sutures placed just above its point of junction to the common duct. Exploration upward is usually impeded by the angle at the juncture of the two ducts so that the common duct must be opened to remove the stone after which it can be closed tightly and drainage carried out via a catheter in the cystic duct. Whether the cystic duct or the common duct be opened, the operation proceeds in the same fashion. With the duct held open, it is customary to explore the common duct first with a small English webbing catheter, size No. 10 or 12. This should be gently inserted first downward and then upward to test the patency of the duct. If this is manipulated with the right hand and the left forefinger is in the foramen of Winslow, one may be able to feel the stone against the catheter, even if the catheter seems to pass freely through the papilla of Vater. After this exploration the simplest method of securing the stone should be utilized. This method is depicted in Figure 16, and consists in instilling normal salt solution from a syringe into the catheter, irrigating both upward and downward. In a great many instances the stones which are light in weight are dislodged by the fluid just as wax is dislodged in the ear, and the stones float into the opening in the duct and can be picked out. The next step (Fig 17) is to insert a small scoop which should have a pliable handle

which can be bent to the necessary curve of the duct in each case. This should be passed upward in both hepatic ducts and then downward into the region of the papilla. Stones may be easily brought out with such a scoop. Sometimes in the case of a stone impacted in a diverticulum to one side of the papilla the left forefinger and thumb may fix the stone and with the scoop break it into fragments. These may be removed either piece meal or by washing them into the opening with a syringe of warm salt solution. The scooping is often carried out before the irrigation. Care should be taken in the use of scoops and all other metal instruments, lest perforation occur or cicatrization be increased. When the operator has determined that no further stones are present in the duct he should test the patency of the papilla by inserting an English webbing olive tipped catheter, sizes No. 14 to 16, which he should be able to pass without resistance into the duodenum (Cheever).

We do not believe that an attempt should be made to dilate the papilla once its patency has been established. Experiments have shown that the papilla returns to its original size or smaller as a result of scar formation from extensive dilatation (5). Likewise it has been shown (5), following dilatation of the papilla of Vater in patients, that during the first few days after this procedure there is considerable increase in resistance to the escape of fluids through the common duct into the duodenum, as is demonstrated by consistent elevation of the perfusion pressure.

In cases in which the jaundice has been of long standing and particularly when there has been a great deal of vomiting preceding the operation, it has been our custom to instill 50 cubic centimeters of a 50 per cent glucose solution into the duodenum by way of the catheter used to test the patency of the papilla for the purpose of giving the patient food for the next few hours. After the manipulations upon the duct are finished a small soft, open end common duct rubber catheter is inserted into the common duct either through the opening made in the duct (Fig 19) or down the cystic duct (Fig 20) into the common duct. The opening in the duct is closed securely about the catheter and tested for possible leakage by the injection of saline through the catheter. We always use fine black silk sutures. One of these sutures should be engaged in the rubber of the catheter about 1 inch from the tip and then lightly engage the outer coat of the duct (Fig 18). This ligature is then tied and suffices to hold the catheter in the position desired. Since this suture

Figs 22 to 27 Cholecystectomy

includes only a few millimeters of duct tissue, it is deliberately tied very tightly, and will eventually become free in perhaps a week so that the catheter can be pulled out without any discomfort to the patient. Following the placement of this catheter (Figs 19 and 20), the gall bladder is removed according to the technique described under cholecystectomy.

The closure of this wound is modified from that described in cholecystectomy only by addition of the catheter as well as a small cigarette drain. It is our custom to place a skin suture at the point where we wish the common duct catheter to be held, tying this about the catheter to hold it in position. In many uncomplicated cases the cigarette drain is omitted. The catheter or drain, or both, may be brought out through a separate stab wound lateral to the incision. The surgeon must be certain that the catheter is connected to a drainage bottle promptly after transfer from the operating table.

CHOLECYSTECTOMY FROM FUNDUS (FIGS 22-27)

General indications. Cholecystectomy from above, as a rule, is limited to cases in which exposure of the region of the cystic duct is difficult and perhaps hazardous, and the surgeon feels that it is much safer and easier to remove the gall bladder from the fundus downward. Extensive adhesions and an acutely inflamed gall bladder, especially with a large calculus impacted in the region of the ampulla, are some of the factors which make such a procedure the wiser choice.

Details of the procedure. Having exposed the fundus of the gall bladder at the edge of the liver, the surgeon now determines, from the appearance of the operative field, whether it is safer to remove the gall bladder from the fundus downward or to proceed with the classical cholecystectomy. If the former method is adopted, it is wiser to empty the gall bladder of its contents immediately through a trochar, in order that there may

thickness of the wall, the presence of inflammation and any other pathological findings, together with the factors mentioned previously, to determine whether exploration of the common duct is necessary. In doubtful situations the common duct is identified by its position in the hepatoduodenal ligament, by its direct relation to the cystic duct, by the presence of a vein running over its wall, and by aspiration of bile through a fine needle.

Details of the procedure. To explore the common duct, two silk sutures are placed a few millimeters apart in its wall at a point as a rule, just below the entrance of the cystic duct into the common duct (Fig 15). By traction on these sutures and by traction on the gall bladder, which is never disconnected from the duct system until after the procedures upon the common duct have been completed, an excellent exposure of the field is provided. The common duct is then opened between these sutures over a distance of at least 1 centimeter (Fig 16). A variation of this procedure suggested by Halsted has been utilized in certain cases, i. e., in cases in which the cystic duct is sufficiently large it may be possible to explore the common duct through it. If this is to be done, the cystic duct is opened between the same type of sutures placed just above its point of junction to the common duct. Exploration upward is usually impeded by the angle at the juncture of the two ducts so that the common duct must be opened to remove the stone after which it can be closed tightly and drainage carried out via a catheter in the cystic duct. Whether the cystic duct or the common duct be opened the operation proceeds in the same fashion. With the duct held open, it is customary to explore the common duct first with a small English webbing catheter, size No. 10 or 12. This should be gently inserted first downward and then upward to test the patency of the duct. If this is manipulated with the right hand and the left forefinger is in the foramen of Winslow, one may be able to feel the stone against the catheter, even if the catheter seems to pass freely through the papilla of Vater. After this exploration, the simplest method of securing the stone should be utilized. This method is depicted in Figure 16, and consists in instilling normal salt solution from a syringe into the catheter, irrigating both upward and downward. In a great many instances the stones which are light in weight are dislodged by the fluid just as wax is dislodged in the ear and the stones float into the opening in the duct and can be picked out. The next step (Fig 17) is to insert a small scoop which should have a pliable handle

which can be bent to the necessary curve of the duct in each case. This should be passed upward in both hepatic ducts and then downward into the region of the papilla. Stones may be easily brought out with such a scoop. Sometimes in the case of a stone impacted in a diverticulum to one side of the papilla, the left forefinger and thumb may fix the stone and with the scoop break it into fragments. These may be removed either piece meal or by washing them into the opening with a syringe of warm salt solution. The scooping is often carried out before the irrigation. Care should be taken in the use of scoops and all other metal instruments, lest perforation occur or cicatrization be increased. When the operator has determined that no further stones are present in the duct, he should test the patency of the papilla by inserting an English webbing olive tipped catheter, sizes No. 14 to 16 which he should be able to pass without resistance into the duodenum (Cheever).

We do not believe that an attempt should be made to dilate the papilla once its patency has been established. Experiments have shown that the papilla returns to its original size or smaller as a result of scar formation from extensive dilatation (5). Likewise, it has been shown (5) following dilatation of the papilla of Vater in patients, that during the first few days after this procedure there is considerable increase in resistance to the escape of fluids through the common duct into the duodenum, as is demonstrated by consistent elevation of the perium pressure.

In cases in which the jaundice has been of long standing and particularly when there has been a great deal of vomiting preceding the operation it has been our custom to instill 50 cubic centimeters of a 50 per cent glucose solution into the duodenum by way of the catheter used to test the patency of the papilla for the purpose of giving the patient food for the next few hours. After the manipulations upon the duct are finished, a small soft, open end common duct rubber catheter is inserted into the common duct either through the opening made in the duct (Fig 19) or down the cystic duct (Fig 20) into the common duct. The opening in the duct is closed securely about the catheter and tested for possible leakage by the injection of saline through the catheter. We always use fine black silk sutures. One of these sutures should be engaged in the rubber of the catheter about 1 inch from the tip and then lightly engage the outer coat of the duct (Fig 18). This ligature is then tied and suffices to hold the catheter in the position desired. Since this suture

above, in that the indications for this procedure are usually those which demand cholecystectomy. However, in patients who are very poor risks and particularly in patients with gross purulent infection of the gall bladder, it may become the operation of choice.

Anesthesia Novocain infiltration anesthesia is advisable.

Position, incision and exposure The position is the same as that for classical cholecystectomy. The incision should be as small as will conveniently expose the fundus of the gall bladder. It is usually preferable to place the incision over the maximum point of tenderness to insure proximity of the fundus of the gall bladder to the overlying incision and aid in anchoring it to the peritoneum at the time of closure.

Walling-off gauzes are inserted completely around the fundus of the gall bladder to wall off the remainder of the peritoneal cavity.

Details of the procedure Figure 28 shows aspiration of the gall bladder through a trochar. Figure 29 shows enlargement of the trochar opening so that a "sucker" can be inserted into the gall bladder to aid in the evacuation of its contents. A culture of the contents of the gall bladder is taken. Suction rapidly evacuates the fluid contents. The cavity of the gall bladder may be washed with salt solution, which tends to dislodge coherent stones, and on the whole the procedure is far less traumatizing than the use of metal scoops and spoons. Figure 30 shows a

step in removing stones with a scoop or spoon. When the gall bladder has been thoroughly emptied and irrigated and no stones remain, a soft piece of rubber tubing or an open-end common duct catheter is placed in the gall bladder and held there by a transfixing suture (Fig. 31). A pursestring suture is then placed about the opening in the gall bladder and the opening tightened around the catheter or tube (Figs. 32 and 33). Before the peritoneum is closed, sutures are placed between the fundus of the gall bladder and the peritoneum in order to anchor the gall bladder at this point. It is important to adjust this point of fixation to the position the gall bladder will naturally assume with the patient erect.

Closure is made as is customary, care being taken to pack the omentum about the gall bladder.

Figs 28 to 34 Cholecystostomy

be less bulk to the gall bladder in the way of subsequent steps. The trochar may be thrust immediately into the fundus of the gall bladder (Fig. 22) and the gall bladder emptied of its contents by pressure upon it and suction through the trochar when the trochar is removed one or two curved hemostats are placed so as to prevent the further regurgitation of bile through the opening made by the trochar. Or if there be considerable infection present and the dangers of soiling the field from the contents of the gall bladder are felt to be of serious consequence then a pursestring suture may be laid in the top of the fundus of the gall bladder and the trochar thrust in the middle of the circle of the previously laid suture. As the trochar is withdrawn this pursestring suture is tightened to prevent the escape of the contents of the gall bladder. Figures 33 and 34 depict the beginning of the dissection of the gall bladder from its cleft in the liver. It is well to begin the first incision into the serosa of the gall bladder with a knife. Following this and especially if the zone of loose areolar tissue beneath the serosal coat is distended or edematous the remainder of the dissection is easily carried out with a pair of scissors (Fig. 25). The main principle is to dissect as close to the gall bladder as possible if necessary leaving most of the serosa attached to the liver bed. It is the

removal of the lining of the gall bladder only that is important. In some instances, because of advanced inflammatory changes, the full thickness of the gall bladder is removed excepting that portion in the liver bed. Phenol or electrocoagulation is applied to the remaining mucosa to complete its destruction. As the surgeon exposes the cystic duct he should be sure (1) that the clamp (Fig. 24) is placed so as to include both the cystic duct and artery, and (2) that the inclusion of any part of the common duct is avoided. With the gall bladder thus removed the cystic duct and cystic artery may be ligated either jointly or separately. Closure of the denuded gall bladder bed by utilization of what is left of the serosa of the gall bladder should be attempted (Fig. 27) with a continuous or interrupted silk suture.

Closure. These steps are carried out in exactly the same fashion as in the operation for cholecystectomy from above except that in cases in which removal of the gall bladder is from above downward it is always wiser to insert a cigarette drain which lies in the cleft of the liver and extends to the renal fossa.

CHOLECYSTOSTOMY (FIGS 28-34)

General indications and preoperative preparation. This operation is less frequently performed than the operation of cholecystectomy from

Fig 2

Fig 2 A, Diagram showing center of rotation of head fragment of left hip as considered in the present discussion as seen from the front. Note that rotation is always in an upward direction anteriorly. B, Shows the reverse curve of the head and neck junction which will impinge against the acetabular rim if rotation is much over 100 degrees as is also shown by x-ray in Figure 1 to the left.

Fig 3 Diagram. The clear circle represents the fractured surface of the head fragment, the shaded one the neck fragment as seen from the side. 1, The two are superimposed before any displacement has occurred. 2, Displacement occurring. circle occurs as external rotation of the femur takes place following fracture. The clear circle (head) rotates due to the locked spicules. 3, 4, and 5, Continued external rotation of neck fragment with upward displacement carrying head into further rotation. 6, Fragments finally unlocked with complete displacement.

sharp contrast to the usual fracture history today. The question arises whether the patient makes a misstep, twisting the hip slightly, fractures it and falls, having sustained the fracture by torsion, or falls and fractures the hip by impact with the floor. Our feeling is that most of these patients have a fractured hip before they come to rest on the ground or floor.

Length of hospital stay and expense incident to

a fracture of the neck of the femur. The average patient who enters the ward of most hospitals with a fracture of the neck of the femur is a rather unwelcome guest for a prolonged stay. Our series showed 41 patients, excluding those who died shortly after admission or were transferred elsewhere during treatment, who stayed in the hospital for an average of 122½ days each. Of these patients 24 occupied ward beds at a cost of \$5.48

Fig 4

Fig 5

Fig 4 Diagram of left hip from the front showing that the location of earliest separation at the line of fracture is above and in front and that contact of spicules persists at the lowest point of line of fracture. It is the locking of these spicules at this point which causes rotation of the head fragment to occur. Incomplete, undisplaced, or fragmented fractures will not present this same mechanical situation and therefore rotation will not occur.

Beyond this point fragments unlock as complete displacement occurs.

FRACTURES OF THE NECK OF THE FEMUR

A Critical Analysis of Fifty Consecutive Cases

MATHUR CLEVELAND, M.D., F.A.C.S., and DAVID M. BOSWORTH, M.D.,
New York, New York

THE extensive literature on the subject serves to emphasize the fact that fracture of the neck of the femur presents one of the most difficult problems in bone and joint surgery. The numerous technical procedures which have recently been advocated for the reduction and fixation of these fractures indicate a feeling of dissatisfaction with results obtained by the formerly accepted methods. Some of these procedures which are so enthusiastically proclaimed may prove to be real advances in treatment but time will be required to gather statistical data. The reports of new operations with one or several cases followed for a year or less are too inconclusive to warrant serious attention.

The thought and action of the majority of surgeons who have treated these fractures have been dominated by the teaching of Royal Whitman, to whom we owe a debt of gratitude for his pioneering in principles of treatment. It is unfortunate, however, that he did not report any final results.

This series of 50 consecutive fractures of the neck of the femur is presented from the surgical and orthopedic services of St. Luke's Hospital over a 5 year period from January 1930 to

From the Surgical and Orthopedic Services of St. Luke's Hospital

December, 1934. These patients are from the wards and private pavilion, representing the work of 15 surgeons which of course, means considerable variation in technique, but the principles of treatment have been similar.

Age. These 50 patients were an elderly group with an average age of 64½ years. The youngest were 36 and 40 years old respectively, 62 per cent were in the seventh, eighth and ninth decades of life, while the remaining 38 per cent were in the fourth, fifth and sixth decades.

The age distribution is as follows:

Age in years	Number of patients	Per cent
31-40	2	4
41-50	6	12
51-60	11	22
61-70	11	22
71-80	14	28
81-90	6	12

Sex. The sex incidence shows 39 of 50, or 78 per cent, were women; a ratio of women to men of almost 4 to 1. Our feeling is that any series of fractures of the neck of the femur from a similar hospital will show a marked preponderance of women.

Type of injury producing the fracture. This is often trivial; a simple fall, tripping over a rug, some slight misstep. Only 3 of the 50 were injured by being struck by an automobile which is in

Fig. 1. The original case of derotation for fracture of the neck of the femur. Left shows the pointed femoral neck caught on the head and rotating it upward and forward in front slightly more than 90 degrees so that the anterior border of the head fragment now lies above. The portion of the neck attached to the head at this situation reverses

the curve of the head and it would form a point of impingement against the acetabular margin in full abduction even though union should occur without derotation. Center shows derotation with perfect matching of the bone ends. Right shows solid perfect union with no absorption in 6 months.

Fig 2

Fig 2 A, Diagram showing center of rotation of head fragment of left hip as considered in the present discussion as seen from the front. Note that rotation is always in an upward direction anteriorly. B, Shows the reverse curve of the head and neck junction which will impinge against the acetabular rim if rotation is much over 100 degrees as is also shown by x-ray in Figure 1 to the left.

Fig 3 Diagram. Beyond this point fragments unlock as complete displacement occurs.

Fig. 7 a Mismatching of pterional sutures is clear evidence of head rotation and demands derotation for best chance of union. b Note contour of upper head/neck margin with projecting eminence due to rotation of head fragment bringing antero-inferior border of head above. If union

occurs this way abduction will be limited by this contour or faulty articular alignment. c Rotation of head causes end-to-end position but no apposition. Spicules lock fragments apart. Increased blood clot between fragments favors non union.

Fig. 8 Angulation of fragments with end-on position as shown in a is direct evidence of rotation of head and mis-

matching of fragments. Derotation of head 160 degrees shown in b.

per day or a total of \$671.50 each, excluding the cost of the roentgenograms and the use of the operating room and rating the surgeon's services gratis, as they are. Very few of these ward patients pay even a small fraction of the cost of their care so the hospital assumes a heavy financial burden in treating them.

The cost for a private patient is little short of appalling. There were 17 private patients who

stayed in the hospital an average of 134 days. Figuring their expense at an absolutely minimal rate of \$7.00 per day it brings the bare charge for a room to \$1000 roentgenograms the day and night nurses' use of the operating room and lastly the surgeon's fee being excluded. The economic problem for either class of patients can not be denied.

Method of treatment. This series of patients has been treated by what are considered conservative methods. In 40 manipulation was used; legs were put in varying degrees of abduction and internal rotation and were immobilized by a plaster of Paris spica bandage. In 5 manipulation and immobilization were not used. Five patients were treated with traction.

END RESULTS

Mortality. This is an elderly group of patients with relatively short expectancy of life. From January 1930 to July 1936 a 6½ year period there were 11 deaths in the 50 cases or a gross mortality of 22 per cent. Four of these deaths

Fig. 9 Non union resulting from 90 degree rotation of head. Fragments could not have been opposed without derotation of head.

Fig. 10. Case 6, A B, a housewife of 57, with an undisplaced fracture of the neck of the left femur, treated by sandbag immobilization for 68 days. She has a perfect end-result without shortening 6 years after her injury. The roentgenograms show the original fracture and the 6 year end-result with the right hip for comparison.

Fig. 11. Case 47, E D, a clerk of 50 years, with an undisplaced fracture of the neck of the left femur, treated by a plaster-of-Paris spica for 98 days. She has a perfect functional and cosmetic end-result with a little shortening of the femoral neck and a slight tilt of the head. The roentgenograms show the original fracture of the left hip and the end-result 2 years later.

occurred from unrelated causes from 7 months to 3 years after the injury. Of these 4 patients, 1 had a united fracture. The immediate mortality in which the injury played the important part was 7, or 14 per cent. The average age of those dying was 76 years, which is 11 years greater than the group average. The contributing causes of death were senility, myocardial disease, and cerebral arterial disease. There is a marked difference in immediate mortality between ward and private patients. Of the ward patients 6 of 33, or 18 per cent, died under treatment, while 1 private patient of 17, or 5.8 per cent, died under treatment. This difference is in a large part due to the better and more constant care which special nursing insures. This factor is paramount in treating any old person by immobilization in a plaster-of-Paris spica bandage.

EVALUATION OF RESULTS

The end-results of fracture of the neck of the femur are not easy to evaluate. Excellent results with complete or almost complete restitution,

anatomical and functional, are rare. If union is the only criterion, the problem is simplified. A united fracture is a success, and an ununited fracture is a failure. Pain, limp, limited motion, and attendant disability rank higher with the patient than union or non-union. Union of the fracture does not always insure freedom from pain and disability, nor does the patient with non-union invariably suffer these symptoms.

We have studied the roentgenograms of all these 50 patients and have personally examined 30 of the 39 survivors with check-up roentgenograms. The remaining living patients have been seen in follow-up. The end-result in the dead is known in every instance but one. We know the end-result in 48 of these 50 patients, a 96 per cent follow-up. Those unknown are a woman who died 3 years after her injury and a man who has so far declined to be examined.

Union of the fracture. There were 19 patients of the 48 known end-results who had bony union of their fractures. This makes a variable percentage as one chooses to figure it: 38 per cent of

Fig 12 Case 49 N D a housewife of 40 years who walked into the clinic 6 weeks after she had twisted her left thigh. A roentgenogram revealed an undisplaced fracture of the neck of the femur. She was kept on crutches for 4 months without immobilization. She has a perfect anatomical, cosmetic and functional end result. The roentgenograms show the recent undisplaced fracture of the left hip and the same healed 1 year later in anteroposterior and lateral views.

Fig 13 Case 9 E S a housewife of 44 years with a displaced fracture of the neck of the left femur treated by reduction and plaster of Paris spica for 78 days. The end result 6½ years after her injury shows bony union, a little shortening, no lump and a little pain. She walks very well. The roentgenograms show an original displaced fracture with definite evidence of rotation of the femoral head. Six and one half years later they show union with *coxa vara* at least 1 inch shortening but no degenerative changes in the femoral head.

the entire series of 50, 39.5 per cent of the known 48, or 46.5 per cent of the 41 surviving long enough to get union. The average age of these patients with union is 59.5 years, about 5 years younger than the group average.

Of these 19 patients who had united fractures, 10 had no original displacement. We prefer to

Fig 14 Case 29 J C a 57 year old hospital clerk with a fracture of the neck of the left femur with original displacement not reduced but a plaster of Paris spica was applied and maintained for 89 days. Three and one half year follow up shows a firmly healed fracture but with limp, pain, shortening and motion limited somewhat. The roentgenogram shows at 3½ years a marked *coxa vara* of the left hip with shortening and some productive change in the femoral head. This is a rare case of union with malposition of the fragments.

discard the term impacted fractures because we have in no instance in this series noted any bulging of the cortex or compression of the spicules such as is seen in impacted fractures elsewhere. Of the patients whose fractures showed no original displacement, 8 have an almost perfect range of motion, little or no shortening, and no lump and may be rated as excellent from cosmetic, functional and anatomical standpoints. The 2 others

Fig 15 Case 45 M J a 75 year old housewife with a fracture of the neck of the left femur with original displacement reduced twice and maintained in plaster of Paris spica for 105 days. A 3½ year end result which is clinically excellent. She walks well with no pain or limp and very little limitation of motion. The roentgenogram shows some shortening of the femoral neck with degenerative changes in the head of the left femur.

Fig. 16 Case 10, S. E., a housewife of 54 years, with a fracture of the neck of the left femur, treated with reduction and a plaster-of-Paris spica for 70 days. This fracture showed no original displacement but was displaced by manipulation. A 6 year follow-up shows union with 1 inch shortening, a wide range of motion, and only a little pain. The roentgenograms show the original fracture without displacement. There is some displacement 3 months later, and 6 years later the fragmentation of the femoral head is marked with union in coxa vara. If not manipulated this patient should have had a perfect end-result.

with no original displacement were so vigorously manipulated in a mistaken attempt to reduce the fracture that, though they united, there resulted marked changes in the femoral head which led to partial absorption, stiffness, and limp.

The 9 remaining patients with union all showed original displacement of the fragments and only 2 of these had perfect functional, cosmetic, and anatomical results. The 7 others showed either malunion or degenerative changes in the femoral head or both. The secret of an excellent result in a fracture of the neck of the femur in our series is one that shows no original displacement and is then unmolested other than to protect it until union takes place.

Union in relation to function. Over 60 per cent of the patients with union showed a wide range of motion in hip and knee. Medial rotation of the hip was more apt to be limited than any other motion.

The 10 patients with excellent results all walk well and are not in the least incapacitated. Of the 9 patients who had union with varying degrees of fragmentation or degeneration of the femoral

head or with angulation of the fragments, 6 walk well with very little disability, while 3 walk badly with pain and disability. One of these had pain sufficient to consult a surgeon at another hospital where an arthrodesis of the hip joint was performed.

Non-union of the fracture. There are 20 living patients who we know have non-union, and of the 11 dead, only 1 had union. The average age of these patients with non-union was 68.5 years, 9 years above the average age of those with union and 4 years above the average age for the group. Of these 20 patients with ununited fractures, 7 walk

Fig. 14 Case 20 J C a 57-year-old hospital clerk with a fracture of the neck of the left femur with original displacement, not reduced, but a plaster-of-Paris spica was applied and maintained for 90 days. Three and one half years follow-up shows a firmly healed fracture but with limp, pain, shortening and motion limited somewhat. The roentgenogram shows at 3½ years a marked coxa vara of the left hip with shortening and some productive change in the femoral head. This is a case of union with malposition of the fragments.

Fig. 15 Case 43 M J a 75-year-old housewife with a fracture of the neck of the left femur with original displacement, reduced twice and maintained in plaster-of-Paris spica for 105 days. A 3½-year end result which is clinically excellent. She walks well with no pain or limp and very little limitation of motion. The roentgenogram shows some shortening of the femoral neck with degenerative changes in the head of the left femur.

Fig 18 Case 5 M E, a dressmaker, 65 years of age, fractured the neck of the left femur with original displacement. She had two attempted reductions of the fracture, and after each the roentgenograms were unreadable. Her latest roentgenogram shows non-union and the follow-up examination reveals 6 years after her injury that she is able to walk only short distances using a cane. She has a marked limp, pain, and great disability. This patient is shown to emphasize the importance of having roentgenograms which can be interpreted.

fact that a fracture of this type, if correctly diagnosed, is almost certain to unite if it is not meddled with. The one non-union in this group was definitely displaced originally and not recognized as such.

The method of treatment in relation to union of fracture is shown in Table III.

2. *Failure to reduce the fracture* in various ways is the commonest single factor we have encountered. There were 16 patients in this series whose fractures were not reduced. Anteroposterior roentgenograms must be supplemented with lateral views of the hip to insure end-to-end apposition. It is not uncommon to see one of these fractures which is apparently reduced in which the rotation of the head fragment persists, and the fractured surfaces will not lock in apposition. This rotation of the femoral head is herewith described in detail, because we consider it of very great importance. Failure or inability to correct this rotation has, we believe, accounted for many of the non-unions.

3. *Rotation of the femoral head*. Displacements of the femoral head have been emphasized by Magnuson, Darrach, and Stimson, but the following conception of rotation has, we think, not been mentioned by them. It was first drawn to our

attention by one of us (D M B.) in February, 1934.

We had previously found that end-to-end position was frequently secured without close apposition of fragments, that is, while the fragments might be end to end, the serrations or spiculations did not match and that they were either locked and angulated or held apart for a variable distance. At that time a patient was encountered in whom an open reduction seemed advisable. At open reduction the fragments could be easily placed end to end, but they did not match and mesh with each other. A gap existed between them in places of over one quarter of an inch. While cleaning off the capsular attachment on the anterior margin of the acetabulum, the periosteal elevator caught on the anterior border of the head fragment rotating it forward and downward about 100 degrees. The assistant who was holding the leg then remarked that it seemed to assume a more normal position. On inspection of the fracture site, the fragments were seen exactly to match with each other, and a perfect reduction was present (Fig. 1). The significance of this fact did not strike us at once, but a few months later during another open reduction the same findings were confirmed, and following this, cases suitable

Fig 19 Case 46, L S, a housewife 61 years of age, with a fracture of the neck of the right femur, with original displacement of the fragments. The fracture was reduced and a plaster-of-Paris spica was applied. The reduction did not suit the surgeon so a second reduction was done, and the fragments were separated by further internal rotation and wider abduction. The end-result was non-union and the patient is unable to walk without a brace and cane. This patient is shown as an example of over-treatment. The second manipulation forced the fragments out of apposition.

b

Fig 17 Case 48 E S a housewife of 50 years who sustained a fracture of the neck of the right femur without displacement. It was manipulated and a plaster-of-Paris spica was applied and kept on for 94 days. Follow up examination 3½ years after injury shows very slight shortening. Her hip has only 10 to 15 degrees of motion. She has no pain and very little limp. The roentgenograms show a fracture without displacement which in reduction was forced into extreme internal rotation and the end result is a united fracture with very marked degenerative changes in the femoral head. This fracture should have attained a perfect result if there had been no forcible manipulation. Protection was all that it required.

fairly well and enjoy a certain amount of normal activity, while 13 or 65 per cent, are unable to walk without support, and some of these are practically bedridden.

Patients with non union almost invariably showed motion limited in all directions at the hip and to a slightly lesser degree at the knee joint. The disability attendant on non union is very real and distressing in spite of the occasional case which is almost symptomless. Only the symptomless cases are able to report to clinics to be seen.

The 15 known private patients are similarly summarized in Table II.

The reason for the higher percentage of union among the private patients than among the entire group is purely fortuitous. Five of the 9 patients with union had no original displacement and only one of these was displaced by manipulation.

TABLE II — PRIVATE PATIENTS

	Number	Union		Non union	
		Number	Per cent	Number	Per cent
Total known	15	9	60	6	40
Total living	3	3	100	0	0
Total dead	2	2	100	0	0

Factors concerned in union of the fracture. In attempting to analyze certain factors which, in our series, seem to have had a definite bearing on union of the fracture we present the following discussion.

1. Method of treatment. Those patients treated with plaster of Paris spica, after manipulation, in most instances showed a percentage of union equal to that of the entire group.

Traction, although employed in a very limited number of patients, has been the least successful and has, we believe, no place as the principal treatment in fractures of the neck of the femur.

Those patients who had no immobilization or only sandbags showed the highest percentage of union. These were with one exception patients who showed no original displacement of the fracture. This merely serves again to emphasize the

TABLE III — TREATMENT IN RELATION TO UNION

	Total number of cases	Union of fracture	Per cent
Reduction and plaster of Paris	38	24	63
Traction	5	3	60
No immobilization or sandbags	5	4	80

Fig 18 Case 5, M E, a dressmaker, 65 years of age, fractured the neck of the left femur with original displacement. She had two attempted reductions of the fracture, and after each the roentgenograms were unreadable. Her latest roentgenogram shows non-union and the follow-up examination reveals 6 years after her injury that she is able to walk only short distances using a cane. She has a marked lump, pain, and great disability. This patient is shown to emphasize the importance of having roentgenograms which can be interpreted

fact that a fracture of this type, if correctly diagnosed, is almost certain to unite if it is not meddled with. The one non-union in this group was definitely displaced originally and not recognized as such.

The method of treatment in relation to union of fracture is shown in Table III.

2 *Failure to reduce the fracture* in various ways is the commonest single factor we have encountered. There were 16 patients in this series whose fractures were not reduced. Anteroposterior roentgenograms must be supplemented with lateral views of the hip to insure end-to-end apposition. It is not uncommon to see one of these fractures which is apparently reduced in which the rotation of the head fragment persists, and the fractured surfaces will not lock in apposition. This rotation of the femoral head is herewith described in detail, because we consider it of very great importance. Failure or inability to correct this rotation has, we believe, accounted for many of the non-unions.

3 *Rotation of the femoral head* Displacements of the femoral head have been emphasized by Magnuson, Darrach, and Stimson, but the following conception of rotation has, we think, not been mentioned by them. It was first drawn to our

attention by one of us (D M B.) in February, 1934.

We had previously found that end-to-end position was frequently secured without close apposition of fragments, that is, while the fragments might be end to end, the serrations or spiculations did not match and that they were either locked and angulated or held apart for a variable distance. At that time a patient was encountered in whom an open reduction seemed advisable. At open reduction the fragments could be easily placed end to end, but they did not match and mesh with each other. A gap existed between them in places of over one quarter of an inch. While cleaning off the capsular attachment on the anterior margin of the acetabulum, the periosteal elevator caught on the anterior border of the head fragment rotating it forward and downward about 100 degrees. The assistant who was holding the leg then remarked that it seemed to assume a more normal position. On inspection of the fracture site, the fragments were seen exactly to match with each other, and a perfect reduction was present (Fig. 1). The significance of this fact did not strike us at once, but a few months later during another open reduction the same findings were confirmed, and following this, cases suitable

Fig 19 Case 46, L S, a housewife 61 years of age, with a fracture of the neck of the right femur, with original displacement of the fragments. The fracture was reduced and a plaster-of-Paris spica was applied. The reduction did not suit the surgeon so a second reduction was done and the fragments were separated by further internal rotation and wider abduction. The end-result was non-union and the patient is unable to walk without a brace and cane. This patient is shown as an example of over-treatment. The second manipulation forced the fragments out of apposition.

Fig. 20 Case 2 J. T. a merchant 67 years of age with a fracture of the neck of the left femur with original displacement. Two attempts were made to reduce this, both completely unsuccessful as shown by the roentgenograms. He was kept in plaster of Paris spica for nearly 3 months

The end result was non union with $3\frac{1}{2}$ inches of shortening, marked limp and pain on weight bearing, though the patient is able to walk with a cane. This case is shown as an example typical of failure to obtain reduction of the fracture.

for derotation of the head fragment have been watched for.

Rotation of the head in this discussion shall be considered to be about an axis passing through the center of the articular surface of the head and emerging from the center of the fractured surface thereof (Fig. 2). When present it is always with the rotation in an upward direction anteriorly. In the undisplaced incomplete and fragmented fractures, as will be seen, the mechanics causing this rotation is not in force. In the usual occurrence of fracture of the neck of the femur the posterior cortex of the neck gives way, the fracture opens above and in front (Fig. 4) and the outer or trochanteric fragment rotates forward due to the pull of the gluteus maximus and short rotator muscles (Fig. 5). At the same time that the distal fragment travels forward it also moves upward due to the pull of the long muscles of the thigh and to weight bearing if the patient is in an erect position (Fig. 6). As it travels upward the thigh becomes adducted due to the pull of the adductor muscles, the relaxation of the gluteus medius muscle and the weight of the pelvis. Many of these fractures occur from indirect vio-

lence while the patient is erect, the head of the femur being actually twisted off and the patient then falling. Taking this mechanical situation into consideration, it can be seen that the lower portion of the head and neck remains in contact longest and that, as the spicules of these fragments mesh, the lower part of the head will be carried forward with the neck and then upward in an arc of rotation, the head turning about the axis as given above (Fig. 3). Rotation has been noted in numerous cases at open operation and has been found to be present up to 160 degrees. Once it has occurred, no form of closed manipulation can derotate the head so that its spicules will exactly match those of the neck, for as the thigh is flexed the head will turn farther upward maintaining its relation of abnormal rotation with the neck.

The importance of rotation of the head lies in the fact that even though end to end position of fractured surfaces be secured, the spiculation of the fragments will prevent close apposition of the fracture surfaces and several unsatisfactory conditions result. These are cited in the following paragraphs.

Fig. 21 Case 47 L. A. an unemployed mendicant who usually used a crutch owing to an amputation of the left leg. At the time of his accident he was wearing an artificial leg on his left stump and he fell and broke the left hip. The reduction shows end-to-end apposition in the anteroposterior and lateral views, but the spicules did not match owing to the failure to remove the rotation of the femoral

head, and 1 year later there was no evidence of bony union but the head followed the neck in a flexion and abduction so there must be fibrous union. If this can be said to exist. This case is presented as an example of end-to-end apposition which failed to unite owing to rotation of the femoral head and perhaps to the presence of interposed soft tissue.

Fig 22 Case 11, B B, a woman of 57 years of age, who fractured the neck of the left femur. The original roentgenogram was interpreted as showing no displacement. She was merely immobilized with sandbags for 105 days. A recheck of these roentgenograms shows absolutely definite displacement originally and progression to non-union. This patient is pretty completely incapacitated owing to the ununited fracture, an old Pott's disease, and arthritis. This is an illustration of inability or failure to interpret correctly the original roentgenograms.

1. If the rotation is above 90 degrees, the shape of the head in its misplaced position at the upper margin may prevent satisfactory abduction of the thigh even though excellent union is secured (Fig 7b).

2. An abnormal amount of blood clot will form between the fragment ends, and this in itself is an excellent cause of non-union, as it is in any fracture (Fig 7c).

3. True anatomical position of the head on the neck is frequently impossible to secure, some degree of angulation being present (Fig 8).

4. The holding apart of the fractured surfaces by the mismatched spiculations will cause undue tautness of the capsular and ligamentous structures surrounding the fracture site, and this tension may well be in itself a cause of arterial obstruction, decreasing the vascular supply to the neck fragment.

Rotation of the head fragment can always be assumed to exist except in incomplete, comminuted, and undisplaced fractures. It can be determined by x-rays, if carefully looked for, by the following points: (1) a mismatching of position of the gross spiculations of fragments, either in flat or stereoscopic views (Figs 7a and 9), (2) angulation of the fragments following closed or open reduction (Fig 8), (3) by abnormal contour of the upper surface of the head fragment.

Rotation, as has been described, when it is present, will always be in an upward direction of the head fragment anteriorly, no case having been seen with rotation in the opposite direction. We have studied the roentgenograms of every patient in this series with rotation of the femoral head in mind and have arrived at the conclusion that this

type of displacement should be determined in every fracture of the neck of the femur before instituting treatment.

If rotation is found, it would seem advisable to open the joint capsule, derotate the head, and match the spiculations in cases in which any form of reduction is considered. Percussion impaction of mismatched spicules is illogical, as it destroys anchoring irregularities of surfaces and creates additional trauma.

Locking spicules make derotation difficult even with the hip widely exposed, and with closed reduction it is often impossible. Derotation of the femoral head has not always been successful, and in the cases in which failure to secure perfect apposition is encountered, fragmentation has been found to be originally present or other previous attempts at reduction have destroyed the spiculation usually present and have caused fragmentation to exist.

4. *Fractures that suffer from overtreatment.* Too wide abduction, too much internal rotation will pull the fractured surfaces apart. There have been several instances with a good original reduction which has not pleased the surgeon, and a second attempt has resulted in displacement.

5. *Incorrect interpretation of roentgenograms.* Failure to immobilize a fracture which was considered undisplaced resulted in further displacement and non-union in two instances. This is due to an incorrect interpretation of roentgenograms.

6. There have been several instances of adequate reduction of the fracture, firmly held for a sufficient length of time, which have gone on to non-union. When the femoral head shows increasing density signifying death of bone, the

problem is that of blood supply. Since we have been reducing these fractures by open operation we have found not infrequently, interposed capsule or articular cartilage between the fractured surfaces, and we believe that this is an important cause of non union.

7 *Unreadable roentgenograms* In two instances the chance of union was gambled on post reduction roentgenograms which were impossible to read. Both patients had non union and one died 7 months after her injury. This fault has been remedied and has not been noted during past 5 years.

SUMMARY

A group of 50 elderly patients 78 per cent women, with fractures of the neck of the femur is presented. They have been treated conservatively and the length of their hospital stay and the expense incident to it is discussed. The immediate mortality was 14 per cent. There were 19 of 48 who had bony union of their fracture. According to the way it is figured, this varies between 38 and 46.5 per cent of the series. Two thirds of the patients with non union had serious disability. Factors which played a part in union are discussed. Emphasis is placed on rotation of femoral head.

REASONS FOR STUDY

This report is the result of dissatisfaction on the part of the surgical and orthopedic services of

St. Luke's Hospital with methods of treatment which offer less than 50 per cent chance of union. We realize that the problem is not altogether one of methods, however. The average age of these patients and the deficient blood supply at the fracture site will probably always insure a fairly high percentage of failures. The authors have come to the conclusion that the chances of getting union with a useful hip may be greatly enhanced by open reduction, derotation of the femoral head where rotation exists and internal fixation if surgery can be employed with no greater immediate mortality than this series shows, that is 14 per cent. If these results can be improved upon or only equaled by a method which secures complete reduction and fixation and shortens the hospital stay from 122 days to 30 or 40 days at the outside, with corresponding reduction in expense to patient and hospital such a method is bound to be adopted.

The end results obtained in this series of patients are such that open reduction and internal fixation should insure greater chance of bony union. It can scarcely result in less. However, until we can report a similar series, treated by open reduction and internal fixation and followed for a similar period of time with known end results in at least 95 per cent of the patients, expressions of opinion about improved results are merely idle surmise.

ASEPTIC URETERO-INTESTINAL ANASTOMOSIS

JAMES I FARRELL, M D , F A.C.S , and YALE LYMAN, B S , Evanston, Illinois

IT HAS been definitely established that uretero-intestinal anastomosis is clinically applicable in the human. Many advances have been made in recent years, and successful results have been obtained. Most of the present methods, however, are technically difficult, and require the use of catheters, cautery, and special preparation of the bowel.

Coffey (1) in 1930 introduced a rather simple technique of uretero-intestinal anastomosis. By this method a suture was placed through the ureter and bowel, tied securely, and allowed to slough through into the bowel. The resultant opening made by the slough of ureteral wall and bowel wall is the ureteral stoma into the bowel.

In 1932, Coffey (2) modified this procedure by placing in the rectum a metal ring to which the transfixion suture was anchored. This assures a penetration of the intestinal lumen and makes for more certain and rapid cutting through of the suture by means of traction on a string tied to the ring leading down to the anus.

Higgins in 1933 presented a similar method in which simultaneous transplantation of both ureters into the bowel was done at one sitting. Briefly, the principle of the sloughing suture was used. The ureters remained attached to the bladder after the first operation. At a later date the ureters were to be divided and ligated between the ureteral implantation and the bladder.

Hinman in 1933 proposed an extraperitoneal ureterostomy for drainage of urine until such time as the suture cut through to establish a new orifice.

Ferguson and Path used a cautery to make the opening between the ureter and bowel.

Wodhaus and Carobba in 1935 obtained an apparently successful opening in one dog by coagulation of ureteral and intestinal surfaces in apposition. Following the coagulation the ureter was placed in apposition with the coagulated surface of the bowel, the ureter being transplanted in the bowel musculature.

The author, having performed an operation known as the Eck fistula operation (3), decided to apply the principle of this operation to the implantation of the ureter into the bowel. An Eck fistula is an anastomosis of the portal vein and the inferior vena cava, in which no opening is made

in these structures until they are firmly united. The opening is later made by means of a cutting loop of strong silk thread. The patency of the new opening is maintained by forcing all the blood through the new opening. The maintenance of the opening is very necessary, as these artificial openings tend to close spontaneously.

PROCEDURE

A portion of the sigmoid is grasped between two Allis clamps and an incision is made longitudinally in the serosa. The longitudinal muscle of the bowel is separated until the circular muscle is exposed. The circular muscle is not cut, but is separated from the submucosa (Fig. 1, A) at the lowermost portion of the incision. The submucosa is then grasped with a small mosquito forceps and brought out through the opening made in the circular muscle (Fig. 1, A). The ureter is approximated to the submucosa by a continuous suture of No. 00 chromic catgut. A small vein clamp is placed on the ureter above the site of anastomosis (Fig. 1, B). A curved needle with black silk thread pierces the ureteral lumen and emerges about 1 centimeter distally. This same curved needle enters the lumen of the bowel and emerges from the bowel opposite its insertion into the ureter (Fig. 1, C). A second suture of catgut is used to approximate the ureter to the bowel (Fig. 1, D). The silk thread is now used to make the opening between the ureter and bowel. This is done by a sawing motion with the thread. When the thread is removed, a second suture line is placed along the point of the ureterosigmoidal junction (Fig. 1, E).

A clamp is now placed on the ureter between the site of anastomosis and the bladder, if any point of leakage occurs it can be seen and closed. The ureter is ligated and cut. The cut end of the ureter is then buried in the bowel wall between the submucosa and the circular muscle (Fig. 1, F). No attempt is made to close the circular muscle since it forms a sphincter at entrance of ureter into the bowel. The longitudinal muscle is approximated with sutures over the ureter (Fig. 1, E).

The resulting anastomosis is completed in one operation. Urine appears in the bowel almost immediately. The ureter is securely anchored to the submucosa thereby preventing it from becoming

From the Departments of Surgery and Urology of Northwestern University

Fig 1 Technique of operative procedure

detached. Side to-side anastomosis allows for a large longitudinal opening in the ureter, which prevents a contraction of its orifice. The circular muscle of the bowel surrounds the intramural portion of the ureter thereby forming a closure mechanism which prevents regurgitation of intestinal contents into the ureter. Because of the ease of doing a side to-side anastomosis a water tight anastomosis is made. This is most important because a leak from the bowel usually causes a fatal peritonitis. It is much safer to do this type of anastomosis than to insert the end of the ureter through an opening in the bowel. Leakage is more likely to occur when the ureter is inserted into the bowel.

EXPERIMENTAL DATA

Seven dogs had an anastomosis of both ureters and the sigmoid. These dogs were allowed to survive for 6 months then 4 of the animals were sacrificed to study the end results. One dog died at end of 4 months and autopsy was performed. Two dogs are alive and well after an 8 month period.

Gross findings. Figure 2a autopsy specimens of the kidneys, ureter and bowel of the sacrificed dogs. Figure 2a shows the specimen of the dog which died with an ascending urinary infection. We attribute the cause of infection to implanting the ureter too close to the kidney. In our experiments it is best to transplant the lower third of the ureter rather than the higher third.

Fig 2 Autopsy specimens of kidneys, ureters and bowel of dogs

Figure 2b shows an autopsy specimen of ureteral transplantation by the Higgins method. The ureters still open into the bladder. This dog passed urine per rectum for about 6 weeks; the stool then became firmer in consistency, and the dog began to void through the urethra. When the

dog was sacrificed later, the stoma between the ureter and the bowel was completely closed. Figure 3b shows the bladder distended with sodium iodide; the ureters and kidney pelvises are also filled with sodium iodide. But no iodide is found in the bowel. This serves to illustrate the danger

of closure when the ureterosigmoidal opening is made by the sloughing suture. Unless the ureter is divided between the ureter and bowel the urine tends to follow its normal course. And likewise an incision into the unoccluded ureter tends to close. In ureterolithotomy the ureter closes without the use of suture material.

Figures 2c and d show the autopsy specimens of 2 dogs 6 months after implantation of the

ureters by our method. Both kidneys appear healthy and the roentgenograms Figures 3c and d show a normal ureter and renal pelvis.

Figure 4a shows one of the kidneys 6 months after implantation. There is no evidence of infection, or dilatation from the long transplantation. Figure 4b was taken to show the ureteral opening in the bowel. The rectal mucosa is clean and pink with no evidence of irritation or infection after 6

Fig 4 a, kidney 6 months after implantation, b, specimen shows ureteral opening, c, lower power photomicrograph of ureter after implantation, d microscopic section of kidney 6 months after uretero-intestinal anastomosis

months constant contact with urine. Figure 4c is a low power microscopic view of the ureter after implantation in the bowel. Figure 4d is a microscopic section of a kidney 6 months after uretero-intestinal anastomosis.

Microscopic examination. Examination of the ureter as it passes through the bowel was made. There was no evidence of infection at the site of anastomosis; the ureter was in no way narrowed, and the musculature of the bowel closely surrounded the ureter (Fig. 4).

ADVANTAGES OF TECHNIQUE

The transplantation of the ureters into the bowel is a physiological problem in which one must adhere to fundamental principles. First if an anastomosis is to be done between the ureter and sigmoid, it must be an airtight and water tight anastomosis. The escape of urine, fecal material or gas into the peritoneum after the completion of the operation is certain to cause peritonitis. The method of transplantation, described as the side-to-side type, makes it possible to test the anastomosis after its completion.

Second, the maintenance of the original size of the ureteral opening into the bowel is important. Stricture of the ureter following transplantation is often due to the large number of sutures taken in the circumference of the ureter. This is obviated in our operation by the suture of the side of the ureter to the side of the bowel instead of implanting the cut end of the ureter. In the Higgins technique the ureterosigmoidal opening closes spontaneously, if the ureter remains connected with the bladder over a period of 6 to 8 weeks.

In attempting to construct a valve like action at the site of anastomosis we have cut no muscle in the bowel wall. The ureter is transplanted so that it traverses the longitudinal and circular muscle layers of the bowel and ends just beneath the mucosa of the bowel lumen. The ureter does not project into the lumen of the bowel. We feel that this is a factor in preventing postoperative blocking of the ureter during the healing process.

Anastomosis of the ureter and sigmoid without opening either structure in the peritoneal cavity certainly tends to prevent peritonitis which is a danger in other procedures. The use of the sawing ligature in blood vessel surgery has long been known. We feel that its use in ureterosigmoidal anastomosis is worthwhile.

SUMMARY AND CONCLUSION

An improved technique is presented for uretero-intestinal anastomosis. This method has several advantages over previous procedures. No cathe-

ters, cautery or bowel preparation is necessary in the technique. The ureter and the bowel mucosa are firmly united before the opening is made. Neither the ureter nor bowel is opened directly into the peritoneal cavity. The bowel musculature is not cut but is separated from the submucosa by blunt dissection. We believe that this preserves and maintains the musculature. Implantation of the ureter between bands of circular muscle helps to form a competent sphincter like mechanism.

A long longitudinal opening, about 1 to 2 centimeters is made between the ureter and the bowel. This size opening is more than adequate and allows for a reasonable amount of contraction.

The ureter between the anastomosis and the bladder is divided at the time the anastomosis is made. This forces the urine to flow through the new anastomosis immediately. We believe that this is an important factor in maintaining the caliber of the anastomosis. A study of ureteral physiology and surgery impresses one that an opening made in the unoccluded ureter tends to close rapidly. In ureteral lithotomy there may be no drainage of urine from the ureteral opening after the second or third day. We have demonstrated that the anastomosis made by the Higgins method will close completely in 6 to 8 weeks. In all likelihood the contraction and closure of this opening is a rather rapid process.

A group of old principles of blood vessel anastomosis are applied to uretero-intestinal anastomosis. Seven dogs had survived 6 months following this procedure and autopsy studies were made.

Roentgenograms of the autopsied specimens were made to show the results.

The closure of the anastomosis made by the sloughing suture is emphasized.

Microscopic studies show the implanted ureter in the bowel wall.

SPURS OF THE OS CALCIS

ARTHUR STEINDLER, M D , F A C S , and ALBERT R. SMITH, M.D., Iowa City, Iowa

THE association of painful heels with calcaneal spurs is comparatively recent. Plettner, in 1900, first discovered the spurs—quite by accident¹ Increasingly widespread use of the X-ray has shown that remarkably few such spurs give rise to symptoms² In those individuals who do have pain in the heel associated with a spur of the tuber of the os calcis, avoidance of weight bearing affords relief from the painful symptoms. The following study was undertaken with the view of ascertaining the permanency of relief obtained by such simple measures in comparison with the results of operative therapy.

In this investigation only those cases of painful heel in which the existence of a calcaneal spur is demonstrable roentgenographically have been used In all cases, both those treated conservatively and those treated operatively, the spur was on the plantar surface of the bone.

THE CONSERVATIVE TREATMENT

The number of patients treated conservatively was 49,³ of which 27 had unilateral and 22 bilateral defects Thus there is a total of 71 painful heels associated with calcaneal spur in the series. The age of these patients was 18 to 75 years at the

time treatment was instituted, the average was 41 8 years Trauma other than walking was of possible etiological significance in 9 heels in the series Gonorrheal urethritis was known to antedate the onset of symptoms in only 2 instances

In all cases the conservative treatment consisted of an insole, either felt or solid leather, with a hole cut out over the point of the spur. Occasionally a soft rubber sponge was applied over this area. In addition to these measures in 28 feet a posterior wedge in the heel of the shoe was used in order further to relieve the tuber of the os calcis from weight bearing stress. The results are shown in Table I.

In compiling the data given in Table I it was noticed also that in the bilateral cases with treatment by insoles alone patients were required to wear their shoe corrections for more than 1 year in all but 2 cases In the unilateral cases, on the other hand, patients were able to discard all appliances in an average of 8 months The longest time that corrections were worn by a patient with a unilateral defect was 19 months

Thus we see that the painful symptoms were controlled by conservative measures in 46 4 per cent of the feet involved

THE OPERATIVE TREATMENT

In this group there are 10 patients with a calcaneal spur and symptoms unilaterally and 6 patients with both feet affected, making a total

¹Quoted from Sack.
²Sack (2) reports that 43 per cent of the spurs of the os calcis give rise to no symptoms

³In addition to these there are 47 patients with painful heel associated with spur of the os calcis which are not included either because of insufficient observation period or because the results of therapy are unknown

TABLE I—RESULTS OF THE CONSERVATIVE TREATMENT OF SPURS OF THE OS CALCIS—71 FEET

Group	Total No. of feet in group	Time shoe corrections were worn	Results	Observation period average in yrs	No. of feet ultimately requiring operation
I Insole only	36	2 wks to 4 yrs, average 10 4 mos	16 or 44 4 per cent complete* and permanent relief 20 or 55 5 per cent slight or no relief †	3 8 0 83	None 13 after an average of 9 mos conservative therapy
II Insole and Steindler heel	35	1 mo to 2 yrs average 7 3 mos	17 or 48 5 per cent complete and permanent relief 18 or 51 4 per cent slight or no relief ‡	2 96	None 9 after an average of 1 mos conservative therapy
Total	71	average 8 8 mos	33 or 46 4 per cent complete and permanent relief 38 or 53 5 per cent slight or no relief	2 1 for entire series	22 or 30 9 per cent

*Two of these feet were operated upon previously elsewhere without relief and with recurrence of both symptoms and calcaneal spur Corrections were worn for 4 years Now observed for 6½ years Have had complete relief during these 6½ years

†Two of these were completely and permanently relieved after 2 weeks in plaster casts

‡Two of these subsided spontaneously and have been painless for 5 years The corrections were worn for 6 months without apparent benefit. Symptoms subsided 1 year later

months constant contact with urine. Figure 4c is a low power microscopic view of the ureter after implantation in the bowel. Figure 4d is a microscopic section of a kidney 6 months after uretero-intestinal anastomosis.

Microscopic examination. Examination of the ureter as it passes through the bowel was made. There was no evidence of infection at the site of anastomosis; the ureter was in no way narrowed and the musculature of the bowel closely surrounded the ureter (Fig. 4).

ADVANTAGES OF TECHNIQUE

The transplantation of the ureters into the bowel is a physiological problem, in which one must adhere to fundamental principles. First, if an anastomosis is to be done between the ureter and sigmoid it must be an airtight and water tight anastomosis. The escape of urine fecal material or gas into the peritoneum, after the completion of the operation, is certain to cause peritonitis. The method of transplantation, described as the side-to-side type, makes it possible to test the anastomosis after its completion.

Second, the maintenance of the original size of the ureteral opening into the bowel is important. Stricture of the ureter following transplantation is often due to the large number of sutures taken in the circumference of the ureter. This is obviated in our operation by the suture of the side of the ureter to the side of the bowel instead of implanting the cut end of the ureter. In the Higgins technique the ureterosigmoidal opening, closes spontaneously if the ureter remains connected with the bladder over a period of 6 to 8 weeks.

In attempting to construct a valve like action at the site of anastomosis we have cut no muscle in the bowel wall. The ureter is transplanted so that it traverses the longitudinal and circular muscle layers of the bowel and ends just beneath the mucosa of the bowel lumen. The ureter does not project into the lumen of the bowel. We feel that this is a factor in preventing postoperative blocking of the ureter during the healing process.

Anastomosis of the ureter and sigmoid without opening either structure in the peritoneal cavity certainly tends to prevent peritonitis which is a danger in other procedures. The use of the sawing ligature in blood vessel surgery has long been known. We feel that its use in ureterosigmoidal anastomosis is worthwhile.

SUMMARY AND CONCLUSION

An improved technique is presented for uretero-intestinal anastomosis. This method has several advantages over previous procedures. No cathe-

ters, cautery, or bowel preparation is necessary in the technique. The ureter and the bowel mucosa are firmly united before the opening is made. Neither the ureter nor bowel is opened directly into the peritoneal cavity. The bowel musculature is not cut but is separated from the submucosa by blunt dissection. We believe that this preserves and maintains the musculature. Implantation of the ureter between bands of circular muscle helps to form a competent sphincter like mechanism.

A long longitudinal opening, about 1 to 2 centimeters, is made between the ureter and the bowel. This size opening is more than adequate and allows for a reasonable amount of contraction.

The ureter between the anastomosis and the bladder is divided at the time the anastomosis is made. This forces the urine to flow through the new anastomosis immediately. We believe that this is an important factor in maintaining the caliber of the anastomosis. A study of ureteral physiology and surgery impresses one that an opening made in the unoccluded ureter tends to close rapidly. In ureteral lithotomy there may be no drainage of urine from the ureteral opening after the second or third day. We have demonstrated that the anastomosis made by the Higgins method will close completely in 6 to 8 weeks. In all likelihood the contraction and closure of this opening is a rather rapid process.

A group of old principles of blood vessel anastomosis are applied to uretero-intestinal anastomosis. Seven dogs had survived 6 months following this procedure and autopsy studies were made.

Roentgenograms of the autopsy specimens were made to show the results.

The closure of the anastomosis made by the sloughing suture is emphasized.

Microscopic studies show the implanted ureter in the bowel wall.

by rotating the posterior portion of the os calcis in such a manner that the spur comes to lie in the horizontal plane and not in a vertical or oblique plane. The operation is performed as follows.

A curved incision, starting on the lateral aspect of the foot one inch above the insertion of the tendo achillis, is made. The incision follows the tendo achillis and then curves anteriorly and inferiorly, ending at the lateral margin of the sole, anterior to the tuber of the os calcis. The calcaneus is then exposed, the periosteum stripped away, thus exposing the entire posterior and inferior portion of the os calcis. When this is done, a curved osteotomy through the os calcis is performed. The line of the osteotomy passes from a point anterior to the insertion of the tendo achillis to a point just anterior to the insertion of the plantar fascia at the tuber. The plane of the osteotomy is at right angles to the lateral surface of the os calcis (Fig. 1).

A wedge is then removed from the inferior surface of the anterior portion of the os calcis (Fig. 2).

The tendo achillis is then lengthened, following which the posterior portion of the os calcis, carrying the spur with it, is rotated anteriorly and superiorly into its new position. The two portions of the os calcis are fixed in their new relation with an ivory bone peg or steel pin. This brings the spur into the horizontal plane (Fig. 3).

CONCLUSIONS

1 Approximately half of the cases of painful heel with spur of the os calcis may be controlled symptomatically by conservative measures.

2 If conservative measures fail, then operative removal of the spur is indicated.

3 If simple excision of the spur is followed by recurrence of both the spur and the symptoms, the rotation osteotomy is indicated. This, however, is a radical procedure and not without danger.

of 22 feet. Eighteen of these feet are among those in which conservative measures failed to control the symptoms. One of the two types of conservative treatment was used for 1 week to 2 years before operation in these 18. In addition a brace was worn by 2 of these patients without ameliorating their symptoms before operation. Four feet were operated upon without the previous use of conservative measures. In all but one patient (a unilateral case) one of the two types of conservative therapy was instituted for a varying length of time after operation. Two types of operation were performed. A simple excision of the spur through a medial incision such as is used for a Steindler stripping was carried out in

16 instances. On 8 occasions a Steindler rotation osteotomy of the os calcis was used.* (See diagram and description of technique.) In none of the cases was the goblet incision advocated by Miltner used. The results are shown in Table II.

Comparison of the tables shows that approximately the same proportion of the patients had their symptoms controlled by conservative measures as by simple excision alone. In comparison of the totals of the operative and conservative groups we find an insignificant difference in the percentage relieved from distress. As stated all those operated upon were (with 4 exceptions) given a trial on the conservative regimen. *Failure of the conservative treatment formed the basis for the operative indication.* The rotation osteotomy is too radical a procedure to be used in any but the most recalcitrant type of case.

THE STEINDLER ROTATION OSTEOTOMY OF THE OS CALCIS

This operation is designed to take all weight bearing off the point of the spur. It achieves this

*Two of these cases, which recurrence of spur and pain followed simple excision.

Two of the group that recalcitrant to treatment with conservative measures, failed to respond to the conservative treatment. One of these patients had both feet affected and in the same patient in which a simple excision failed to effect any relief bilaterally.

TABLE II—RESULTS OF THE OPERATIVE TREATMENT OF SPURS OF THE OS CALCIS—22 FEET

Type of operation	No. of feet operated upon	Result	Postoperative observation period	Recurrence of pain (No. of feet)
Simple excision	16	70.63 per cent complete and permanent relief 9 or 56.2 per cent slight or no relief	1 mo to 3 yrs aver 17 mos	8 or 50 per cent
Rotation osteotomy of os calcis	8	6 or 75 per cent complete and permanent relief 2 or 25 per cent slight or no relief	6 mos to 3 yrs 8 mos aver 24 mos	3 or 37.5 per cent
Total	24	50 or 62.5 per cent complete and permanent relief 9 or 40 per cent slight or no relief	1 mo to 3 yrs 8 mos aver 22 mos 25 mos	11 or 45.8 per cent

*Two of these represent failure of simple excision. They are included but once in the total where they appear among those having complete and permanent relief. The figures appearing in the total of the table represent the final proportion of feet relieved of pain and in which the symptoms were not controlled.

One of these had a postoperative osteomyelitis of the os calcis which necessitated amputation of the foot 3 years after the osteotomy. The foot is painful and function is excellent. The individual had both feet affected and in the same patient in which a simple excision failed to effect any relief bilaterally.

Fig 1 Specimen No 22, 1937 Chronic erosive antrum gastritis. Pronounced round cell infiltration into the hypertrophic stomach wall. Hyperplasia of the lymphoid follicles. Superficial erosions, \times ; marked edema between muscularis mucosae and muscularis propria. $\times 18$

Fig 2 Specimen No 22, 1937 Erosive hemorrhagic antrum gastritis. Deep erosion (left), mucosa surrounding the erosion is infiltrated with round cells, inflammatory exudate and red cells, profuse hemorrhage between mucosa and muscularis mucosae (right). $\times 18$

Puhl interested in pathological anatomy, and knowing how to prepare tissues obtained by gastric resection, were the first to explore the histological genesis of gastritis. Gastroscopic studies advanced by Schindler (21, 22); Henning, Moutier, Swalm, Jackson, Morrison, and others, and an improved x-ray technique, helped to clarify this disease.

Gastritis (simplex) appears in two forms—the acute and the chronic. Acute gastritis is either a so-called irritation gastritis with round cell infiltration of the stomach wall and profuse discharge of mucus, or, it is hemorrhagic, as an attendant of acute infectious diseases. Chronic gastritis is either hypertrophic, usually limited to the antrum and accompanied by erosions and ulcers or is atrophic, usually involving the entire stomach. It has been shown, however, (Faber, 9, Konjetzny, 13) that the hypertrophic antrum gastritis may finally change into an atrophic antrum gastritis.

It is the chronic hypertrophic gastritis, associated with erosions and acute ulcers that is the usual companion of peptic ulcers in Central Europe, and which, as it is said, is uncommon in the United States. It is well understood in this country why the conservative methods of operation have been abandoned in Central Europe as not being satisfactory: the stoma made at pyloroplasty or gastro-enterostomy in gastritis cases

must be placed directly in the involved region of the stomach. Since hypertrophic erosive gastritis usually is limited to the antrum, subtotal gastric resection, as surgical treatment for peptic ulcer, offers more chances of permanent cure. In this connection, it is of interest to know that in this country, Balfour (3, 7) of the Mayo clinic, where Walters and his collaborators found a low incidence of gastritis associated with peptic ulcers, reports good results following conservative methods of operation, however, a number of surgeons in New York, where Aschner and Grossman of A. A. Berg's service, found an ulcerative gastroduodenitis in 64 per cent of 124 resected stomach specimens, report unfavorable results with the same kind of treatment (Lewisohn, and Hinton and Church).

From these reports, it is reasonable to assume that so far as peptic ulcers and gastroduodenitis are concerned, so-called geographical regions exist also in this country, but only in a few parts have examinations been made upon this important subject. For the purpose of encouraging further examinations, the result of a thorough macroscopic and microscopic examination of two resected stomach specimens might be recorded. In order to overcome autodigestion of the tissue, I put the resected specimens immediately after the resection, and while they were still body warm, into a solution of 4 per cent formalin. After 2 or 3 days, the mucous membrane was macroscopically examined with the naked eye and with the loupe. Certain places were excised

THE EXTENT AND CHARACTER OF PEPTIC ULCERS AND GASTRODUODENITIS IN DIFFERENT COUNTRIES

HANS MAY, M D, Philadelphia Pennsylvania

WITHIN the last decade, attention has been called by numerous writers to the difference in the behavior of peptic ulcers and gastroduodenitis in various countries. Walters, after returning from a visit to European clinics made a special study of this subject. His investigations brought him to the conclusion that there was a low incidence of gastritis associated with peptic ulcers in patients operated upon at the Mayo Clinic, compared with the high degree of gastritis associated with peptic ulcer cases in Central Europe. Following his publications others in this country made similar statements generally however without research proof.

I quote Walters (27) In 1930, after Snell and I had visited various surgical clinics abroad particularly those in Central Europe, we published a series of papers (25 26 29 30), describing and illustrating the difference between the lesions of duodenal ulcer, for which we saw operations performed in Germany, and those for which it has been my privilege to operate at the Mayo Clinic. This difference lay largely in the high degree of gastritis associated with duodenal ulcer of German patients operated upon at German surgical clinics as compared with the low incidence of associated gastritis in a series of patients operated upon at the Mayo clinic. Accuracy of these observations was confirmed by Sebenius, (*3, 28), of Schmiedens clinic (Frankfurt am Main) who spent several months in study at the Mayo clinic.

There is no doubt as to the truth of the findings of Walters. They are, however only valid for those regions of the country in which the observations were made. That there are certain diseases *gosters* etc (H May 16) which show a so called geomedical variation is an acknowledged fact. Since it has been proved in Europe that the lesions of peptic ulcers and gastritis also differ in various localities, and sometimes within the short distance of 100 to 200 miles it seemed reasonable to assume that such conditions could also exist in this country, with its vast extent of territory its racial and climatic differences.

From the Surgical Service B of the Lankenau Hospital Philadelphia

Presented before the Philadelphia Academy of Surgery October 5 1917

I had the opportunity to practice surgery both in regions where peptic ulcers are very rare and in places, which in medical circles are called 'ulcer regions' and I can confirm the statement that there is a difference in the behavior of peptic ulcers in various countries. While in Freiburg in Baden the number of patients treated at the University Hospital for peptic ulcers was comparatively low yet the number of such patients admitted to the University Hospital at Munich (200 miles away from Freiburg) was strikingly high nearly ten times higher than in Freiburg. Particularly high was the incidence of ulcer perforation (Buerkle De la Camp). Since I have had the privilege of doing surgical work in this country I have observed that in Philadelphia with the exception of perforations (between 7 and 11 per cent according to Eliason and Ebeling) the incidence of peptic ulcers is about as high as in Munich.

The difference in the prevalence of peptic ulcers in different localities has been variously attributed to racial characteristics different environment, and dietary habits of the population. No explanation however can be given at the present time, why duodenal ulcers compared with gastric ulcers, in some parts of the world are more common than in other parts, and why in this country and Central Europe males are more subject to the disease than females, while according to Alvarez in some other parts of the world men and women are equally affected.

A short time ago, the fact that peptic ulcers responded differently to surgical treatment in various countries was a mystery. Now more light has been thrown upon this subject since the relation between peptic ulcers and gastroduodenitis has been investigated.

The disease entity gastritis has been known for more than one hundred years but only recently has the medical profession begun to recognize its importance. Investigations were delayed by the seeming difficulty of preventing postmortem tissue autolysis of the digestive organs which sets in so rapidly. Faber of Copenhagen overcame this obstacle by injecting a 4 per cent formaldehyde solution into the stomach immediately after death. But surgeons such as Konjetzny and

were found within, either the anterior or posterior walls of the stomach. All of them, however, were situated nearer to the pylorus than to the proximal part of the stomach. In addition to these defects, several dark brown spots were discernible, either with the naked eye or the loupe. It was assumed that they were blood extravasations.

By microscopic examination, the mucous membrane of both specimens exhibited definite signs of inflammation, such as cell infiltrations into the stomach wall, chiefly into the mucosa, consisting of polymorphonuclear leucocytes and plasma cells (Fig 1). The process was accompanied by hyperplasia of the lymphoid follicles (follicular gastritis—Johnston). A marked edema separated the muscularis mucosæ from the muscularis propria. In numerous places the epithelium of the apex of the papillæ and in the depths of the crypts was breaking down, causing loss of superficial tissue, erosions (erosive gastritis), an exudate escaped from these erosions "*rauchscheidenartig*"—like a smoke screen—(Fig 1 and Fig 6). Besides these superficial erosions, other defects could be found which penetrated to the deepest layer of the mucous membrane, so that the muscularis mucosæ formed the floor of the defect (Fig 2 and following). At several places the muscularis mucosæ was found perforated. Such a picture resembles that of acute ulcer—ulcerative gastritis (Fig 5). The mucous membrane surrounding these ulcers was heavily infiltrated with round cells and inflammatory exudate. Some of these ulcers, however, had a wall rich in connective tissue which spoke for chronicity (Fig 6).

Besides these ulcers, numerous hemorrhages into the subepithelial tissue or between mucosa and muscularis mucosæ were seen—hemorrhagic gastritis (Fig 2 and following). At some places the hemorrhages were very extensive, and resembled the blood extravasations which are commonly found in acute infectious diseases (Figs 2 and 4). These hemorrhages also formed the base of many of the ulcers, and it is probable that they had been the origin of these ulcers (Fig 2 and following).

While erosions, ulcers, and hemorrhages were confined to the pyloric region, yet the round cell infiltration was also found in the proximal parts of the resected stomach specimens, definitely less, however, than in the distal part. It is unfortunate that nothing can be said as to how far the inflammation reached down below the pylorus, since the duodenum had not been removed but had been left in place.

CONCLUSION

The two specimens represented the resected antrum and a part of the fundus of the stomach in cases of inoperable duodenal ulcers. They exhibited severe pictures of chronic follicular gastritis with numerous erosions, ulcers, and hemorrhages. The 3 last named were confined to the antrum. European writers believe that the ulcers are the consequence of erosions and that the latter are due to the round cell invasion. However in these 2 cases, as described here, it must be assumed that most of the ulcers originated independently of the erosions and are due to hemorrhages. As a matter of fact, hemorrhages are uncommon findings in the European chronic hypertrophic gastritis cases.

These findings, obtained from two consecutive resections for treatment of duodenal ulcers, urge further examination. That erosive chronic gastritis is a frequent companion of peptic ulcers treated in New York City has been shown by the thorough examinations of Aschner and Grossman. The same report comes from Bloch in Chicago. Gastroscopic studies made in Philadelphia by Swalm, Jackson and Morrison, revealed chronic gastritis with or without erosions in 9 of 10 chronic peptic ulcer cases.

So it must be assumed that in some parts of this country, chronic erosive gastritis is more frequent than has been previously assumed. Which parts of the country these are, or whether, since the absence of prohibition, gastritis in general has become more frequent, will remain questions until further investigations give answers of great importance to both internist and surgeon.

ADVANCED EXTRA-UTERINE PREGNANCY

M ALEXANDER NOVEY, M D., F A.C S., Baltimore, Maryland

THE lodging and imbedding of a fertilized ovum in any situation outside the lumen of the uterus is spoken of as extra-uterine pregnancy, ectopic pregnancy or eccyesis. The development of this fecundated ovum so abnormally located may continue for a variable period of time, depending upon its situation and many other factors involving the reaction of the tissues of the host.

Space does not permit a detailed discussion of the interesting history of extra-uterine pregnancy, beginning with the first recorded case in the middle of the 11th century by Albucasis, an Arabian physician residing in Spain, and extending to the modern conception of its recognition and treatment. The famous lithopedion of Sens reported in the early part of the 16th century, Cornax's case a little later, and the operation by Christopher Ban about the same time for a long retained fetus, all afford a charming picture of some of the earlier reported cases. From this time on instances of the operative removal of a petrified fetus were sporadically reported, first by Prime-rose in 1594, and later followed by others. Evidently in all of these early cases pregnancy was well advanced, and probably all of the cases fell into the group of secondary abdominal pregnancies.

Mauriceau's description of a case of ruptured ectopic pregnancy in 1669 is delightful and well known. Pierre Dionis in 1718 contributed enormously to the known knowledge on this subject in his works. The literature from this time on began to contain more and more on this interesting phenomenon, a very important treatise being written in 1837 by Dezeimeris, revising the older classifications and carefully studying the pathology involved. Many important contributors to the literature on this subject are of necessity omitted. The very slow recognition of the importance of operative interference in extra-uterine pregnancy is in itself an interesting bit of the history of medicine, extending even up to our own day and time.

Extra-uterine pregnancies may be divided into primary and secondary types. They are called primary when development of the fertilized ovum occurs at a point where it is first imbedded, and secondary when the development occurs at a new

site because of rupture or of extrusion from the original location. If there is no treatment, one of several things may happen. The ovum may die and be resorbed, a tubal mole may be formed, a hemocele may develop or, if fetal development continues for a longer time, lithopedion formation, mummification, adipocere formation, skeletonization, or suppuration may occur.

The following tables taken from Schumann's monograph on extra-uterine pregnancy give clearly the primary and secondary terminations of this condition:

TUBAL PREGNANCY

Primary terminations

1. Early death of the ovum with complete resorption and a restoration of the tube to its pre-pregnant condition.

2. Death of the embryo with the formation of a tubal mole.

3. Tubal abortion.

4. Rupture of the pregnant tube, either into the peritoneal cavity or between the folds of the broad ligament.

5. The growth and development of the embryo may proceed to term when either the fetus dies as a result of nutritional failure or is delivered by abdominal section.

6. If the pregnancy be interstitial, the fetus may gradually be extruded into the uterine cavity, the placenta remaining attached to the cornual wall, and the pregnancy may terminate by spontaneous vaginal delivery, as in normal intra-uterine gestation, the placenta being also spontaneously expelled.

Secondary terminations

Tubal rupture or abortion, but far more commonly the former, may be succeeded by:

1. Tubo-abdominal pregnancy, with the placenta remaining attached to the tube wall, either wholly or in part, and the fetus expelled through a rupture of the tube on its free surface, and lying free in the abdominal cavity, surrounded by the amniotic sac or in rare cases entirely devoid of covering. This type of termination is rare although a fairly large number of cases has been reported.

2. Secondary abdominal pregnancies,—that condition found when, following tubal rupture or abortion, more commonly the latter, the entire

ADVANCED EXTRA-UTERINE PREGNANCY

M ALEXANDER NOVEY, M D , F A C S , Baltimore, Maryland

THE lodging and imbedding of a fertilized ovum in any situation outside the lumen of the uterus is spoken of as extra-uterine pregnancy, ectopic pregnancy or *eccyesis*. The development of this fecundated ovum so abnormally located may continue for a variable period of time, depending upon its situation and many other factors involving the reaction of the tissues of the host.

Space does not permit a detailed discussion of the interesting history of extra-uterine pregnancy, beginning with the first recorded case in the middle of the 11th century by Albucasis, an Arabian physician residing in Spain, and extending to the modern conception of its recognition and treatment. The famous lithopedion of Sens reported in the early part of the 16th century, Cornax's case a little later, and the operation by Christopher Bain about the same time for a long retained fetus, all afford a charming picture of some of the earlier reported cases. From this time on instances of the operative removal of a petrified fetus were sporadically reported, first by Prime-rose in 1594, and later followed by others. Evidently in all of these early cases pregnancy was well advanced, and probably all of the cases fell into the group of secondary abdominal pregnancies.

Mauriceau's description of a case of ruptured ectopic pregnancy in 1669 is delightful and well known. Pierre Dionis in 1718 contributed enormously to the known knowledge on this subject in his works. The literature from this time on began to contain more and more on this interesting phenomenon, a very important treatise being written in 1837 by Dezeimiers, revising the older classifications and carefully studying the pathology involved. Many important contributors to the literature on this subject are of necessity omitted. The very slow recognition of the importance of operative interference in extra-uterine pregnancy is in itself an interesting bit of the history of medicine, extending even up to our own day and time.

Extra-uterine pregnancies may be divided into primary and secondary types. They are called primary when development of the fertilized ovum occurs at a point where it is first imbedded, and secondary when the development occurs at a new

site because of rupture or of extrusion from the original location. If there is no treatment, one of several things may happen. The ovum may die and be resorbed, a tubal mole may be formed, a hematocele may develop or, if fetal development continues for a longer time, lithopedion formation, mummification, adipocere formation, skeletonization, or suppuration may occur.

The following tables taken from Schumann's monograph on extra-uterine pregnancy give clearly the primary and secondary terminations of this condition:

TUBAL PREGNANCY

Primary terminations

- 1 Early death of the ovum with complete resorption and a restoration of the tube to its pre-pregnant condition
- 2 Death of the embryo with the formation of a tubal mole
- 3 Tubal abortion.
- 4 Rupture of the pregnant tube, either into the peritoneal cavity or between the folds of the broad ligament.
- 5 The growth and development of the embryo may proceed to term when either the fetus dies as a result of nutritional failure or is delivered by abdominal section.
- 6 If the pregnancy be interstitial, the fetus may gradually be extruded into the uterine cavity, the placenta remaining attached to the cornual wall, and the pregnancy may terminate by spontaneous vaginal delivery, as in normal intra-uterine gestation, the placenta being also spontaneously expelled.

Secondary terminations

Tubal rupture or abortion, but far more commonly the former, may be succeeded by:

- 1 Tubo-abdominal pregnancy, with the placenta remaining attached to the tube wall, either wholly or in part, and the fetus expelled through a rupture of the tube on its free surface, and lying free in the abdominal cavity, surrounded by the amniotic sac or in rare cases entirely devoid of covering. This type of termination is rare although a fairly large number of cases has been reported.

- 2 Secondary abdominal pregnancies,—that condition found when, following tubal rupture or abortion, more commonly the latter, the entire

ovum is expelled into the general peritoneal cavity and the embryo continuing to live, the placenta attaches itself to whatever tissue it may and re imbedding takes place in an entirely new location.

3. Tubo-ovarian pregnancy, occurring when the fetal sac is composed partly of tubal and partly of ovarian tissues. Here the pregnancy may originate in a tubo-ovarian cyst or more commonly in a tube the fimbriated extremity of which was previously adherent to the ovary.

4. Intraligamentous pregnancy, resulting when the tube ruptures between the folds of the broad ligament and the placenta remaining attached to its tube the fetus develops within the broad ligament the entire gestation remaining extra peritoneal.

Termination of ovarian pregnancy

1. Rupture into the peritoneal cavity with hemorrhage and death of the fetus.

2. Rupture of the sac with secondary ovario-abdominal pregnancy, the placenta remaining attached to the ovarian parenchyma and to contiguous structures.

3. Rupture with secondary attachment of the ovum or secondary abdominal pregnancy.

A brief resume of several cases which have come to our attention may serve to bring out some of the points of importance in the diagnosis and treatment of well advanced extra uterine pregnancy. The errors committed in some of the cases cited should be of value in a study of this condition.

CASE 1. H. F. colored age 24 years married multipara. This patient was admitted to the University hospital October 20, 1920. Her previous pregnancy occurred 6 years ago and presented no abnormalities. On November 22, 1919, she menstruated normally. Her previous menstrual period was normal. Beginning with December amenorrhea had persisted. December 15, the patient had an acute pain over the left tubo-ovarian region which lasted for several days and gradually subsided. Her pain entirely disappeared after about 2 or 3 weeks. Fetal movements were first noticed in April of the following year. On August 10 the patient had what appeared to be labor pains for 2 days, which gradually subsided and the fetal movements which heretofore had been quite pronounced became vague and indefinite. There was a marked decrease in the size of the abdomen and retrogressive changes were noticed in the breasts. Beginning on October 1 the patient had slight vaginal bleeding, which lasted for 5 days. On October 17 the bleeding recurred and continued until the date of admission to the hospital. Throughout all this time the bleeding was only slight in amount except for one occasion when the patient passed what appeared to be a rather large clot. There had been no abdominal pains since August. On admission the patient complained of a slight frontal headache and occasional nausea.

Abdominal palpation showed an ovoid mass about the size of a thirty-two weeks pregnancy the consistency of the tumor being somewhat more resistant and less elastic than normal. No fetal outlines were palpated. The mass was not fixed and was freely movable from side to side. There was a second mass about the size of a grapefruit in the right lower quadrant which was somewhat flattened anteriorly and contracted and relaxed upon palpation. There was marked tenderness over the entire abdomen particularly in the lower left quadrant. No fetal heart could be heard. On vaginal examination the fetal head could be easily felt bulging in the pelvis pushing down into the cul de sac. Anteriorly a soft patulous partially dilated cervix could be made out very high in the vagina which seemed to be continuous with the smaller contracting tumor occupying the right lower quadrant. The patient bled moderately but continuously from the cervix.

A diagnosis of secondary abdominal pregnancy was made and the peritoneal cavity was opened. A dark grayish dull sac was exposed which was adherent to the abdominal peritoneum. Many adhesions to the large and small intestine were encountered some of which required ligation. The tumor extended deep into the pouch of Douglas and at its lowest point could not be entirely separated. The tube and ovary on the right side were intact although they were adherent to the sac wall. On the left side the tube was evident at the uterine insertion only for about 5 centimeters and from that point was lost in the sac wall. The left ovary was not seen probably being concealed by adhesions. Incision into the sac wall immediately exposed placental tissue. A considerable quantity of meconium stained amniotic fluid escaped. The child was lying in the left occiput anterior position with the head below the pelvic brim. The sac wall was covered with peritoneum throughout. A full term well developed dead female child much macerated was delivered. After many more adhesions were separated and tied off and the left broad ligament was tied off the entire sac wall consisting of amnion chorion placenta and adhesions was removed—a procedure which resulted in considerable hemorrhage that was finally controlled. Three cigarette drains were inserted back of the uterus and the abdomen was closed with silk-worm gut sutures. The uterus itself corresponded to the size of about a 16 weeks pregnancy. The patient was considerably shocked by the operation and remained so for about 2 hours. She soon rallied and from this time on made a totally uneventful recovery—her temperature never going above 100 degrees. On November 8 she was discharged from the hospital her incision having healed *per primam*. On vaginal examination the uterus was found in normal position freely movable and not sensitive. Her general condition on discharge was excellent.

CASE 2. P. J. colored age 35 years married multipara. About 1910 this patient had a 7 months premature labor cause unknown. On February 14, 1921, she was admitted to the University hospital with a diagnosis of intra uterine death of baby and postmaturity. An attempt was made to induce labor by rupturing the membranes on the following day but since no membranes could be felt it was thought that they had ruptured spontaneously. Castor oil and quinine were given without effect. On February 16 a Vothees bag was introduced and after about 3 hours came away. The patient did not go into labor. On February 21 she was again prepared and anesthetized. The cervix was dilated manually and at this time it was found that the uterus was small being about the size of an orange and empty. Diagnosis now was made of a secondary abdominal pregnancy and plans were made for laparotomy upon her recovery from the previous manipulations.

On February 22 x-ray examination had revealed the presence of a pregnancy, near term, occiput presenting, the position of the fetus unusual with the occiput on a plane about 2 inches below the umbilicus. The extremities extended further laterally than is usually seen. All of these conditions would fit in with an abdominal pregnancy, although from the x-ray examination, it was impossible to tell whether or not the fetus was in the uterus.

Before the laparotomy was performed, however, the patient developed a lobar pneumonia, at the height of which she suffered an acute shock early on the morning of February 26. This was accompanied by very marked abdominal distention which did not improve under treatment. After medical consultation, it was thought best to open the abdomen with a very small button-hole incision. This was done late that night. There escaped considerable gas under pressure, and several quarts of bloody fluid. The patient died before morning.

Autopsy revealed a secondary abdominal pregnancy with sac loose in the abdominal cavity. There was an opening in the lower left corner of the sac, and it was through this that the fluid had escaped into the abdominal cavity.

CASE 3. H. T., colored, age 25 years, married, multipara. This patient was admitted May 18, 1930 at 7:00 p.m. According to her menstrual history, she was about 40 to 42 weeks' pregnant. She had labor pains from April 19 to April 24, which gradually ceased. They did not begin again until May 13, at which time she vomited some blood. These pains lasted for 2 days, ceased, and began again on the afternoon of May 17. No fetal movements had been felt since May 13. During the week prior to admission she had been seen by two colored doctors and one midwife, and at least four vaginal examinations had been made under non-sterile technique.

On admission, her temperature was 101.2 degrees, pulse 140, blood pressure 110/60. The abdomen was markedly distended, rather firm, and somewhat tender on palpation. Laparotomy was done the following day and an extra-uterine pregnancy found. The placenta was attached to the peritoneal surface of the fundus of the uterus and the membranes formed a large sac adherent to the intestines and abdominal wall. A large macerated child weighing 8 pounds, 6 ounces, was contained in the sac, which was extensively infected with colon bacilli.

The patient died on the operating table from shock, infection, and hemorrhage.

CASE 4. A. B., colored, age 31 years, married, primipara. This patient was admitted at 7:00 p.m. on July 5 for prolonged labor, her pains having started at 1:00 a.m. of the same day. Examination under anesthetic revealed the head low in pelvis covered with a thick portion of lower uterine segment. The cervical canal was displaced upward and to the left, and the external os would not admit the tip of the finger. The head, which could not be palpated through the cervix, was pushed up and out of the pelvis and the cervix was drawn down into position with the aid of vulsellum forceps.

On July 8 the patient had not delivered, although the uterus continued to undergo regular contractions. The possibility of abdominal pregnancy was considered and exploratory laparotomy was decided upon. The abdomen was opened, and a mass containing the baby presented directly under the incision. The mass was very thick walled, vascular, and covered with numerous adhesions. It was opened and a living female child weighing 5 pounds 8 ounces was extracted.

The cyst was found to be composed of the right broad ligament and within it were the placenta and the fetal membranes. It was adherent to the right tube and affixed

to numerous coils of the small intestines. The uterus was slightly enlarged and adherent to the left portion of the cyst.

An attempt was made to free the adhesions and deliver the cyst, but this was found to be impossible. The bleeding vessels were ligated and the cavity of the cyst was packed with gauze. The umbilical cord was ligated and cut just long enough to reach out over the abdomen.

The patient's condition at this time was extremely poor. The abdomen was closed in the usual manner, but before the skin closure could be completed, the patient ceased to breathe.

The child, which had a marked congenital deformity of both feet, contracted impetigo during its stay in the hospital, but when this had cleared up it was transferred to the Kerman Hospital for Crippled Children for treatment of the deformity. Its course from this time on was uneventful.

CASE 5. E. J., colored, age 25 years, married, multipara. This patient had delivered normally of a full term, living child 6 years previously. Her family history, past history, and menstrual history were essentially normal throughout. She was admitted to the University hospital August 21, 1932, having been sent in by her family physician with a history of having been in labor for 36 hours. Upon careful questioning, she gave a history of sharp pain in the lower part of her abdomen followed by an illness lasting several days in the early part of her pregnancy. Following this she was up and about and her pregnancy followed an essentially normal course until about 2 weeks before admission. Beginning with this time she had a considerable amount of abdominal discomfort and fetal movements were quite painful.

Examination upon admission to the hospital revealed that the patient had a normal temperature, pulse, and respiration, and a blood pressure of 130/60. Upon abdominal examination, the fetus was found to be extremely palpable and there was some tenderness of the abdomen. The fetal heart was heard beating at a normal rate. Rectal examination revealed the head to be low down in the pelvis but it was impossible to feel the cervix. On vaginal examination it was found that the head was pushing down into the pelvis through the posterior cul-de-sac, and that the cervix was drawn high up behind the symphysis, the cervical canal being only large enough to admit a thin applicator. The abdominal examination, combined with the pelvic examination and the history, served to make a diagnosis of secondary abdominal pregnancy the most likely probability, and the abdominal operation was decided upon. The abdomen was opened the same afternoon under ether anesthesia and the first thing seen was the baby's hand which protruded through the peritoneal incision. The child was lying loose in the abdominal cavity, and was removed without difficulty. It was now possible to see the sac in which the child had been lying, it was apparently made up of broad ligament and was extremely vascular, being in effect a large varicocele sac, the walls of which were thin and friable. There had occurred at some time previous a rupture in the right lower border, and through this rupture the child had escaped into the abdominal cavity.

The placenta, which was apparently attached to the left side of the sac and probably covered a rather large area, was at this time seen to be partially protruding through the rupture, the fetal surface being seen. The cord could be traced down to its placental attachment.

In the manipulation of the sac it began to bleed at what would be the fundus of the uterus, had it been a uterus near the left side. This bleeding began without any instrumentation whatever, and was rather profuse. A clamp was placed on the bleeding area and hemorrhage was controlled in this way, but after two attempts to whip over

the bleeding point with a needle and after an attempt was made to tie it off with a free hand tie it was concluded that the tissues were too friable for successful suturing. Each suture caused a little more bleeding than the last, and finally it was decided to allow the clamp to remain in position.

The sac at this time was about the size of a recently delivered uterus. There was no hemorrhage where it had ruptured and there was no blood in the abdominal cavity. The patient's condition was extremely good and it was feared that if any attempt was made to remove the sac profuse and possibly uncontrollable hemorrhage would be encountered. Therefore the cord was tied close to its placental insertion and severed allowing the ligature to remain outside of the abdomen. Two cigarette drains were introduced near the site of the rupture and the abdomen was closed.

The patient left the table very little shocked and was returned to her bed in good condition.

Following operation the patient ran a surprisingly smooth course. For the first 10 days there was a slightly septic type of temperature never going above 100 degrees and for the next week or so the temperature was essentially normal. Following this it again began to assume a somewhat septic type never completely returning to normal. On October 16, 1932, she was discharged in apparently good condition after having remained in the hospital for about 8 weeks.

It is interesting to note that the sac containing the placenta which was not removed at the time of operation gradually decreased in size so that at the time of discharge one was still able to palpate through the abdominal wall a mass about the size of a small grapefruit which was not tender and easily movable. The patient was instructed to return to the clinic for postpartum follow up.

The baby which weighed 5 pounds 15 ounces at birth lived very nicely and upon discharge weighed 7 pounds 9½ ounces.

The patient was examined at periodic intervals after her discharge from the hospital and after about 18 months pelvic examination was negative except for a very small firm mass in the broad ligament which was freely movable, not tender, and about the size of a walnut. Recently about 3 years after operation the patient delivered spontaneously of a normal full term child after a very short labor.

CASE 6. C. C. colored age 21 years married multipara. This patient was admitted to the Provident hospital October 25 complaining of abdominal pain since October 17. Her first pregnancy was normal the child is living and well at present. The last menstrual period was June 15. On July 25 she fainted twice but had never remained in bed.

On examination a mass was found occupying the left portion of the abdomen. The tumor seemed to be divided into two parts and over the upper portion the fetal heart could be heard. Pelvic examination was extremely painful and quite unsatisfactory. Upon the basis of a possible diagnosis of abdominal pregnancy a laparotomy was done on November 22. Among other factors the anemia and general poor condition of the patient coupled with the great amount of abdominal pain played a great part in the decision to operate without delay.

When the abdomen was opened there was found a sac occupying the left upper abdominal region which contained a fetus. A living child weighing 3 pounds 4 ounces was removed but the infant died of prematurity a few hours later. The sac was closed and the abdominal wall was repaired without the use of drainage. The placenta was left in situ.

The patient had a very stormy convalescence but finally left the hospital on April 15 a small draining sinus still present in the abdominal wound. There was a definite mass in the left lower abdominal quadrant. The general condition of the patient was only fair on discharge.

Follow up examination of the patient 3 months later revealed a gain in weight of about 40 pounds associated with complete healing of the incision and a state of comfort and well being.

In summary, there are reported 6 cases of extra uterine pregnancy with a maternal mortality of 3 and an infant mortality of 4. In addition to these cases, there have occurred several others all of which seemed to demonstrate the seriousness of advanced extra uterine pregnancy, and the ease with which errors in recognition and treatment may be made.

DIAGNOSIS

The diagnosis of abdominal pregnancy in the later months whether primary or secondary, is usually a question of determining if the fetus is really extra uterine. As a rule there is little necessity for the confirmation of the existence of a pregnancy, and the confusing differential diagnosis and symptomatology of the early ectopic gestation does not confront the attendant.

If the pregnancy is well advanced there are certain points of aid in diagnosing an abdominal gestation. The history of an acute attack of illness at a time corresponding to the third or fourth month of pregnancy is of great value. This corresponds to the rupture of an ectopic pregnancy, and the patient states that at this time she suffered an acute sharp pain in one or the other lower abdominal quadrants following which she was quite faint and ill for a week or more. There may or may not have been a slight amount of bloody vaginal discharge at this time. The abdominal discomfort and general malaise may wear off in due time and the patient feel well again, often with little or no medical attention. Frequently however there is a continued semi invalidism and symptoms of peritoneal irritation, such as abdominal pain, nausea and vomiting, alternating constipation and diarrhea, and painful urination. Painful, vigorous and easily demonstrable fetal movements are frequently encountered. On palpation of the abdomen one is impressed by the unusual palpability of the fetus, it being possible at times almost to pick up the small parts through the abdominal wall. If the child is alive the fetal heart tones may be heard very loudly. The abdominal tumor is itself often asymmetrical and the position of the fetus often oblique as regards the midplane of the pelvis. In some instances the enlarged empty uterus

which is drawn up out of the pelvis, by the growing fetal mass, may be felt just above the symphysis to the right or left or in the midline. The sac containing the fetus does not contract, and often in a case of suspected abdominal pregnancy, a firm, strong contraction of the abdominal mass makes a positive diagnosis of an intra-uterine gestation. In general, the abdominal examination is painful and unsatisfactory.

If the fetus has gone to term, there usually occurs what is known as false labor, often associated with some vaginal bleeding. This continues for a short time, when fetal death occurs, and movements and uterine contractions cease.

On rectal examination, one may be misled by the degree to which the head of the fetus has descended into the birth canal, at times even to the level of the ischial spines. On careful palpation one is, however, unable to make out the cervix, the low level of the head occurring as the presenting part descends covered by one of the cul-de-sacs. The writer knows of several attempts to rupture the membranes in such cases because a diagnosis of abdominal pregnancy had not been made.

Vaginal examination reveals the soft cervix of pregnancy but in our experience in almost every instance the cervix is so pulled upward by the displaced uterus that it is found with great difficulty, and then only as a tiny opening well up under the symphysis, the lips of the cervix often not being palpable at all. There is present no evidence of Hegar's sign. The body of the uterus is often palpable, varying in size from a comparatively small organ to that of a 20 weeks' pregnancy. Its consistency varies but as a rule it is much less firm than the uterus in the non-pregnant condition. It is most often displaced by, and usually can be outlined as, a separate and distinct structure from the sac containing the fetus.

The x-ray as an aid in the diagnosis may be of value, in determining the oblique and atypical position of the fetus as regards the midplane of the pelvis. The use of the uterine sound or skiagraphy may be of value in establishing a diagnosis if properly employed.

TREATMENT

In any consideration of the treatment of advanced extra-uterine pregnancy, it is essential to consider not only the life of the mother but also the possible infant life, if the fetus is still alive. Here, as in many other situations throughout the practice of medicine, no set rule can be established for treatment, but each case must be in-

dividualized and treated as that particular case demands.

Immediate operation as contrasted to waiting until the fetus reaches the period of viability is recommended by some very good authorities. On the other hand, there are many who favor close observation of the patient to be followed by laparotomy at a time when the child is thought to be viable. It is true that in a certain number of instances malformations of the fetus are encountered, but the presence of normal, healthy children is sufficiently frequent to discount this point as a reason for immediate interference. If the patient is at term, some recommend waiting for false labor to occur and the subsequent death of the fetus, and then about one to three weeks later to operate, hoping that the decrease in blood supply at this time will render the operation more safe. This has not been found advisable by many, and, in the writer's opinion, far better results can be obtained by operating 1 or 2 weeks before term, a procedure, in the hands of many, fairly frequently resulting in a living mother and baby. In the event that the fetus is known to be dead, the delay of several weeks may be advisable until thrombosis of the placental vessels has occurred, rendering operation less formidable.

If possible, the sac should be incised extra-peritoneally, but this is not always feasible. The fetus should be removed and the placenta should be treated in different manner, depending on its site of attachment. Where the placenta is attached to the omentum, intestines, peritoneal wall, and the surface of the uterus, any attempt to separate it is extremely dangerous. It should be left alone, drains should be inserted, and the placenta should be allowed to slough out. If, on the other hand, the placenta lies between the folds of the broad ligament and there is no infection present, the placenta should be left *in situ*, the sac tightly closed, and the abdominal cavity closed without drainage. Attempts at removal of the placenta in most instances is attended by uncontrollable hemorrhage. In rare instances, the entire blood supply of the sac can be ligated, and the sac and placenta within removed; but unless this is extremely easy to do it is best not to attempt it. In a definitely infected case, marsupialization, stitching the edge of the sac to the abdominal wound, and packing the sac with gauze, often gives the best results. Each case, therefore, must be handled as it demands and it is highly important to decide the procedure to be followed as early as possible and to avoid unnecessary manipulation with exposure of the patient to serious hemorrhage and infection.

the bleeding point with a needle and after an attempt was made to tie it off with a free hand tie it was concluded that the tissues were too feeble for successful suturing. Each suture caused a little more bleeding than the last and finally it was decided to allow the clamp to remain in position.

The sac at this time was about the size of a recently delivered uterus. There was no hemorrhage where it had ruptured and there was no blood in the abdominal cavity. The patient's condition was extremely good and it was feared that if any attempt was made to remove the sac profuse and possibly uncontrollable hemorrhage would be encountered. Therefore the cord was tied close to its placental insertion and severed allowing the ligature to remain outside of the abdomen. Two cigarette drains were introduced near the site of the rupture and the abdomen was closed.

The patient left the table very little shocked and was returned to her bed in good condition.

Following operation the patient ran a surprisingly smooth course. For the first 10 days there was a slightly septic type of temperature never going above 100 degrees and for the next week or so the temperature was essentially normal. Following this it again began to assume a somewhat septic type never completely returning to normal. On October 16, 1932, she was discharged in apparently good condition after having remained in the hospital for about 8 weeks.

It is interesting to note that the sac containing the placenta which was not removed at the time of operation gradually decreased in size so that at the time of discharge one was still able to palpate through the abdominal wall a mass about the size of a small grapefruit which was not tender and easily movable. The patient was instructed to return to the clinic for postpartum follow up.

The baby which weighed 5 pounds 15 ounces at birth did very nicely and upon discharge weighed 7 pounds 9 1/2 ounces.

The patient was examined at periodic intervals after her discharge from the hospital and after about 18 months pelvic examination was negative except for a very small firm mass in the broad ligament which was freely movable not tender and about the size of a walnut. Recently about 5 years after operation the patient delivered spontaneously of a normal full term child after a very short labor.

CASE 6. C. C. colored age 21 years married multipara. This patient was admitted to the Provident Hospital October 25 complaining of abdominal pain since October 17. Her first pregnancy was normal the child is living and well at present. The last menstrual period was June 15. On July 25 she fainted twice but had never remained in bed.

On examination a mass was found occupying the left portion of the abdomen. The tumor seemed to be divided into two parts and over the upper portion the fetal heart could be heard. Pelvic examination was extremely painful and quite unsatisfactory. Upon the basis of a possible diagnosis of abdominal pregnancy a laparotomy was done on November 22. Among other factors the anemia and generally poor condition of the patient coupled with the great amount of abdominal pain played a great part in the decision to operate without delay.

When the abdomen was opened there was found a sac occupying the left upper abdominal region which contained a fetus. A living child weighing 3 pounds 4 ounces was removed but the infant died of prematurity a few hours later. The sac was closed and the abdominal wall was repaired without the use of drainage. ANAEROBIC INFECTIONS FOLLOWING OPERATIONS ON THE URINARY TRACT

W. H. MENCHER, M D., and H. E. LEITER, M D., New York, New York

THE occurrence of an anaerobic infection complicating surgical procedures on the urinary tract seems to be infrequent, as evidenced by the paucity of case reports. Yet, the development of this type of infection is of such serious moment as to warrant calling attention to the importance of early recognition and treatment. The reader is referred to an article by Goldstein and Abeshouse in which the literature on *Bacillus welchii* infections is reviewed *in extenso*. Since then, Turner added 2 other cases of *Bacillus welchii* infection: one followed a nephrotomy for stone and ended fatally, while the second followed a nephrectomy for renal calculus with cortical abscesses, and ended with recovery. In addition to these, we have been able to find references to 3 cases of tetanus. Two of these cases were reported by Wainwright and followed prostatectomy, the third, reported by Miller and Rogers, occurred after a nephrectomy.

Of the 27 cases of gas bacillus infection after operations on the urinary tract which were found in the literature, the outcome was mentioned in 22. The calculated mortality for this series is 45 per cent. All 3 instances of tetanus ended fatally.

Following are the abstracts of 14 cases of post-operative anaerobic infection of the urinary tract that were encountered at Mount Sinai Hospital during the past 11 years. Eleven were due to *Bacillus welchii*, and 3 showed the typical symptoms of tetanus.

INFECTION DUE TO GAS BACILLUS

CASE 1. A R., aged 61 years, had had three series of x-ray treatments for an enlarged prostate. May 21, 1931, a suprapubic cystostomy and lithotomy were done. One week later, two large, adherent prostatic adenomas were enucleated and the prostatic bed was packed with thromboplastin soaked gauze. The same afternoon, the patient bled from the prostatic bed and had to be repacked. This was followed by the administration of a transfusion of 500 cubic centimeters of blood. At midnight of the same day, another hemorrhage necessitated a second repacking and transfusion. Thirty-six hours following this, the patient's high temperature forced the removal of one packing. Several hours later, a serous and urinous discharge containing gas bubbles was noted alongside the remaining packing. Smears from this fluid showed the presence of gram

positive thick rods and on culture the organism was found to be *Bacillus welchii*. In view of this finding and the temperature of 104 degrees, the remaining packing was removed; the wound was opened widely; polyvalent anaerobic serum was administered intramuscularly and continuous irrigation with hydrogen peroxide was instituted. The patient's condition improved and 1 week later the suprapubic tube was removed. This was followed by a third hemorrhage, which was controlled by packing the prostatic bed. A week later the packing was removed, and a fourth, and fatal hemorrhage followed.

In this case the anaerobic infection was controlled, as evidenced by the subsequent negative cultures and smears. Death occurred 2 weeks after the infection was first noted, and was due to hemorrhage. Possibly the frequent packing of the prostatic bed may have been accompanied by contamination with *Bacillus welchii*.

CASE 2. L. B., aged 60 years, male, had a nephrectomy for left renal carcinoma September 1, 1931. The following day, crepitation was noted about the wound. The latter was opened widely after smears suggested the presence of a gas bacillus infection. Culture subsequently verified the presence of this organism. The patient was given polyvalent serum and the wound was irrigated through catheters in the depths with hydrogen peroxide. Recovery was uneventful, though the wound healed slowly, and he was discharged October 25, 1931.

This is the only case of anaerobic infection following nephrectomy in over 150 cases of renal neoplasm. As far as we know, the operative technique was identical in all these cases. The tumor was infected and broken down. Whether the organism was already present in the tumor (which ruptured during delivery), or was introduced in other ways, cannot be stated.

CASE 3. A. E. R., aged 60 years, male, was operated upon February 25, 1932; a right pyelotomy and nephrotomy were done under x-ray control for renal calculi, as described by Beer and Benjamin. Three days after operation his temperature was 102 degrees, but he showed no signs of toxicity. When the wound was dressed the surrounding area was found to have a purplish discoloration with distinct crepitation. The superficial and deep sutures were then removed, revealing the presence of necrotic tissues, pus, and air bubbles. Smears and cultures were positive for *Bacillus welchii*. Serum was administered and irrigations of the wound with hydrogen peroxide were instituted. His temperature subsided and the wound gradually cleared and granulated. He was discharged 6 weeks after operation.

In addition to all the factors which may have been responsible in the previous case, there were

From the Surgical Service of Dr. Edwin Beer, Mt. Sinai Hospital.

SUMMARY AND CONCLUSIONS

From the preceding discussion, it can be seen that we are dealing here with a formidable condition, which necessitates a great amount of diagnostic skill, seasoned judgment, and proper handling if one is to avoid a tremendous mortality rate. In general, it is safe to say that indecision and faulty treatment of the placenta and fetal sac will add more than anything else to a tragic result. In spite of the fact that each case must be handled individually, certain points will be found of value in the diagnosis and treatment of a well advanced extra uterine pregnancy.

As to diagnosis, the following points are important:

- 1 History of rupture in the early months with its accompanying signs and symptoms
- 2 Painful fetal movements
- 3 Extremely easily palpable fetus
- 4 Tender abdomen on palpation.
- 5 Palpation and demonstration of a small

empty uterus separate and distinct from the sac containing the fetus

6 Markedly retracted cervix, high up under the symphysis

7 Failure of the fetal sac to contract

8 Asymmetry of the mass on palpation and by x ray

As to treatment, the following should be mentioned:

1 The patient may be safely carried under close observation to a period when the fetus is viable

2 Attempt should be made to open the sac extraperitoneally

3 Each case should be studied individually but wherever possible the placenta should be left *in situ* and the sac and the abdominal cavity closed without drainage

4 Unnecessary manipulation should be avoided for it will almost invariably result in death of the patient from shock, hemorrhage or infection

lus welchii in one flask. Smears and cultures were taken from the sinus tract and were found to contain gas bacilli. Serum and peroxide irrigations were administered. By the third day following this therapy, the temperature had fallen from 103.6 to 100 degrees. The cultures from the wound showed *Bacillus welchii* for 4 weeks. Her convalescence thereafter was uneventful.

This case is of interest because (1) there were no local manifestations of anaerobic infection; (2) the complication was first suggested by the positive blood culture; (3) the possibility arose that a localized *Bacillus welchii* phlebitis of the inferior vena cava existed at the point of application of the clamps. This patient, as well as 2 patients mentioned by R. K. Ghormley are the exception to the statement of Rhodes that "when gas bacillus infection invades the blood stream, the outcome is fatal."

CASE 7. A. L., aged 50 years, male, was admitted to Mount Sinai Hospital April 11, 1936, for a left upper abdominal mass, which was ballotable from the lumbar region and felt cystic. In addition, he had a considerably enlarged prostate gland. Ten days later, April 21, 1936, exploration under spinal anesthesia revealed a cyst the size of a grapefruit in the lower pole of the left kidney and a smaller one in the upper pole. Both cysts were evacuated and the cyst walls were removed. At the same sitting, a suprapubic cystostomy was done. The postoperative course was uneventful, except for a daily rise in temperature to 101.8 degrees. On the seventh day, some pus was evacuated from the posterior portion of the lumbar wound, which on smear and culture showed the presence of *Bacillus welchii*. Blood culture was negative. Polyvalent serum and peroxide irrigations were given, as well as oxygen introduced through a tube in the depths of the wound, which was opened widely. Except for a slowly granulating wound, the subsequent course and recovery were uneventful, and 2 months later a second stage prostatectomy was performed.

CASE 8. L. B., aged 50 years, male. Operation, September 3, 1930, consisted of right nephrectomy for tuberculosis. On the second day after operation, patient developed an acute dilatation of the stomach which contained over 50 ounces of retained fluid. On the third day, the temperature was 104 degrees, there was marked abdominal distention and the patient hiccoughed occasionally. Flatness and diminished breathing at the right base were noted. The wound was inspected and definite crepitation was found in the anterior two thirds of the line of incision. Immediate smears were made and were found to be positive for gram positive bacilli. Cultures were reported positive for *Bacillus welchii*. The wound was laid open widely, and irrigated with oxygen and Dakin solution. Polyvalent anaerobic serum was administered intramuscularly. The patient's general condition at this time was only fair. X-ray examination of the chest revealed marked elevation of the right leaf of the diaphragm. In view of the possibility of a subphrenic abscess, the wound was explored in the upper angle. The exploring finger found a cavity going up toward the diaphragm and turning inward. There was a discharge of about an ounce of old blood, following this procedure, and in addition a slight puff of air was noted. The patient was cyanotic during this time and required oxygen administered in a tent. Despite vigorous measures to support the patient and at the same time to combat the anaerobic infection, patient died on eighth day after operation.

It is possible that the anaerobic infection was overlooked or did not become manifest until the third day after operation. Earlier diagnosis might have made a difference in this case.

CASE 9. E. A. R., aged 24 years, male, was operated upon December 17, 1936, at which time a pelvic ureterolithotomy was performed. The incision in the ureter was closed with three interrupted adventitial sutures. The night after operation the temperature rose to 103 degrees. Inspection of the wound was negative. The patient ran some temperature for 6 days. During this period a small amount of pus was evacuated from the superficial part of the wound. On the sixth day after operation, the temperature rose sharply to 105 degrees. There was slight urinary leakage from the wound. Definite gas bubbles could be expressed from the depths of the wound. Immediate smear was made of the pus and reported positive for gram positive bacilli. Later cultures grew *Bacillus welchii*. The wound was laid widely open under anesthesia. Several Dakin tubes and catheters were inserted for continuous irrigation with hydrogen peroxide, and Dakin solution alternately. In addition, Lederle polyvalent anti-gas serum was administered intramuscularly and also placed in the wound. Following this regimen, the wound became clean quickly, and the patient was discharged with the wounds well healed 1 month after operation.

CASE 10. G. W. K., aged 50 years, male. Patient had the first stage of a proposed two stage suprapubic prostatectomy. Following the first operation, he developed a rise in temperature, which was at first thought to be due to an acute exacerbation of a chronic pulmonary process. Examination of the wound revealed crepitus in the upper angle, and a suture was removed. A small amount of thin pus and gas was expressed. Smears and culture were positive for anaerobic bacilli of the *Bacillus welchii* type. The patient's temperature was not particularly high, and his general condition was good. Adequate drainage of the superficially infected wound was obtained. Infection cleared up quickly without resort to drastic wound cleansing measures. Subsequent smears and cultures were negative. Patient was later subjected to second stage of operation.

This case is an example of mild anaerobic infection, which cleared up after simple drainage measures.

CASE 11. F. M., aged 44 years, female, was a case of calculus in the pelvic portion of the right ureter. A tooth in a dermoid ovarian cyst on this side was at first mistaken for the calculus. At operation, the stone was found in the ureter just below the shadow cast by the tooth. On re-examination of the x-ray plates, the smaller calculus shadow was identified. After removal of the calculus the ureter was sutured with plain catgut, and rubber dam was employed for drainage. Immediately after operation, the temperature rose to the 102-103 degrees level and remained there. Copious urinary leakage occurred through the wound, but despite the copious drainage the temperature remained elevated. One week after operation, massive edema of the posterior-vaginal wall was noted. A diagnosis of retroperitoneal cellulitis due to urinary extravasation was made. Blood culture was positive for the *Streptococcus hemolyticus*. A catheter was passed up into the right renal pelvis and left indwelling. The patient's condition became steadily worse and she ceased. At the postmortem examination, a gas bacillus infection of the wound was found and *Bacillus welchii* cultured from the liver and lungs. In addition, there were found an acute peritonitis,

three additional possible sources of contamination (1) urine (2) calculi, (3) x ray control

The next case is presented in greater detail because of the various unusual features attributable directly and indirectly to the gas infection

CASE 4 H S H aged 36 years male was admitted to the hospital June 3 1933 with a diagnosis of right renal tuberculosis and left tuberculous epididymitis. For 5 years he had had pains in both lumbar regions and in the penis. There was a definite history of the passage of gravel. X ray examination revealed calcifications in the right kidney and in the regions of the upper and lower ureter on the right side. Physical examination revealed a typical tuberculous left epididymis and some bilateral lumbar tenderness. There were a few nodules at the base of the right lobe of the prostate atrophy of the left lobe and a thickened left seminal vesicle. Cystoscopy was carried out the bladder urine was found to be cloudy the left ureteral orifice was normal and when catheterized yielded a clear urine without pus strong indigocarmine was present and no tubercle bacilli were found. The right ureter was obstructed temporarily at 4 centimeters and 11 centimeters but the catheter was finally passed to the right renal pelvis. From this side there was no excretion of indigocarmine and the urine showed many pus cells with tubercle bacilli in the centrifuged smears.

June 10 1933 an aseptic nephro ureterectomy (Ree technique) was performed and in addition through a separate inguinal incision a left orchidectomy was done. Due to the marked perinephritis the kidney was removed subcapsularly. The specimen showed a small right kidney adherent in the thickened perinephric fat. The ureter was dilated thickened and markedly adherent in the region of the ureterovesical junction where several small impacted calculi were noted. In lower pole of kidney was a partially calcified abscess while the other calices showed calculosis.

The day following operation the patient's temperature rose to 105 degrees and was attributed to a sore throat. The temperature and throat infection began to subside but on the fifth day after operation about 3 ounces of sero pus was evacuated from the anterior angle of the lumbar wound. The following day when three chromic sutures were removed there was an escape of pus fat globules and air bubbles from the depths of the wound. Cultures and smears were positive for *Bacillus welchii*. Polyvalent serum was administered and through two catheters in the bottom of the wound the latter was irrigated with hydrogen peroxide. By the eighth day the lumbar wound seemed cleaner but crepitation and tenderness were noted in the anterior ureterectomy wound. The temperature rose to 105.4 degrees. The ureterectomy wound was therefore split open and a tube was introduced into the pelvis for oxygen and peroxide insufflations. Cultures from this wound also showed *Bacillus welchii* but the blood culture was negative. This was followed by a subsidence of the fever to almost normal. Serum was still administered. On the twelfth day the temperature again rose to 104 degrees. The right lumbar and anterior wounds were clean but there was tenderness in the left iliac fossa. Rectal examination was negative.

Fifteenth day after operation temperature was 102-104 degrees respirations rapid rectal examination negative blood pressure 70/50 hemoglobin 76 per cent white blood count 35,000 with 82 per cent polymorphonuclears.

Twenty first day signs of consolidation over left lower lobe. Given a transfusion of 300 cubic centimeters of blood.

Thirtieth day temperature still 102-104 degrees rises present at both bases.

Thirty second day irrigation of the anterior wound yielded a considerable amount of pus and necrotic tissue temperature lower.

Forty second day an indurated tender mass appeared over the left pubic bone. Flat x ray showed the catheter to enter the right side of the pelvis and to extend to the left pubic region. It was felt that this abscess accounted for the fever diarrhea and persistent discharge. The following day incision with drainage of the left inguinal abscess was performed.

Forty seventh day patient voided for the first time a milky urine with some blood. The fourth voiding was again clear. It was thought therefore that this was due to a rupture of an extraperitoneal abscess into the bladder. A few days after this he began to improve and he was discharged from the hospital 70 days after operation.

During the patient's stay in the hospital opaque material injected into the right sinus tract appeared to run behind the rectum and sigmoid in the hollow of the sacrum. The wounds continued to drain for some time after discharge from the hospital. He was readmitted March 27 1933 and a retrorectal abscess of the pelvis was drained after the coccyx was removed. Following this procedure all wounds rapidly closed.

In this case at one time the diagnosis of miliary tuberculosis was entertained. The extensive dissection of the retroperitoneal infection from the right to the left side behind the rectum may have been due to the anaerobic organism or to the measures used to combat the gas bacillus. It is questionable whether this patient would have recovered without careful watching and early recognition of complications.

CASE 5 J L aged 22 years male had a right nephrectomy for tuberculosis in May 1933. On the second day after operation his temperature rose to 104 so that it was deemed advisable to inspect his wound. Definite crepitation was found and when the sutures were removed smears from the depths showed large gram positive rods, which on culture were subsequently found to be *Bacillus welchii*. The wound was immediately opened widely and continuous irrigations with hydrogen peroxide were instituted. Polyvalent serum was also given. Cultures from the wound were positive for gas bacilli for 335 weeks. His subsequent course was uneventful.

CASE 6 R W aged 42 years female was subjected to a right nephrectomy March 6 1934 for a calculous pyonephrosis. The kidney was enlarged and very adherent to all the surrounding tissue. After ligation of the pedicle and removal of the kidney profuse bleeding ensued which was found to come from an opening in the vena cava. Bleeding was controlled by the application of clamps to the opening in the vena cava. Due to the friability of the infiltrated wall of the vessel the opening was not sutured but the clamps were left in place. For one week after operation the patient's condition was satisfactory the temperature ranged between 100 and 101. On the ninth day the clamps were removed and the wound appeared clean except for some serosanguineous discharge along the drainage tract. Despite her apparently good general condition the temperature between the tenth and fourteenth days after operation varied between 100 and 103 degrees. There were no local evidences of wound infection. A blood culture was taken and to our surprise it showed the presence of *Bacil*

POSSIBLE SOURCES OF INFECTION

The occurrence of postoperative anaerobic infections has always given rise to theoretical discussions as to the portals of entry. The following sources of contamination are to be considered: (1) skin, (2) rectum, (3) operative materials, and (4) urine, pus and urinary calculi

1. *Skin* Park and Williams and Gilles comment on the presence of the *Bacillus tetani* in the dirt about the feet, hair, street clothes, and dust in the house and hospital. Meyer and Spector in culturing the skin of the inguinal region found 5 positive cultures of *Bacillus welchii* before and 2 positive cultures after surgical preparation of the skin. These facts are self evident and emphasize the importance of meticulous care in the cleansing and sterilization of the skin before operation, as the first step in the control of postoperative anaerobic infections.

2. *Rectum* It is well known that both *Bacillus tetani* and *Bacillus welchii* may be harbored normally in the lower intestinal tract. This incidence has been variously estimated from 1 to 2 per cent in urban districts to 40 per cent in the rural population (6, 11, 27). The reasons for this difference are self evident. Several cases of postoperative tetanus have been reported in which positive cultures of tetanus bacilli were obtained from the stool of the same patient. In one of Tulloch's cases, following appendectomy, the organism was isolated from the wound, from the stump of the appendix, and from the descending colon. Speed recovered the organism from the exudate around a deep stitch which passed through the sigmoid during a hernioplasty. These reports indicate a possible association between postoperative tetanus and the lower intestinal tract. It is of interest to note that our 3 cases of tetanus followed a second stage prostatectomy. In the usual technique of suprapubic prostatectomy, the enucleation of the adenoma is facilitated by the introduction of a finger into the rectum. Anaerobic organisms from the latter may then find their way into the wound or prostatic bed by migration through the bruised layer of tissue separating the prostate from the rectum or by faulty technique in the care of the contaminated rectal glove or hand.

3. *Operative materials* Numerous substantial reports are to be found in the literature (19) of anaerobic infections due to contaminated catgut. In investigating a few other sources, cultural studies were made of a hemostatic agent used in packing the prostatic bed (7). Much to our surprise, this hemostatic agent was found to be contaminated with various types of organisms. Al-

though tetanus bacilli were not isolated from this preparation, organisms resembling *Bacillus welchii* were found. It is obvious that the use of such contaminated materials may be another means of introducing anaerobic organisms into the wound.

4. *Urine, pus, and urinary calculi.* Weiser reported the case of a 60 year old man with hematuria and pneumaturia. Culture from the urethra and bladder yielded *Bacillus welchii*, staphylococci, and streptococci. Bennett noted the abundant presence of *Bacillus welchii* in the urine of a patient whose kidney had been traumatized by a projectile without the development of an anaerobic infection. Doering cultured anaerobic organisms from a patient with a perinephric abscess secondary to a pyonephrosis. Albarran and Cottet stated that in rare cases, cystitis may be induced by anaerobic bacteria alone or in combination with aerobic organisms. Duvoir et al. mention a case of tetanus with cystitis that followed the introduction of a sound into the bladder in an attempted abortion with recovery from the tetanus and continuation of the pregnancy. Runeberg isolated anaerobic bacteria 6 times from the urines of 47 patients with urinary calculi.

In the past 3 years, over 1,000 cultures from the genito-urinary tract were made at Mount Sinai Hospital. In two instances, *Bacillus welchii* was recovered from the urine. The first patient was a man who was admitted with symptoms of a right pyelonephritis and prostaticitis, 6 weeks after a transurethral resection at another hospital. This man recovered. The second patient was a colored male of 27 years, who was explored for acute upper abdominal symptoms. Laparotomy showed edema of the peritoneum and gastrocolic omentum and an incidental appendectomy was performed. After operation he had a moderate fever and marked oliguria with a rise in his blood urea to 120 milligrams per cent. Gross hematuria appeared on the fourth day, and evidences of a gas bacillus infection developed on the eleventh day after operation, at which time his urine culture was also positive for *Bacillus welchii*, but his blood culture was negative. Postmortem examination revealed a bronchopneumonia, peripancratic and perirenal fat necrosis, a necrotizing cystitis, and hemorrhages into the renal pelvis. This case clearly showed that anaerobic organisms may find their way into the urinary tract from other tissues which may harbor these bacteria. It has been shown by Franck in about 20 per cent of the cases he studied that the lymph channels of the right kidney capsule are intimately related to the appendix and cecum. He believes that this lymphatic arrangement is at times responsible

right traumatic (operative) ureteritis acute phlebitis of the left ovarian vein thrombosis of the right renal vein embolism of the left lower pulmonary artery and dermoid cyst of the right ovary

INFECTION DUE TO TETANUS BACILLUS, ALL AFTER A SECOND STAGE PROSTATECTOMY

CASE 1. L. H. aged 65 years male was admitted to the hospital and a suprapubic cystostomy was done January 16 1931 under local anesthesia. Convalescence was uneventful so that on January 23 1931 the second stage prostatectomy was done under gas-oxygen anesthesia. Two very large lateral lobes and a median lobe were enucleated and the prostatic bed packed with three thromboplastin soaked packings. These packings were removed as usual on the fifth day after operation and the patient was allowed out of bed the following day. Eleven days after the second stage (February 4) the patient began to complain of difficulty in opening his mouth widely. Physical examination at this time was entirely negative. There was no apparent spasm of the masseters and the mouth could be opened the full distance. That evening he developed typical trismus which became more intense and was accompanied by rigidity of the abdominal muscles and exaggeration of all the deep reflexes. The clinical picture resembled typical tetanus. He was given tetanus antitoxin intramuscularly and large doses of sedatives. His temperature was only 100 degrees at this time. The following day although he felt better subjectively there was still some difficulty in swallowing. The temperature then rose to 104 degrees and the general condition became progressively worse. February 8 he developed signs of pneumonia at the right base and he died February 10 1931. Postmortem examination was not obtained.

CASE 2. G. K. aged 68 years male had a suprapubic cystostomy under local anesthesia November 19 1931 for enlargement of his prostate. Except for the development of a left scrotal abscess which was incised and drained his postoperative course was uneventful. Accordingly December 8 1931 the second stage prostatectomy was performed parascrotal and epidural block anesthesia being used. After the large prostate was removed in several pieces the bed was packed with two packings soaked in thromboplastin gauze and the bladder was drained with a large tube. Immediate postoperative course appeared normal and the packings were removed on the fourth day. Ten days after the second stage the patient developed epigastric distress cyanosis and an irregular pulse attributed to extra systoles of the heart. His temperature rose to 103 degrees. Examination revealed a rigidity of the abdominal muscles some involuntary spasms of the left thigh muscles and slight difficulty in opening the mouth. There was a bilateral Kernig sign present with hyperirritability and some nuchal rigidity. Tetanus antitoxin was administered intramuscularly intravenously and intraspinally so that in the first 24 hours he received 125 000 units of antitoxin. His general condition however became worse and with the development of signs of pneumonia he died 36 hours after the first symptom of tetanus appeared. The specimen was reported as a fibro adenoma of the prostate with areas of squamous cell metaplasia. The postmortem examination showed that the prostatic bed was hemorrhagic and black and that it contained a small amount of purulent material. The periprostatic tissues were indurated. The ejaculatory ducts as well as the seminal vesicles were filled with pus. Cultures from the bed showed the following organisms: (1) *Staphylococcus aureus* (2) *Streptococcus hemolyticus* B (3) diphtheroid bacilli and (4) *Bacillus proteus*.

CASE 3. R. C. aged 60 years male was subjected to a bilateral vasectomy and suprapubic cystostomy January 24 1934 for hypertrophy of the prostate. February 4 1934 a second stage prostatectomy was performed under spinal anesthesia. The entire prostate was removed in one piece and one thromboplastin soaked packing was inserted into the prostatic bed. Three chromic sutures were used to approximate the separated fascia. On the first day after operation the temperature rose to 101.8 degrees and came down to 99 degrees the following day. Five days after operation the packing was removed from the prostatic bed. The next morning his general condition appeared to be excellent and he had had a normal temperature for 3 days. On the afternoon of the sixth day he complained that his tongue felt thick. There was no dysphagia no trismus and a careful neurological examination revealed no abnormalities. However on the suspicion that this thick sensation of his tongue might be an early symptom of tetanus he was given 1500 units of tetanus antitoxin intramuscularly. The following morning distinct trismus was present. He was immediately given 40 000 units of tetanus antitoxin intraspinally 40 000 units intravenously and 20 000 units intramuscularly. The posterior urethra was irrigated with peroxide and he was given sedatives liberally. Despite this therapy he developed generalized twitchings a few hours later. During the first 24 hours he was given 150 000 units of tetanus antitoxin by the routes mentioned. His general condition rapidly grew worse his blood pressure fell to 83/60 and his urinary output dropped. He died 36 hours after the onset of trismus with signs of bronchopneumonia. In all 245 000 units of tetanus antitoxin had been given. The specimen showed typical fibro adenoma of the prostate with areas of acute inflammation.

The postmortem examination showed a bronchopneumonia of both lower lobes. The liver myocardium and kidneys showed severe degeneration. The right and left ventricles were dilated. The sinus tract which surrounded the drainage tube going into the bladder was free from edema and hemorrhage and showed no exudate. The smears from the sinus tract showed no organisms. The kidneys and ureters were not abnormal. The bladder showed evidences of trauma in the region of the prostatic urethra trigone and adjacent bladder wall with congestion and denudation of the mucosa. Smears from the exudate in the prostatic bed showed a single spore bearing bacillus after prolonged search. Culture of this exudate yielded *Bacillus welchii* but no tetanus bacilli and the guinea pigs inoculated did not develop tetanus.

This case is an example of fulminating clinical tetanus. At postmortem examination, *Bacillus welchii* was isolated from the prostatic bed while tetanus bacilli was not. The difficulties of finding the latter organisms in wounds of patients with tetanus are well known. In retrospect one may conjecture as to the possible recovery of this patient were he given large doses of antitoxin immediately on the complaint of thickness of his tongue. He was given 1500 units merely as a compromise because the possibility of tetanus was entertained. His general condition was so good at the time that one could hardly have foreseen a fatality in less than 48 hours. This case also emphasizes the difficulty of recognizing tetanus before the more classical symptoms develop.

air bubbles Smears and cultures are immediately made, and a positive spread is followed by the early institution of active therapy to combat the infection The wound is split wide open, tubes and catheters are placed into the depths for continuous irrigation with peroxide and oxygen, large quantities of polyvalent perfringens serum are administered intramuscularly, locally, and even intravenously. The patient is isolated and given individual nursing care Daily smears and cultures are made from wound Blood cultures are taken, if the temperature is high Intravenous fluids and blood transfusions are used as necessary.

When the infection subsides, Dakin solution may be alternated with the peroxide irrigations to hasten the separation of necrotic tissue and to stimulate granulation of the wound The early recognition and intensive treatment, as outlined, will be followed by a rapid subsidence of the infection and its concomitant symptoms We have not had a fatality that has been due directly to the *Bacillus welchii* infection in our last 9 cases

X-ray therapy (18) has recently been advocated for gas bacillus infections, but we ourselves have had no experience with it. This type of therapy may be of value, especially with the measures mentioned

The early recognition of tetanus is a more difficult matter General symptoms signify late manifestations of the disease. The appearance of the wound is of no aid in the diagnosis It might be of help to suggest that any unexplainable neurological symptoms must take into consideration the possibility of tetanus Our first case was recognized only after trismus appeared The second (G K) developed abdominal rigidity and spasms of the muscles of the left thigh In the third case (R. C), the diagnosis of tetanus was suggested, and treatment begun, on the mere complaint of "thickness" of the patient's tongue The mortality in tetanus is appalling Any hope of combating the complication is dependent upon early diagnosis and the administration of large doses of tetanus antitoxin by all routes It might be well to use a very large dose such as is given in the treatment of diphtheria and then to follow its administration with repeated smaller doses The wound should be exposed and irrigations with peroxide should be carried out In addition to this, adequate sedation and supportive therapy should be carried out as required

SUMMARY OF THE CASES IN TWO GROUPS

Case	Disease	Operation	Organism	Result
8 L B	Tuberculosis of the kidney right	Nephrectomy	B. welchii	Died
5 S L	Tuberculosis of the kidney right	Nephrectomy	B. welchii	Well
4 H S H	Tuberculosis of the kidney right	Nephro-ureterectomy	B. welchii	Well
3 A E R	Renal calculus right	Pyelotomy and nephrotomy	B. welchii	Well
6 R W	Renal calculus right	Nephrectomy	B. welchii	Well
2 L B	Renal neoplasm right	Nephrectomy	B. welchii	Well
11 F M	Ureteral calculus	Ureterolithotomy	B. welchii	Died
9 E A R	Ureteral calculus	Ureterolithotomy	B. welchii	Well
7 A L	Renal cysts left	Apyclation and excision	B. welchii	Well
10 G W K	Prostatic hypertrophy	First stage cystostomy	B. welchii	Died
1 A R	Prostatic hypertrophy	Second stage prostatectomy	B. welchii	Died
3 L H	Prostatic hypertrophy	Second stage prostatectomy	B. tetani	Died
2 G H	Prostatic hypertrophy	Second stage prostatectomy	B. tetani	Died
1 R C	Prostatic hypertrophy	Second stage prostatectomy	B. tetani	Died

Four out of 11 cases of *Bacillus welchii* infection died (36.3 per cent mortality). Three out of 3 cases of *Bacillus tetani* infection died (100 per cent mortality).

If we are to interpret our mortality figure correctly as those due directly to infection by *Bacillus welchii* we should exclude 2 deaths (G W K died 5 weeks later due to puerperal sepsis; uremia and thrombophlebitis A R died 4 weeks later due to hemorrhage) which occurred long after the infection was controlled. In that event the correct mortality to *Bacillus welchii* infection in this series is 2 per cent.

for the migration of organisms from the right colon to the right kidney. Stahr by microscopic and injection studies demonstrated the connection between the lymphatics of the capsule of the kidney, with the renal parenchyma and pelvis. Hutchison feels that bacteria may pass from the bowel to the kidney by way of the lymphatics when lesions of the bowel are present. He cites a case in which an appendix was adherent to the kidney and the *Bacillus coli* was found in the urine.

From this discussion it is readily conceivable that anaerobic infections may follow operations on the urinary tract due to the incidental presence of these organisms in the urinary organs. It is also of interest to note, in view of the discussed relationship of the right colon to the right kidney, that 7 out of our 9 cases of anaerobic infection of the suprapubic region occurred on the right side. The question arises as to whether during the mobilization of the kidney and ureter one may not open lymphatics from the bowel in the stripping away of the peritoneum and thus allow organisms to enter the traumatized retroperitoneal area. From this standpoint cultural studies of the urine before and after operation in uninfected kidney and ureter cases may be of value.

Ferrier and Bliss were the first to isolate *Bacillus welchii* from the center of a renal calculus in a patient who developed gas gangrene of the operative wound. With this possibility in mind 36 urinary calculi have thus far been studied at Mt

Sinai Hospital. The outside of the stone was first thoroughly flamed and the calculus was then crushed with a sterile instrument and cultured. This was controlled by crushing fragments of sterile sand. In calculi from 3 different patients the *Bacillus welchii* was isolated. Fortunately these patients did not develop wound infections. It is possible that should these organisms be present in a calculus, the crushing of the stone during its delivery might play a part in postoperative anaerobic infections.

DIAGNOSIS AND TREATMENT

The prognosis in this type of infection is directly dependent upon early recognition and adequate treatment. Any patient who has had an inordinate rise in temperature, with or without symptoms of toxemia, should receive a careful inspection of the wound in addition to a general physical examination. Especially is this important within 48 hours after operation, during which time many surgeons are apt to look for other sources of trouble than wound infection and attribute the elevated temperature to a few ribs in the lungs or to postoperative reaction. Discoloration, edema, or crepitation in the region of the wound calls for further investigation of the depths. Crackling may be heard by applying firm pressure with the stethoscope against the involved area in which gas is present. Under these circumstances, we do not hesitate to remove superficial and deep sutures, watching for serum, pus and

air bubbles Smears and cultures are immediately made, and a positive spread is followed by the early institution of active therapy to combat the infection The wound is split wide open, tubes and catheters are placed into the depths for continuous irrigation with peroxide and oxygen, large quantities of polyvalent perfringens serum are administered intramuscularly, locally, and even intravenously The patient is isolated and given individual nursing care Daily smears and cultures are made from wound Blood cultures are taken, if the temperature is high Intravenous fluids and blood transfusions are used as necessary.

When the infection subsides, Dakin solution may be alternated with the peroxide irrigations to hasten the separation of necrotic tissue and to stimulate granulation of the wound The early recognition and intensive treatment, as outlined, will be followed by a rapid subsidence of the infection and its concomitant symptoms We have not had a fatality that has been due directly to the *Bacillus welchii* infection in our last 9 cases

X-ray therapy (18) has recently been advocated for gas bacillus infections, but we ourselves have had no experience with it This type of therapy may be of value, especially with the measures mentioned

The early recognition of tetanus is a more difficult matter General symptoms signify late manifestations of the disease The appearance of the wound is of no aid in the diagnosis It might be of help to suggest that any unexplainable neurological symptoms must take into consideration the possibility of tetanus Our first case was recognized only after trismus appeared The second (G K) developed abdominal rigidity and spasms of the muscles of the left thigh In the third case (R C), the diagnosis of tetanus was suggested, and treatment begun, on the mere complaint of "thickness" of the patient's tongue The mortality in tetanus is appalling Any hope of combating the complication is dependent upon early diagnosis and the administration of large doses of tetanus antitoxin by all routes It might be well to use a very large dose such as is given in the treatment of diphtheria and then to follow its administration with repeated smaller doses The wound should be exposed and irrigations with peroxide should be carried out In addition to this, adequate sedation and supportive therapy should be carried out as required

THE VALUE OF DETERMINATIONS OF PROTEIN PRIOR TO OPERATIONS ON THE GASTRO-INTESTINAL TRACT

ALTERATIONS in the protein of the blood serum have heretofore been of greater interest to the internist than the surgeon. Recent observations, however, indicate that estimations of the serum proteins and of the colloid osmotic pressure which they exert may be of equal value in the surgical management of gastro intestinal lesions.

It is well known that the serum proteins usually are lowered in cases of edema resulting from an inadequate intake of protein, from inadequate absorption from the gastro intestinal tract of ingested protein, or from excessive loss of protein in the urine. "War edema," "prison dropsy," and the anasarca that so often occurs in sprue, certain diarrheas and nephrosis, are examples of foregoing processes. Hypoproteinemia in certain diseases of the

liver is well known, and here again the low level of serum protein often is intimately related to the formation of edema and ascites.

From this one can assume that edematous changes can and do occur in the tissue of individuals with hypoproteinemia. All investigators are agreed on the importance of the pull of the plasma colloids on the control of the fluid balance between blood and tissue. The force exerted by the plasma proteins tends to absorb fluid from the tissue spaces, while capillary pressure, on the contrary, tends to force fluid from the blood stream into the tissue spaces. Thus, theoretically, the relative constancy of blood volume and tissue fluid volume should depend primarily upon a balance between these two forces.

It has been repeatedly demonstrated that generalized edema develops in animals fed diets deficient in protein, ulcers in the stomach and duodenum may also appear (Hoelzel and Da Costa, 1937). In addition it has been shown experimentally that hypoproteinemia in normal dogs is accompanied by a decreased gastric emptying time, and that dogs which have undergone pyloric resection, with restoration of gastro intestinal continuity by various standard methods, show the same delay in gastric emptying time when the serum proteins are decreased by a diet deficient in protein and by plasmapheresis. Fluoroscopic examination of the stomachs of these animals presents a picture difficult to distinguish from that observed during anatomical obstruction (McCray, Barden, and Ravdin, 1937). At necropsy, these animals show definite edema of the gastro intestinal tract. This water logged type of mucosa has also been observed in the intestinal tract of man.

Moreover, it has been observed that an inadequate intake of food may produce defects in the gastro-intestinal tract of man (Jones and Eaton, 1933), and recently it has been reported that a reduction in the plasma proteins after a gastro-intestinal operation is accompanied by a deformity of the stoma which resembles in every way a real anatomical defect as seen roentgenologically. Such defects, according to Barden, Ravdin, and Frazier (1937), are said to disappear when the serum proteins are raised to a normal level. These authors suggest that the presence of edema in the mucosa reduces the size of the stoma and so interferes with emptying of the viscus. The observed retention might conceivably result from decreased gastric activity or defective muscular contraction, but these investigators favor the view that local edema is responsible.

The desirability of determining the serum proteins in cases in which gastric emptying is delayed, either before or after operation, is obvious. It is well to remember, however, that estimation of total protein is not always an accurate indication of the effective osmotic pressure. Even with pure protein solutions the colloid osmotic pressure is not linearly related to the concentration of protein but tends to increase per gram of protein as the total protein concentration is increased. The converse of this is also true. A satisfactory theoretical explanation of this relation between concentration of protein and the colloid osmotic pressure is not known. However, this fact should be clearly understood and always considered when studying pathological serums. In such cases a better but still imperfect relation can be obtained by analysis of the proteins as albumins and globulins (Butt and Keys, 1937).

Certainly, in view of these recent contributions, the possibility of hypoproteinemia and

edema of the gastric mucosa must be considered in cases in which there is clinical and roentgenological evidence of pyloric or stomal obstruction. It is, of course, well known that non-functioning stomas begin normal function without any type of treatment other than gastric aspiration. Often the administration of saline or glucose solutions to the patients will be followed by a decrease in the observed gastric retention. The explanation for this phenomenon is not entirely clear, but certainly it is not the result of increasing the colloid osmotic pressure. If the protein values are low, however, an attempt ought to be made to increase them by transfusion and a high protein diet if standard methods prove ineffective.

HUGH R. BUTT

THE ANTISEPTIC ERA

THE antiseptic era has been marked by an interesting paradox. Pasteur was responsible perhaps for the fact that surgeons have been overapprehensive regarding germ infection. Lister, on the other hand, may be charged with having inspired in the hearts of most surgeons a greatly exaggerated overconfidence in the value of chemical antiseptics. Careful reading of the works of both Pasteur and Lister will indicate, however, that they appreciated, as few of their followers have done, the importance of inherent immunity and bodily resistance against invasion by micro-organisms.

On more than one occasion Lister called attention to the fact that much of the successful surgery done before his time was due to the ability of the body to overcome infection. Lister's original proposal was not to combat infection by means of carbolic acid but to employ carbolic dressings for the purpose of excluding micro-organisms from wounds. That Lister has been generally misunderstood on this point is indicated in much of the litera-

ture of wound treatment and antiseptics. In his recent autobiography¹ Dr Robert T Morris says

It was some twenty years later that Lister introduced his theory of air infection and with the backing of Pasteur developed his antiseptic method of wound treatment. Von Bergmann in 1892 went a step farther and introduced asepsis. This theory developed by Schimmelbusch showed that it was more important to prevent the entrance of microbes into the operative field than it was to destroy them after they had gained entrance. The von Bergmann principle of holding microbes at a distance quickly succeeded the Listerian idea though founded upon it.

The thousands of attempts that have since been made both upon patients and in the laboratory to discover a chemical specific for infected wounds have led to much confusion in surgical practice. These attempts, also, have caused many surgeons to lose sight of the importance of supporting the patient in every possible way and of building up his bodily resistance to infection. Likewise too little has been done in the direction of protecting the patient from outside influences and of helping him to defend himself against invasion by septic micro organisms. This, in spite of Lister's specific injunction on this point. Some of the most recent successes in the field of surgery have resulted from a better perception of this important truth. Urologists, by their recent work in prostatic surgery, have, for example, called our attention again to the importance of building up the patient with fluids, of providing drainage for infected blad-

ders and kidneys, and of balancing intake and output in body metabolism before resorting to surgical procedures. They have thereby very greatly improved their surgical results.

The influence of physiological rest in the treatment of all kinds of acute and chronic infections may now be employed similarly to conserve the resources of the patient. In fractures and other injuries with infection it is of paramount importance to protect him against improper movement and muscle spasm and to contribute to his own ability to resist infection. Immobilized in correct position and at rest, with nerves and circulation able to function efficiently, he can employ his own healing powers in co-operation with the surgeon to bring about a cure.

Very little is still known about the actual chemistry either of infectious processes in wounds or in the body or of the underlying processes of immunity or resistance. Those physiological processes that we do know more about should be employed in every way until chemical specific treatment may be better understood and others added to the very short list of really useful antiseptics now available. So many laboratory experiments have been unintelligently applied to human beings without any reasonable prospect of success, and so many have been exploited even when their failure was foredoomed that an adherence to first principles would seem to be demanded if we are to give our patients the benefit of best surgical practice.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE fifth edition of the popular English *Textbook of the Practice of Medicine*,¹ a compilation of several well known English physicians, contains many additions and revisions since the last edition 4 years ago. Among these are, a discussion of such topics as total thyroidectomy in congestive heart failure, oxygen therapy in anoxemia, the use of mandelic acid in pyelitis, and a good up-to-date discussion of the treatment of amebic dysentery.

The text contains nearly 1900 pages exclusive of the index. The latter is complete. There are 112 illustrations, many of which are of electrocardiograms. Additions have been made to the section on psychological medicine, and the section devoted to diseases of the nervous system has been largely revised. No bibliography is included.

This book contains an enormous amount of material, and is as complete as a text covering so many phases of medicine can be. Its popularity attests to the fact that the editor has been successful in compiling a work which is of service to the student, teacher, and practitioner of medicine.

J. ROSCOE MILLER

GRAY presents in a most readable, enjoyable, and instructive diary² form the daily life of a medical student in London two hundred years ago. The crowded wards, emergency operations, puerperal fevers, anatomy classes with body snatching, treatment of criminals, and street brawls pass most interestingly through the pages. The last half of the book portrays the picture of life on shipboard with its scurvy, harsh discipline, and emergency treatment of battle injured seamen. While the book should not be regarded as an authentic diary it can be warmly recommended for the doctor's leisure hour.

THE fact that the bodily balance in accord with the principles of mechanics is a means for conservation of nervous energy is discussed and developed from an anatomical, physiological and mechanical point of view by Todd in her recent work, *The Thinking Body*.³ A full chapter is devoted to breathing and another to locomotion. Emphasis is placed upon the conception that the emotional aspect of behavior finds an expression in the body posture.

¹ A TEXTBOOK OF THE PRACTICE OF MEDICINE. By various authors. Edited by Frederick W. Price, M.D., C.M., F.R.C.P., F.R.S., (Edin.) 5th ed. New York and London: Oxford University Press, 1937.

² THE DIARY OF A SURGEON IN THE YEAR 1751-1752. By John Kniveton. Edited and transcribed by Ernest Gray. New York and London: Appleton-Century Co., 1937.

³ THE THINKING BODY, a Study of the Balancing Forces of Dynamic Man. By Mabel Elsworth Todd. Foreword by E. G. Brackett, M.D. New York and London: Paul B. Hoeber, Inc., 1937.

As is stated in the foreword, "New views, even though correct, find their place in the community but slowly; the author of this book, however, has a large amount of material to substantiate her claims for her methods, and she has given this to the public only after long and practical experience, the results of which demonstrate the soundness of her views."

EMIL HAUSER.

NO BOOK that I have thus far read so adequately covers the field of abdominal surgery in children as that by Sir Lancelot Barrington-Ward, the new second edition⁴ of which is now being published by the Oxford University Press of London.

Following a discussion of the general principles of surgery, the author takes up in order: the congenital defects of the abdominal wall; hernia and undescended testis, hydrocele; hematogenous peritonitis; abdominal peritoneal tuberculosis, congenital hypertrophic pyloric stenosis; appendicitis and its complications, diseases of the gall bladder, pancreas and spleen, intestinal obstruction of various types with special emphasis on intussusception, errors in the development of the intestinal tract (especially Meckel's diverticulum), Hirschsprung's disease; mesenteric cysts, and, finally, a brief discussion of anesthesia in children and intravenous therapy.

Each topic is thoroughly and completely discussed in a manner most pleasing to read, and evidencing a broad knowledge of general surgery by the author. The book is very well illustrated with excellent photographs, accurate drawings, clear x-ray films, and a few beautiful color plates. For any one interested in obtaining the latest and most complete book in the field of abdominal surgery in children I cannot too strongly recommend this volume.

EDWIN M. MILLEP

IN *The Management of the Pneumonias*,⁵ by Dr. Bullowa, an enthusiastic author well known in American medical literature on the subject of oxygen therapy and pneumonia treatment, Oxford University Press presents a monograph of 508 pages, characteristically well printed on good paper. Many of the illustrations are not up to the standard of the rest of the volume. The first 75 pages are given to a discussion of classification, course, diagnosis, symptoms and physical findings of pneumonia. The section on the laboratory examination is well illustrated

⁴ THE ABDOMINAL SURGERY OF CHILDREN. By Sir Lancelot Barrington-Ward, K.C.V.O., Ch.M., F.R.C.S. (Edin.), F.R.C.S. (Eng.) 2d ed. London: Oxford University Press, 1937.

⁵ THE MANAGEMENT OF THE PNEUMONIAS; for Physicians and Medical Students. By Jesse G. M. Bullowa, B.A., M.D. New York: Oxford University Press, 1937.

ture of wound treatment and antiseptics. In his recent autobiography¹ Dr Robert T Morris says

It was some twenty years later that Lister introduced his theory of air infection and with the backing of Pasteur developed his antiseptic method of wound treatment. Von Bergmann in 1892 went a step farther and introduced asepsis. This theory developed by Schimmelbusch showed that it was more important to prevent the entrance of microbes into the operative field than it was to destroy them after they had gained entrance. The von Bergmann principle of holding microbes at a distance quickly succeeded the Listerian idea though founded upon it. (1)

The thousands of attempts that have since been made both upon patients and in the laboratory to discover a chemical specific for infected wounds have led to much confusion in surgical practice. These attempts, also, have caused many surgeons to lose sight of the importance of supporting the patient in every possible way and of building up his bodily resistance to infection. Likewise too little has been done in the direction of protecting the patient from outside influences and of helping him to defend himself against invasion by septic micro-organisms. This, in spite of Lister's specific injunction on this point. Some of the most recent successes in the field of surgery have resulted from a better perception of this important truth. Urologists, by their recent work in prostatic surgery, have for example called our attention again to the importance of building up the patient with fluids, of providing drainage for infected blad-

ders and kidneys, and of balancing intake and output in body metabolism before resorting to surgical procedures. They have thereby very greatly improved their surgical results.

The influence of physiological rest in the treatment of all kinds of acute and chronic infections may now be employed similarly to conserve the resources of the patient. In fractures and other injuries with infection it is of paramount importance to protect him against improper movement and muscle spasm and to contribute to his own ability to resist infection. Immobilized in correct position and at rest with nerves and circulation able to function efficiently, he can employ his own healing powers in co operation with the surgeon to bring about a cure.

Very little is still known about the actual chemistry either of infectious processes in wounds or in the body or of the underlying processes of immunity or resistance. Those physiological processes that we do know more about should be employed in every way until chemical specific treatment may be better understood and others added to the very short list of really useful antiseptics now available. So many laboratory experiments have been unintelligently applied to human beings without any reasonable prospect of success, and so many have been exploited even when their failure was foredoomed that an adherence to first principles would seem to be demanded if we are to give our patients the benefit of best surgical practice.

H WINNETT ORR

¹For Dr Robert T. Morris: *Twenty Years a Surgeon*, p. 67. New York: E. P. Dutton & Co. Inc. 1937.

ever, where we are still far from standardization of opinion concerning many questions. The technique of treatment for each condition is outlined in great detail, so as to give the radiotherapist a schedule of treatment for each lesion mentioned.

The discussion is executed from the point of view of a clinician, in so far as clinical considerations have entered the field very extensively. A small but precise summary as to diagnosis, the surgical indications, the pathology as far as this is necessary for clinical understanding and for radiologic indications always precedes the discussion of the radiation therapy. In this way the book provides a convenient guide for the general practitioner and for the student as to the possibilities and indications of radiation therapy. At the same time, it gives to the radiologist a schematic outline of the technical procedure recommended which will be useful for those who know how to adapt this scheme carefully to the individual case to which they wish to apply it.

MAX CUTLER

PRACTICAL NEUROANATOMY,¹ by J. H. Globus, is the outgrowth of an earlier laboratory guide-book for "study of the form and internal structure of the brain and spinal cord" which went through six editions. The original form and contents have not been changed greatly but much material has been added. There are now 256 pages of text as compared with 121 pages in the previous book. The increase results principally from the addition of two new sections devoted to résumés of the author's lectures to his students and to neurological technical methods. The main portion of the text is arranged in 25 "assignments" containing directions for the day by day study of the nervous system, questions intended to stimulate students' thought and brief descriptions of the structures encountered in the laboratory material. Following an embryological introduction, the reader is led to consider the external and internal anatomy of the cerebrum, corpus striatum, spinal cord and brainstem but is not introduced to the cellular elements of the nervous system until the last few pages.

Although the book has been vastly improved in its present form, it still seems to the reviewer that it possesses some unfortunate features. Can the student profit by studying the internal anatomy of the brain before examining nerve cells and fibers? Can he be expected to discuss intelligently and profitably "nuclei, their morphology and functional types and tracts, their make-up and varieties" in the first assignment when he is unacquainted with the fundamentals of nervous tissue?

The illustrations of the text have been improved and made usable by the addition of labels with guide lines. Their number has been increased from 36 to 92 in this edition. Some could be improved still more by judicious addition of a few more labels and

by increasing the magnification especially in the case of the higher brainstem photographs. A very commendable feature is found in the use of diagrams of truncated brainstems accompanying the photographs of sections to give the student a three-dimensional conception of the intrinsic structures. The diagrams are adequate throughout the lower part of the medulla oblongata but, unfortunately, the illustrator seems to have been somewhat confused in his representation of the levels at the junction of the medulla oblongata and pons, Figure 52, in particular, is very misleading.

There are several good textbooks of neuroanatomy available but any new one with real improvement in the methods of teaching the subject or with successful digestion of the many new facts which are accumulating so rapidly will be most welcome. This book does offer a fresh method of study and probably fills a real need for the author's course. It does not contain much new information and will consequently prove to be less useful to advanced students and clinical readers than could be hoped for.

WILLIAM F. WINDLE

DISEASES of veins are less well understood than are those of other systems. That this is so is perhaps due to the neglect of the venous system by the physiologists. Franklin's very scholarly *Monograph on Veins*² attempts to overcome this lack. According to the author, it is the first treatise of its kind in English, and has only two predecessors in other languages. This volume, which encompasses the author's own investigations as well as an exhaustive compilation of the literature, is concerned essentially with the physiology of veins, although embryology and anatomy are also discussed. The veins assume an important rôle in the circulatory mechanism. They do not function merely as passive channels for the return of the blood to the heart, but actively regulate the volume of circulating blood and the cardiac output. Propulsion of blood within the veins is effected by means of their intrinsic neuromuscular mechanism and by virtue of external forces acting upon them. The author points out that the data concerning various phases of vein physiology are sometimes conflicting and often incomplete.

It is to be regretted that pathological physiology and its effects upon the other tissues of the body have not been included in this monograph, and that the clinical phases of the subject are compressed into a single chapter where, for the most part, they receive rather superficial treatment. While this book will not be of immediate practical assistance to the clinician confronted with diseases of the veins, it will be invaluable to the student of the venous system. The digest of the literature and the very extensive bibliography should provide the starting point for future work, and will, perhaps, engender the clinical monograph on veins, for which the physician has been waiting.

LEO M. ZIMMERMAN.

¹PRACTICAL NEUROANATOMY, a Textbook and Guide for the Study of the Form and Structure of the Nervous System. By J. H. Globus, B.S., M.D. Baltimore: William Wood & Co., 1937.

²A MONOGRAPH ON VEINS. By Kenneth J. Franklin, D.M., M.P.C.P. Springfield, Ill., and Baltimore, Md.: Charles C. Thomas, 1937.

and clearly written. The author's experience with the typing and administration of serum with its advantages and disadvantages is well brought out.

Oxygen therapy which is the second great advance in the modern management of pneumonia is very well presented. An aggressive attitude is assumed in the adequate administration of 3000 to 3500 cubic centimeters of fluid and as many calories of food. Unfortunately, no adequate rule is presented for the administration of sodium chloride, nor is the over dosage of sodium chloride with formation of edema in the lung, warned against. Wisely 'codeine in adequate doses is given and morphine is rarely given' since it 'greatly depresses all receptors and the respiratory center, slowing respiration and diminishing the cough reflex. It does not greatly depress cerebral activity and it should never be used as a nervous sedative in pneumonia though it may be used for very severe pain in a dose of gr 1/6'. Digitalis is not used by the author since heart failure as such rarely exists.

In the main the book is very well done and the author is entitled to his particular opinions. However, such a comment as 'nasal catheters' are not advised will not be well received by that number of men who are well acquainted with their use in everyday practice where other methods are not suited or not available. It occurs to me that the volume might have been called 'The Treatment of Pneumonia at Harlem Hospital' rather than the broad title 'The Treatment of the Pneumonias'.

M HERBERT BARLER

THE merit of the monograph entitled *Arteriovenous Aneurysm*¹ by Holman is attested to by the fact that it was awarded the 1930 quinquennial Samuel D. Gross Prize by the Philadelphia Academy of Surgery.

The context is presented in a rather unique manner. The first chapter is devoted to experimental work which gives the reader a very clear conception of the pathologic physiology of arteriovenous fistulas. The author then discusses at length acquired arteriovenous communications of the extremities, intra-thoracic fistulas, mycotic arteriovenous aneurysms and the various congenital arteriovenous communications. The last 100 pages of the book are devoted to case reports and protocol of experiments. A liberal bibliography is appended.

The treatise will prove interesting to those men who have been faced by the difficulties which are met with in the surgical management of these lesions. It will be very useful to teachers because it assembles most of the facts relative to this unusual lesion. The author makes an interesting survey of the early literature dealing with arteriovenous communications and supplements this by frequent references to the work of his contemporaries. The book is a scholarly effort and should be read by a great

many who might be dissuaded from doing so because of its rather stiff pedagogic style. As a reference book it will prove valuable to internist and surgeon but its value as a technical guide in the surgical management of these lesions is limited. The volume may properly serve as a source book for future work in this field.

R W McNEALY

THERE has long been a need for a textbook on radiation therapy. The reason for this gap is obviously because of the enormous difficulty in formulating standardized conclusions such as those required of a textbook in a field still in a stage of rapid development. We can therefore be grateful to Dr Kaplan that he has undertaken the task of giving in a precise and comprehensive manner a convenient survey of the possibilities, the indications and the limitations of radiation therapy in all phases of clinical medicine including benign and malignant conditions.²

After a brief historical introduction and a discussion of radiation biology the physics of radiation and of electrosurgical currents are discussed. The chapter on x ray physics is written by C B Braestrup. In these chapters the authors give a convenient survey of the different types of apparatus most commonly used today in modern radiation institutes.

Following the basic chapters of about 100 pages the application of radiation therapy in all its different forms is discussed for the fields of dermatology, ophthalmology, ear nose and throat conditions, thoracic lesions, breast lesions, gastro-intestinal, gynecologic, genito-urinary, and neurologic conditions as well as endocrinology. In all these chapters the benign as well as the malignant lesions are considered. Following the discussion of radiation in the different specialties, there are some chapters dealing with irradiation of special pathologic conditions such as different forms of tuberculosis, osteomyelitis and gonorrheal arthritis, specific diseases of the reticulo-endothelial system, blood dyscrasias, soft tissue sarcomas and bone conditions. The later chapters are devoted to the complications and injuries following irradiation to traumatic cancer and to the nursing care of patients with malignant conditions. In the final chapter a model organization for a radiation therapy department is outlined.

In covering this enormous field in a textbook of this kind the discussion naturally has to be limited to the most outstanding features of each type of lesion and the discussion covers the different phases with differing degrees of thoroughness. Regarding the type of treatment recommended the discussion is based entirely on the author's own extensive experience and the methods used elsewhere are only casually mentioned. Obviously, this gives the book all the advantages and the disadvantages of a subjective and arbitrary discussion by an author who has worked many years in this field in a field hospital.

CORRESPONDENCE

THIRD INTERNATIONAL CANCER CONGRESS

THE Third International Cancer Congress under the auspices of the International Union against Cancer will be held in the United States September 11 to 16 1939 at the Haddon Hall Hotel Atlantic City New Jersey.

The president of the congress is Professor Francis Carter Wood director of the Institute of Cancer Research of Columbia University, New York City. Dr. Donald S. Childs of Syracuse New York is the secretary treasurer and Dr. A. L. Loomis Bell of Long Island College Hospital Brooklyn New York is in charge of transportation and exhibits.

The proposed sections are as follows: General research biophysics genetics general pathology of cancer surgery of cancer radiological diagnosis of cancer radiotherapy of cancer statistics and education. Further details concerning section chairman committees and other data will be announced later.

The membership fee will be \$15. All inquiries regarding the Third International Cancer Congress should be addressed to the Institute of Cancer Research 1145 Amsterdam Avenue New York New York.

INTUBATION STUDIES OF THE HUMAN SMALL INTESTINE

X. A Non-Surgical Method of Treating, Localizing and Diagnosing the Nature of Obstructive Lesions

W. OSLER ABBOTT, M.D., Philadelphia, Pennsylvania, CHARLES G. JOHNSTON, M.D.,
F A C S, Detroit, Michigan

SINCE the decline in the incidence of typhoid fever, intestinal obstruction has become the most lethal affection of the small bowel. Its local treatment consists of (1) reducing the distention of the gut proximal to the lesion, (2) locating and relieving the obstruction, and (3) excising any gangrenous tissue devitalized by a disturbance of its blood supply. Until recently operation was relied upon to accomplish these three ends, but the mortality in cases so handled has always been high. The studies of Wangenstein and Paine, however, have most clearly brought out the facts (a) that deflation of the stomach and, if possible, of the duodenum will often decompress the proximal small intestine, with a reduction in the mortality incident to subsequent operation, and (b) that, when the obstruction is due to kinking by adhesions and perpetuated by the distention itself, it may be permanently relieved by decompression

alone. However, a fairly large group of patients with obstruction remains in which gastroduodenal suction is not enough to relieve the distention and a still larger group in which, though the distention be relieved, the location, as well as the nature, of the obstructive lesion is still unknown. It is for these cases that we now offer a method of management that will often decompress the abdomen by completely emptying the entire small intestine proximal to the obstruction, and that has, in certain cases, enabled a restitution of normal intestinal action to occur without the necessity of surgical intervention. Moreover, having advanced the tube to the point of obstruction, it often becomes possible by the study of aspirated intestinal contents and by the injection of a minimal amount of an opaque medium through the tube to identify both the position and the nature of the obstructing lesion. Thus two of the three objectives of surgery may be met, but it can not be too strongly emphasized that the third indication remains and that whenever gangrene of the gut is suspected operation must continue to be the treatment of immediate choice.

From the Gastro-Intestinal Section, Kinsey-Thomas Foundation of the Medical Clinic, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania, and the Department of Surgery, Wayne University College of Medicine and Receiving Hospital, Detroit, Michigan.
Aided by a grant from the Committee on Scientific Research of the American Medical Association.
Dr. Abbott, H. F. M. Kirby, Fellow in Surgical Physiology.

Sir William Jenner

1815 1898

Fig 1 Paralytic ileus Case 3, F F. a, left, Small intestinal distention 4 days after operation b, Decompression of the intestinal tract by the passage of a No 14 F tube for aspiration fastened to a No 3 F tube bearing an air-filled balloon

hour. A length of 6 to 8 feet of tubing is generally enough to reach from the pylorus to the cecum (8 to 10 feet beyond the teeth) In obstructed cases a rate of about 1 centimeter in 2 minutes (1 foot in an hour) is nearer the average. It is important that the tubes be marked at 6 inch intervals so that the patient or the nurse may be given a schedule to insure correct speed of swallowing, as a coil in the stomach from too rapid passage will sometimes check its advance

RESULTS

Intubation for the relief of intestinal obstruction has been attempted on 16 individuals with failure in only 3 While the symptoms in one or two instances were mild, the patients as a rule, were desperately ill In 9 instances function returned spontaneously following a variable period of decompression Paralytic ileus and organic obstructions have responded in an essentially similar fashion (Figs 1, 2, and 3) In the 4 cases in which the obstructing lesion was studied roentgenologically after the injection of a barium sulphate suspension through the tube, the point of closure was identified and the end of the tube was found to be lying within a finger's length of the obstruction itself (Fig 4)

As the severity of intestinal obstruction can vary so widely, depending on the attendant circumstances, a brief sketch of each case

follows The data bearing upon the technique employed are presented separately in a summary table

CASE REPORTS

Patients who became obstructed while under observation

CASE 1 J K, male, 73 years of age, with symptoms of chronic prostatism, became slowly obstructed by a carcinoma of the cecum Intubation was carried out while he was in a state of shock from pain, distention, and vomiting He was so relieved that he pulled the tube out later that night At that time the abdomen was flat, peristalsis was normal, and his general condition was good Subsequently, however, distention recurred and operation without intubation was attempted, but he died

CASE 2 W S, male, 42 years of age suffered a spontaneous rupture of a duodenal ulcer, was operated upon, and convalesced normally for 7 days Fever and great abdominal distention, accompanied by streptococcic septicemia, then developed rapidly with a disappearance of peristalsis The obstruction was of a paralytic type associated with infection Intubation carried him over the period of ileus and ultimately, when he was able to eat, the tube was withdrawn without a recurrence of the symptoms

CASE 3 F F, male, aged 68 years had undergone an exploratory laparotomy because of sudden weight loss and constipation His abdominal cavity was practically normal but the patient was in an agony of fear, believing that he was dying of cancer. His obstruction was of a paralytic type probably psychogenic in origin A tube was passed and left in place until intestinal activity returned When he was once more able to eat normally, the tube was withdrawn and he continued in good health, free from digestive complaint (Fig 1).

METHOD

The procedure is based on the method described by Miller and Abbott for intubation of the small intestine. For the relief of intestinal obstruction it is best carried out as follows. The patient is lifted to a litter and brought to a fluoroscopic room. The litter mattress with the patient on it is slid upon the fluoroscopic table. A No. 14 or No. 16 F duodenal tube with a No. 3 F rubber tube lightly tied to it is passed in through the patient's nose and out at his mouth. On the end of the larger tube is tied a duodenal bucket and on the end of the fine tube stiffened by a centimeter length of small brass tubing is tied a thin rubber balloon which, when inflated, holds 50 cubic centimeters of air. The collapsed balloon is tied beside the tip of the larger tube and then the distal end of the apparatus is drawn back into the patient's pharynx and swallowed. When the duodenal bucket can be seen by the fluoroscope to have reached the mid duodenum a volume of about 30 cubic centimeters of air is injected into the balloon while constant suction is maintained on the larger tube. As the gas and fluid are sucked out of the gut the intestinal walls contract and, regaining their normal propulsive movement, they force the balloon ahead. The suction likewise collapses the intestine loop by loop, as the tip of the tube advances until the obstruction is reached, by which time relief of distention and with it relief of pain have occurred. In some instances no other treatment is necessary.

Variations in the apparatus are occasionally desirable. Our standard two lumen tube¹ has been used at times but has proved too large and stiff to be passed with ease through the nose of an average patient. The ideal tube should have two lumina, one very large for the aspiration of intestinal contents and one very small for the introduction of air into the balloon. Such a tube has just been devised for us and is proving satisfactory.*

Variations in the method of passing the tube have been used. In many individuals the nose will permit the passage of the tube with the balloon and a Swiss duodenal tip already

attached. When fluoroscopic control seems inadvisable, as is often the case, the tube may be started according to the usual routine for passing any duodenal tube, the balloon being inflated when characteristic duodenal contents begin to flow. If for any reason the patient can not be rolled on his right side to let the bucket "sink" to the pylorus, he may be rolled on his left side and sufficient air placed in the balloon to "float" it to the pylorus. When this is attempted the stomach must first be emptied as air in the stomach will prevent the balloon from "floating," otherwise suction should be deferred until the tube has entered the duodenum as the pylorus is often dilated together with the stomach and so may be more easily traversed before than after deflation has been accomplished.

In the cases in which an organic obstruction is suspected, diagnostic measures may now be undertaken. The injection of a small amount of barium sulphate in dilute suspension will frequently indicate the point of constriction and the pattern of the intestinal mucosa. The examination of the aspirated contents for blood further aids in distinguishing intrinsic lesions involving the mucosa from extrinsic lesions such as adhesions which have obstructed the lumen by pressure from without. Manometric determinations of the pressure exerted by the intestinal wall upon the balloon give further indication of the element of spasm involved.

Having deflated the gut and if possible identified the obstruction by barium injection and study of the intestinal contents, one may leave the apparatus in place for days with constant or intermittent suction. If function has been restored the tube may still be left in place without suction being applied to meet further emergencies should they arise. Otherwise the balloon should be deflated and with gentle traction the tube may be pulled backward through the small gut and stomach, even though the tip had reached the ileocecal valve. The longest time required for the withdrawal of 10 feet of tubing in our experience has been 15 minutes; ordinarily 10 minutes suffice.

In a normal individual the apparatus will advance along the intestine at the rate of about 1 centimeter per minute or 2 feet an

Fig 1 Paralytic ileus Case 3, F F a, left Small intestinal distention 4 days after operation b, Decompression of the intestinal tract by the passage of a No 14 F tube for aspiration fastened to a No 3 F tube bearing an air-filled balloon

hour. A length of 6 to 8 feet of tubing is generally enough to reach from the pylorus to the cecum (8 to 10 feet beyond the teeth) In obstructed cases a rate of about 1 centimeter in 2 minutes (1 foot in an hour) is nearer the average It is important that the tubes be marked at 6 inch intervals so that the patient or the nurse may be given a schedule to insure correct speed of swallowing, as a coil in the stomach from too rapid passage will sometimes check its advance

RESULTS

Intubation for the relief of intestinal obstruction has been attempted on 16 individuals with failure in only 3 While the symptoms in one or two instances were mild, the patients as a rule, were desperately ill In 9 instances function returned spontaneously following a variable period of decompression Paralytic ileus and organic obstructions have responded in an essentially similar fashion (Figs 1, 2, and 3) In the 4 cases in which the obstructing lesion was studied roentgenologically after the injection of a barium sulphate suspension through the tube, the point of closure was identified and the end of the tube was found to be lying within a finger's length of the obstruction itself (Fig 4)

As the severity of intestinal obstruction can vary so widely, depending on the attendant circumstances, a brief sketch of each case

follows. The data bearing upon the technique employed are presented separately in a summary table.

CASE REPORTS

Patients who became obstructed while under observation

CASE 1. J K, male, 73 years of age, with symptoms of chronic prostatism, became slowly obstructed by a carcinoma of the cecum Intubation was carried out while he was in a state of shock from pain, distention, and vomiting He was so relieved that he pulled the tube out later that night At that time the abdomen was flat, peristalsis was normal and his general condition was good Subsequently, however, distention recurred and operation without intubation was attempted, but he died

CASE 2 W S, male, 42 years of age, suffered a spontaneous rupture of a duodenal ulcer, was operated upon, and convalesced normally for 7 days Fever and great abdominal distention, accompanied by streptococcic septicemia, then developed rapidly with a disappearance of peristalsis The obstruction was of a paralytic type associated with infection. Intubation carried him over the period of ileus and ultimately, when he was able to eat, the tube was withdrawn without a recurrence of the symptoms

CASE 3 F F, male, aged 68 years had undergone an exploratory laparotomy because of sudden weight loss and constipation His abdominal cavity was practically normal but the patient was in an agony of fear, believing that he was dying of cancer His obstruction was of a paralytic type probably psychogenic in origin A tube was passed and left in place until intestinal activity returned. When he was once more able to eat normally, the tube was withdrawn and he continued in good health, free from digestive complaint (Fig 1).

Fig 2

Fig 2 Inflammatory intestinal obstruction. Case 4. K. A. a left. Widely dilated small intestinal loops filled the abdomen. b Decompression of the abdomen after intubation. At the time this film was taken the patient had swallowed the tube too rapidly with resultant coiling in the stomach.

Fig 3

Fig 3 Mechanical intestinal obstruction. Case 9. V. B. a left. Marked small intestinal distention was present before intubation. b Decompression of the abdomen following the passage of a No. 14 F. and a No. 3 F. tube.

CASE 4. K. A. male aged 40 years underwent a resection of gangrenous ileum which was found strangulated in a ventral hernia. Convalescence was interrupted by the occurrence of intestinal obstruction which came on with the development and drainage of a pelvic abscess and was probably based on inflammatory swelling of the intestinal wall. Following sustained decompression of the lower ileum he made an uneventful recovery (Fig. 2).

CASE 5. D. P. a young adult male suffered slowly increasing intestinal obstruction from the sixth to the tenth day after an emergency operation for a gunshot wound of the abdomen which had punctured his stomach. The obstruction which was long continued was probably at the start on an inflammatory basis with the mechanical factor of adhesions developing later. The point of obstruction was identified by the fluoroscopic observation of an opaque mixture injected through the tube. He was later operated on the adhesions were released and a satisfactory recovery followed.

CASE 6. J. M. male aged 15 years began to develop symptoms of intestinal obstruction 16 days after the surgical repair of a gunshot wound of the small intestines. The obstruction in this case was on

an inflammatory basis. After adequate decompression of his lower small intestine operation was rendered unnecessary by the patient's recovery.

CASE 7. G. L. a man of 62 years became progressively distended with paralytic ileus during a 9 day period following the performance of a suprapubic cystostomy for the removal of a vesical calculus. Intubation was easily accomplished with relief of his symptoms and restitution of normal intestine activity. He remained free from digestive symptoms thereafter.

Patients admitted to the hospital because of existing intestinal obstruction

CASE 8. R. J. female of 27 years had suffered three hospitalizations for intestinal obstruction following a cesarean section 4 years before. During one of these admissions she was operated on for lysis of adhesions. She was finally admitted after 4 days of vomiting with symptom probably due to edema developing in the intestinal wall at a point of partial obstruction present since her former operation. The location of the obstruction was identified by fluoroscopy of an injected opaque medium. This attack was completely relieved by intestinal intubation.

Fig 4 The localization of a mechanical obstruction. Case 12 W S a, Small intestinal distention was marked prior to intubation. The colon is outlined by the unexpelled residue of a barium enema. b The small intestine has been decompressed by the passage of a No. 14 F and a No. 3 F tube. Barium has been injected down the tube and has regurgitated up a dilated loop of ileum. Its ad-

vance is blocked by a point of narrowing (arrow) just distal to the air-filled balloon and the tip of the tube. c, After film b was taken vigorous massage was successful in forcing barium through the constricted area of intestine (arrow) beyond which the opaque medium passed in a normal manner. Operation revealed a band of omentum binding this loop of ileum to the promontory of the sacrum.

Operation is contemplated as soon as she recovers from an acute pelvic inflammatory disease.

CASE 9 V B, a young negress, had suffered since the delivery of her child 2 months before from attacks of abdominal colic and vomiting, coming on with increasing frequency. Complete intestinal obstruction had occurred 48 hours prior to admission and was probably on a mechanical basis secondary to antecedent inflammation. The point of obstruction was located by the fluoroscopic observation of a suspension of barium sulphate injected through an intestinal tube and was found to be within 4 inches of the ileocecal valve. Normal intestinal activity eventually returned and she was discharged free from symptoms (Fig 3).

CASE 10 W P, negro, male, 68 years of age, was admitted after 3 days of abdominal colic with vomiting and failure to pass gas or feces by rectum. Intestinal intubation relieved his symptoms. The obstruction was of mechanical origin due to a malignancy at the ileocecal valve. This lesion was likewise identified by the injection of a barium sulphate suspension. An ileocolostomy was performed and he has refused to have the mass resected.

CASE 11 J F, male, 31 years of age, was admitted with intestinal obstruction beginning 2 months after the drainage of an appendiceal abscess. Intubation brought complete relief. Subsequently an appendectomy was performed with normal convalescence. At operation a portion of the terminal ileum was found adherent to the abdominal wall. This was not released because of technical difficulties. He was admitted again with intestinal obstruction, swallowed the tube himself, and was relieved. This succession of relief, withdrawal of the tube and recurrence of symptoms occurred repeatedly for a month after

which his digestive tract continued to function fairly normally. Obstruction in this instance was probably due to an underlying mechanical factor with superimposed local inflammation.

Patients with partial intestinal obstruction intubated primarily to locate the lesion after the failure of other diagnostic procedures

CASE 12 W S, the patient previously described as Case 2 was treated for septicemia by transfusion of sulphanilamide, the drainage of metastatic abscesses and supportive treatment until by the seventh week his temperature was normal and convalescence was established. Flatulence then returned, succeeded by slowly increasing distention, nausea, and colic. Roentgenoscopy showed gas filled small intestinal loops. The colon appeared normal when studied by barium enema. Constant suction drainage of the duodenum failed to relieve his symptoms. A tube was passed as far along the ileum as it would go, with prompt relief. A barium suspension was then injected locally and a point of partial obstruction was located. The abdomen was opened, a band of inflamed omentum was found constricting the ileum at the point indicated and with the release of this an uneventful recovery followed. (IV)

CASE 13 R O, female, aged 40 years, had suffered for 14 years from recurrent periumbilical pain with nausea and flatulence. Repeated gastro-intestinal roentgenological studies had failed to identify a diseased point but indicated abnormal small intestinal function. A tube was passed to the middle ileum beyond which point it would not go. A barium sulphate suspension injected through the tube demonstrated an acute angulation which next day was found on surgical exploration, to have been pro-

Fig 2

Fig 3

Fig 3 Mechanical intestinal obstruction. Case 9 V B. a left Marked small intestinal distention was present before intubation. b Decompression of the abdomen following the passage of a No. 14 F and a No. 3 F tube.

CASE 4 K A male aged 40 years underwent a resection of gangrenous ileum which was found strangulated in a ventral hernia. Convalescence was interrupted by the occurrence of intestinal obstruction which came on with the development and drainage of a pelvic abscess and was probably based on inflammatory swelling of the intestinal wall. Following sustained decompression of the lower ileum he made an uneventful recovery (Fig 2).

CASE 5 D P a young adult male suffered slowly increasing intestinal obstruction from the sixth to the tenth day after an emergency operation for a gunshot wound of the abdomen which had punctured his stomach. The obstruction which was long continued was probably at the start on an inflammatory basis with the mechanical factor of adhesions developing later. The point of obstruction was identified by the fluoroscopic observation of an opaque mixture injected through the tube. He was later operated on the adhesions were released and a satisfactory recovery followed.

CASE 6 J M male aged 15 years began to develop symptoms of intestinal obstruction 16 days after the surgical repair of a gunshot wound of the small intestines. The obstruction in this case was on

an inflammatory basis. After adequate decompression of his lower small intestine operation was rendered unnecessary by the patient's recovery.

CASE 7 G L a man of 62 years became progressively distended with paralytic ileus during a 9 day period following the performance of a suprapubic cystostomy for the removal of a vesical calculus. Intubation was easily accomplished with relief of his symptoms and restitution of normal intestine activity. He remained free from digestive symptoms thereafter.

Patients admitted to the hospital because of existing intestinal obstruction

CASE 8 R J female of 27 years had suffered three hospitalizations for intestinal obstruction following a cesarean section 4 years before. During one of these admissions she was operated on for lysis of adhesions. She was finally admitted after 4 days of vomiting with symptoms probably due to edema developing in the intestinal wall at a point of partial obstruction present since her former operation. The location of the obstruction was identified by fluoroscopy of an injected opaque medium. This attack was completely relieved by intestinal intubation.

decompressed has not previously been described. That such is the case and that it offers a valuable therapeutic method for the relief of such cases as are here reported is clear. We feel that the additional handling of a shocked patient, necessitated by the procedure, is justified by the benefit derived and that the delay caused in patients ultimately requiring surgery is not great enough to be of serious consequence. This delay can be lessened, moreover, by the use of the long tube from the start in a patient requiring decompression rather than by passing a duodenal tube first and attempting deflation of the jejunum and ileum only if the shorter instrument is inadequate. The tip of any tube is usually found to have entered the duodenum before it has been many hours in the stomach, so that if one has started with the long tube and the patient's response is not satisfactory he then need but inflate the balloon and allow the apparatus to advance as far as it will. The value of the procedure must depend on the judgment of the individual physician. When gangrene of the intestinal wall or a clear localization of obstruction, as in an external hernia, is present, small intestinal intubation constitutes a definite added hazard, but, excluding these cases, there still remain many for which small intestinal intubation should be tried before surgery, as a means of improving the patient's condition, of decreasing the technical difficulties of the operation, and not infrequently of rendering the operation unnecessary.

CONCLUSION

A double lumen tube or a pair of tubes may be passed rapidly down either a normal or an obstructed small intestine by inflating within the duodenum a rubber balloon on the end of the tube to a degree sufficient to stimulate propulsive peristalsis. This intestinal response

takes place whether the obstruction is due to infection, mechanical occlusion, or paralytic ileus. Gas and fluid may be aspirated from the entire length of the small gut by the application of constant suction as the tube advances. Prompt and striking symptomatic relief occurs as the decompression of the intestine is accomplished.

By the injection of very small amounts of barium sulphate suspension down such a tube, by microscopic study of the intestinal contents aspirated, and by the character of the intestinal contractions, the location and often the nature of the obstructing lesion may be determined.

The advance of the tube has been found to proceed until the tip has reached the obstructed region.

In not a few instances decompression alone has released the obstruction, rendering operation unnecessary.

We wish to thank Dr. Eldridge L. Eliason and Dr. I. S. Ravdin for the privilege of reporting cases from their services and Dr. E. P. Pendergrass and his associates and Dr. C. Kenning and his associates for assistance with roentgenological phases of this work.

duced by a ring of adhesions doubling back the ileum upon itself. Recovery was uneventful.

Failures

CASE 14. A D. female 75 years of age, was intubated 1 hour after operation for a strangulated femoral hernia. The procedure was attempted because inversion of a small gangrenous area of the intestinal wall had been necessary and ileus was expected. The tube could not be made to leave the stomach.

CASE 15. W B. a laborer 50 years of age was intubated for progressive intestinal obstruction coming on insidiously weeks after an operation for the relief of a subdiaphragmatic abscess. He had suffered a spontaneous rupture of a duodenal ulcer a year and a half before had developed a duodenobronchial fistula and at the time intubation was attempted was in extremis with ascites and an open external fistula. The tube could not be made to leave the stomach. Death ensued 48 hours later.

CASE 16. L V. aged 81 years was admitted with intestinal obstruction. A large diaphragmatic hernia was found and intubation was attempted. The tube could not be passed beyond the stomach. Death ensued and at necropsy it was found that the diaphragmatic hernia was inconsequential, the obstruction being caused by a Richter's hernia of the femoral canal.

It has been shown by Scheltema and by Einhorn that a tube left in the digestive tract will ultimately appear at the anus. Jones and Pierce have used a balloon on a tube and observed its passage throughout the gut and the studies of Miller and Abbott have led to methods for rapidly reaching and emptying part of the small intestine. On the basis of their experience similar intubations have been accomplished in patients with varying types of obstruction of the intestine. From the diagnostic point of view, a study of the material aspirated is of importance. Chemical analysis is revealing the degree to which the electrolyte balance of the intestinal contents is disturbed and a microscopic examination of the sediment for blood or cells contributing evidence as to the nature of the obstructing lesion. A manometer or recording instrument connected with the balloon likewise is useful in estimating the motor responses of the intestine above the obstruction. The rapidity with which a distended and silent jejunum or ileum or one vigorously manifesting reverse flow will revert to normal motor function when

terminal arterioles and capillaries into the venous system that determines the amount of blood pumped by the heart. This rate, on the other hand, is determined by the amount of blood required to keep the diffusion pressures in them of oxygen and carbonic acid approximately constant. Y. Henderson has further developed this idea in his "venopressor reflex." Consequently the regulation of both circulation and breathing is essentially chemical and is governed by the same factors.

Thus it becomes obvious that any cause which interferes with the maintenance of normal partial gas pressures in the tissues may start asphyxia. Reduction of oxygen supply, —caused by obstruction of the air-ways or by decreased permeability to gases of the respiratory pulmonary membrane (inflammatory edema, destructive lesions) or by reduction of the respiratory field (retention of exudates, bronchial obstruction, atelectasis, pneumothorax, empyema), or by reduction of oxygen in the inspired air, has its immediate repercussion upon the function of the respiratory center. Anoxemia of the respiratory center causes increase of the respiratory rate which may or may not correct anoxemia. If it does not, a vicious cycle starts which, if not broken, leads to fatigue of the respiratory center and death. This cycle begins with tachypnea which washes out carbon dioxide and leads to apnea. Because of the elimination of the normal stimulus of the respiratory center there is a further increase in anoxemia; furthermore, because of the decreased partial tension of carbon dioxide, hemoglobin is saturated to a higher degree with the available oxygen (Bohr phenomenon). Thus cyanosis may be absent although anoxemia is increased because of the production of a more stable oxyhemoglobin compound under decreased carbon dioxide tension. On the other hand, the drop in partial pressure of carbon dioxide in the tissues decreases the muscular tonus necessary for the propulsion of the blood from the terminal arterioles and capillaries into the veins and the right heart (venopressor reflex of Y. Henderson). This author, to whom we owe so many important contributions on this subject, believes that the decrease of carbon dioxide abolishes mus-

cular tonus. This is possible. However, as we do not know exactly what muscular tonus is, the actual existence of this reflex is subject to discussion. Keith called the terminal arterioles "peripheral hearts" meaning, as does Henderson, their importance in the propulsion of the blood. Whatever the mechanism may be, it is certain that a considerable decrease of carbon dioxide causes a drop of arterial pressure and peripheral stasis which further increases anoxemia.

Moreover, just as respiratory disturbances are caused by anoxemia so does impaired cardiac action due to organic diseases of the heart lead to anoxemia by defective circulation, blood stasis, and finally pulmonary edema. Thus, asphyxial death in cardiac disease is caused by the same mechanism as asphyxial death in pulmonary diseases or in obstruction of the air-ways.

These considerations were necessary, I believe, because, among many internists and surgeons, there is still a tendency, regarding the mechanism of asphyxia, to separate circulation from respiration and to disregard this close correlation and interdependence existing between them. Asphyxia can be defined as "the disturbance of gas exchanges in the tissues caused by abnormal breathing, or abnormal circulation, or of defective oxydative ability of the tissues"; therefore, it should be treated as a whole, with the main objective of re-establishing the normalcy of gas exchanges in the tissues.

It should always be borne in mind that progression of asphyxia due to defective oxygen supply may proceed with extreme rapidity. In fact, we possess no other reserve of oxygen in our organism than 600 cubic centimeters which is present in the 4,000 cubic centimeters of air contained in our lungs (which contains 15 per cent of oxygen). This amount is hardly sufficient for maintaining life for 2½ minutes when all supply from the outside is cut off. In fact, seven or eight breaths of a neutral gas, such as nitrogen, or hydrogen, bring loss of consciousness due to oxygen want and are followed by death if oxygen is not replenished.

The scope of this study does not allow a more detailed discussion of the chemical and

MECHANICAL RESUSCITATION IN ADVANCED FORMS OF ASPHYXIA

A Clinical and Experimental Study in the Different Methods of Resuscitation

POI N CORYLLOS M.D., F.A.C.S. New York, New York

DEATH of the body as a whole in higher organisms, said Paul Bert (1878), is always due to want of oxygen, whatever its cause may be. Life is continued so long as exchanges of oxygen and carbon dioxide in the tissues are carried on in a normal way. Gas exchanges depend upon and are regulated by their respective partial pressures and the aim of pulmonary ventilation is precisely to maintain these pressures at constant levels whatever

From the Departments of Surgical Research of Cornell University Medical College and of Thoracic Surgery of Metropolitan and Sea View Hospitals

may be the metabolic needs of the different tissues

On the other hand, the supply of oxygen and the removal of carbon dioxide are accomplished by the circulating blood. Therefore circulation is but a part of respiration and both co-operate in the closest way in order to maintain and preserve constant the conditions of life in the internal environment of the blood, as Claude Bernard said in his 'Lessons on the Phenomena of Life'

Thus we arrive at the fundamental conception of the physiology of respiration—that respiration and circulation are so regulated as to keep both oxygen pressure and oxygen ion concentration very nearly constant in each part of the body, and that respiration and circulation are regulated by the changes in gas pressures in the tissues during life. When once, says Haldane, the fundamental fact is grasped that the flow of blood through the body is correlated with gas pressures in the capillaries, the whole physiology of circulation appears in a new light. It is neither the heart nor the nervous centers which govern the circulation rate but the tensions of gas in the tissues as a whole and they govern it with an accuracy and delicacy comparable to that with which they govern breathing. The heart and vasomotor system are only the executive agents which carry out the bidding of the tissues just as the lungs and nervous system do in the case of breathing.

Thus the problem of the regulation of circulation under normal conditions seems in the main to resolve itself into that of the regulation by the tissues of the amount of blood supplied to the heart (Haldane). In other words it is the rate at which the systemic blood is allowed through the tissues from the

Fig. 1. Lung of dog. 2. Use of the apparatus during 4 hours. Slight marginal consolidation of the left lower and partial consolidation of the left upper and right leaf of the accessory lobes.

lower jaw relaxes because of gradual suppression of muscular tonus. Spurious inspiratory movements of lips and nostrils replace real respiratory ones and no effective respiratory movements can be detected. The skin is clammy and covered with cold sweat. The radial and femoral pulses are no longer perceptible. Patella reflexes disappear and the sphincters relax. Heart beats are uncertain and it is impossible to say at this phase whether the patient is still alive or that death has occurred.

These are the three principle forms of asphyxia with which we are usually faced. All intermediate forms may be encountered and the passage from one to the other may occur with disconcerting speed.

Time is of paramount importance in the management of asphyxia. One should never forget that it is easy to cope with slight asphyxia whereas it is very difficult, if not impossible, to resuscitate a man or animal after the heart has ceased to beat. Therefore, at the slightest threat of asphyxia, measures for resuscitation should start at once without waiting for possible spontaneous resumption of respiration.

The considerations mentioned give the key to the alarming rapidity with which asphyxial death may occur in patients with pulmonary diseases. In fact these patients are strongly handicapped to any increase of their anoxemia because of their chronic anoxemia due to the pulmonary disease. This factor is of paramount importance in the complete understanding of asphyxial accidents in these patients and of the requirements for successful resuscitation. Therefore, chronic anoxemia deserves special consideration.

Chronic anoxemia In cases with chronic pulmonary suppuration, such as tuberculosis, abscess of the lung, bronchiectasis, extensive silicosis or malignancies and more so in acute pulmonary diseases especially in bronchopneumonia, anoxemia is always present because of uneven pulmonary ventilation, inflammatory edema of the respiratory membrane, partial destruction of the pulmonary parenchyma or atelectatic and fibrotic dismemberment of a portion of the lung. As a rule compensatory polycythemia is present in

these cases. The slightest increase of anoxemia in these patients may be the cause of asphyxia and rapid death, apparently disproportionate to the cause which has produced it. Thus in advanced pulmonary tuberculosis even moderate pulmonary hemorrhage, or passage into the bronchial tree of a few cubic centimeters of pus from an empyema cavity, or obstruction of a bronchus of the healthy lung with bronchial exudate coming from the diseased side, or spontaneous pneumothorax of the diseased or of the contralateral side, may cause rapidly lethal asphyxia. For example, a patient who during bedrest is only slightly dyspneic, and who, disobeying orders, gets out of bed to go to the lavatory, may drop dead because of this otherwise slight exertion.

The knowledge of this chronic anoxemia, to which the organism may be temporarily adjusted by decreased oxygenation rate in the tissues and possibly by active oxygen secretion of the alveolar epithelium (Ludwig, Haldane), is of the greatest importance to the internist and the thoracic surgeon. Haldane wrote in his classic *Treatise on Respiration*: "If there were only one clinical lesson derived from the perusal of this book I hope that it would be that chronic anoxemia is a very serious condition the continuance of which ought to be prevented if at all possible."

These considerations make it easy to understand the dangers to which these patients are exposed when they are operated upon. It is my contention that the prohibitive mortality at the beginning of thoracic surgery, more especially in tuberculosis of the lung and other chronic suppurations of this organ, was due to the imperfect knowledge of chronic oxygen want. Respiratory failures, acute dilation of the right heart, and cardiac decompensation were the usual diagnoses on the death certificates. We know today that all these vague terms must be replaced by "anoxemia." If actually, without any radical changes in operative technique, we are able to operate upon patients with even far advanced and bilateral pulmonary tuberculosis or bronchiectasis with a remarkable degree of safety, it is because of better knowledge of chronic anoxemia, of improved administration

nervous regulation of respiration which I have presented elsewhere in their relation to the tuberculous lung (5, 6) I shall mention here only two more points. First is the so called Herring Breuer reflex in which expansion of the alveoli causes arrest of inspiration and starts expiration, and collapse of the alveoli causes arrest of expiration and starts inspiration. The legs of these reflexes are represented by afferent and efferent fibers included in the vagus acting upon the respiratory center. Conversely, through this reflex, distention and collapse of the lung in the mechanical treatment of asphyxia may act as powerful stimuli upon the respiratory center. The second point to be mentioned is the significance of rhythmic respiratory variations of intrapulmonary and intrapleural pressures upon the function of the heart. It is obvious that marked increase of the intrapulmonary and, consequently, of the intrapleural pressures hinder the suction of blood into the large veins and interfere with their emptying into the right heart. In these cases venous blood pressures rise and the amount of blood passing into the right heart, the lungs, and back into the left heart, may be considerably decreased. However, as will be shown later, this phenomenon is of no great importance so long as intrapulmonary hyperpressures are not very high or of long duration, this is due to the marked differences of blood pressures in the large arteries and the large veins.

ASPHYXIA

Causes. The causes producing asphyxia may be divided into seven major groups (Meakins and Davies)

1. Insufficient partial pressure of oxygen in the inspired air (high altitudes)
2. Obstruction of air passages or resistance to respiration
3. Obstruction to the passage of gases from the alveoli to the blood (edema, inflammation, exudation, destructive lesions emphysema)
4. Alteration of oxygen carrying capacity of the blood (anemia, carbon monoxide nitrate or chlorate poisoning)
5. Circulatory failure
6. Pollution of the oxygenated blood by its

mixing with the venous blood (Uneven ventilation of the lungs unaerated channels, congenital cardiopathies and the like)

7. Inhibition of oxydative processes in the tissues (cyanide poisoning)

Of all forms of asphyxia the most important for the internist and the thoracic surgeon are the ones due to obstruction and resistance to respiration, to inflammatory edema of the alveolar membrane to the creation of unaerated channels with pollution of the oxygenated blood and to the toxic action upon the respiratory center of anesthetic gases.

Forms of asphyxia. Asphyxia should be divided, according to its degree into three forms

1. *Slight asphyxia.* This form is characterized by persistence of respiration and circulation, dyspnea is present and is accompanied by a variable degree of cyanosis. The degree of cyanosis, however, is not always proportionate to the degree of asphyxia. Slight resistance to respiration by partial tracheal obstruction may cause considerable cyanosis with gasping for air, because of retention of carbon dioxide although the grade of anoxemia may be slight. On the contrary in the presence of extensive involvement of the bronchial and alveolar mucosa cyanosis may be slight or absent (gray cyanosis) while periodic or shallow rapid breathing indicate marked anoxemia. Gray cyanosis follows considerable washing out of carbon dioxide (Bohr phenomenon), and shows an advanced degree of anoxemia.

2. *Moderate asphyxia.* If not corrected in time, slight asphyxia progresses rapidly to a more advanced stage. The rate of respiration becomes greatly increased, periodic and shallow breathing develops, leading to fatigue of the respiratory center. Arterial blood pressure falls after a temporary elevation. Venous pressure rises and convulsions may appear at this phase.

3. *Severe asphyxia.* These forms are characterized by apnea, extreme drop of arterial pressures and failing or arrest of the heart. After convulsive attacks the body gradually relaxes and becomes flaccid. Consciousness is gone, the eyes are glassy, corneal reflexes disappear, and pupils begin to dilate. The

there was loss of muscular tonus with dropped jaw, dilated pupils and abolished glottis reflex

This method, however, presents two serious drawbacks. One, common to all resuscitation procedures, is that the air-ways are not always patent. In the operating room or in the postoperative wards this is easily insured by the introduction of an intratracheal catheter. In the field this can be also easily accomplished with Flagg's suction bottle and the introduction of a pharyngeal air-way or of a Magill catheter. The second drawback, specific to this procedure, is the exposure of the operator to contamination by tuberculous patients, and the impossibility, because of the fetor, of carrying the insufflation for any length of time in cases with anaerobic suppuration of the lung.

It was precisely the necessity of replacing the surgeon or the anesthetist by some mechanical device accomplishing the same or similar work that has induced me to investigate the different apparatus on the market based on the pulmotor principle. Thus I was led to the experimental and clinical study of the apparatus known as the E & J resuscitator.

Mechanical resuscitation. The E & J apparatus consists of two parts. One acts as a simple inhalator. The other as resuscitator. The latter is a mechanical device composed of a number of valves which are activated by the pressure of the usual oxygen or carbon dioxide in oxygen mixture delivered in tanks under a pressure of 2,000 pounds. When a positive pressure of 14 millimeters of mercury is built up in the mask of this apparatus the valves are automatically reversed and a suction of -9 millimeters of mercury is produced which is again followed by a positive pressure of 14 millimeters of mercury, and so on. In other words, it is a machine based on the principle of the automatic type of the Draeger pulmotor, in which the pressures are constant whereas the volumes of gas vary with the capacity of the lung of the patient.

Such an apparatus, however, was subject to a number of serious criticisms which required thorough experimental study before any clinical trial could be attempted. The principal objection is that intrapulmonary

Fig 2 Testing the E and J resuscitator. The two tubes coming from the apparatus, 4 and 5, are connected with two T tubes, 1 and 2. The vertical branches of these tubes are connected with a Y tube, 3, which is connected with two registering manometers, mercury and chloroform. On the other hand the two tubes, 4 and 5, are connected with a rubber bag representing the lung.

and intrapleural pressures produced by this apparatus during inspiration and expiration, are positive during inspiration and negative during expiration, that is the opposite to those in normal respiration. Therefore, a list of requirements was drawn which was submitted to strict experimental investigation. These requirements are the following:

1. Is this apparatus technically reliable and constant in its action? Is it constant in both positive and negative pressures independently of pressure in gas tank, does it function regularly under prolonged action?

2. Is its prolonged use without any danger, either organic upon the lung or functional upon respiration and circulation?

3. What is the efficacy of this apparatus in cases of asphyxia; mechanical (submersion, laryngeal, or tracheal obstruction) or chemical (anesthetic gases)?

4. Can this apparatus be used, experimentally, in long operations upon intrathoracic organs (heart, lung, and esophagus) in which the pleural cavity is maintained open for a long period (over 3 hours)?

of anesthesia, and of more rational pre operative preparation and postoperative management of these patients. This has been accomplished by a closer correlation between operating work and the research laboratory. Chest operations are conducted today with the accuracy and minute precautions of physiological experiments, conversely laboratory animals are subjected to similar operations after previous preparation rendering their condition as similar as possible to our patients (5).

The result of this close co-operation of operating room and laboratory during the last 5 years in the two departments of thoracic surgery under my direction, in the Metropolitan and Sea View Hospitals of the City of New York, has been that the mortality has fallen from 20 per cent of 5 years ago to below 8 per cent even though patients with far more advanced conditions are being submitted to surgical treatment, especially during the last 3 years.

The ideas on asphyxia and resuscitation expressed in this study have been developed during this work. They may, occasionally, be in disagreement with generally accepted opinions, nevertheless they are backed, I believe, by substantial clinical and experimental evidence.

MANAGEMENT OF ASPHYXIA

Little will be said regarding the first two forms of asphyxia. Careful removal of any foreign material obstructing the bronchi followed by manual rhythmic compression of the chest and inhalation with 7 to 10 per cent carbon dioxide in oxygen is generally sufficient to restore regular respiration. However prolonged administration of carbon dioxide in oxygen (5 to 7 per cent) may be required after resuscitation until the danger is over. This is especially important in carbon monoxide poisoning in which protracted oxygen carbon dioxide inhalation treatment is of paramount importance for complete recovery and prevention of complications.

More important and far more difficult is the management of the severe forms of asphyxia. I want to insist upon the point that in cases with apnea no time should be

lost with attempts of resuscitation by inhalation and manual artificial respiration. This applies not only in chest surgery where manual resuscitation is out of the question but also in all cases of asphyxia in which the patient does not breathe. It is obvious that in such cases oxygen has to be forcibly introduced into his lungs. Even beginning flaccidity causes the chest to collapse in position of extreme expiration, so that little air, if any, can be aspirated into the lung by the expansion of the chest following the compression by the methods of Shaeffer or Sylvester or any other. I agree perfectly with Yandel Henderson that "the inspirations that occur between compressions (in manual artificial respiration) are produced wholly by the tonic elasticity of the victims' mid expansion. After the body is flaccid no form of manipulation can induce the slightest inspiration."

Mouth to mouth insufflation. The mode of resuscitation that has given me the best results in cases of severe asphyxia, is the immediate application of mouth to mouth insufflation. I know of no method of resuscitation more efficient and more rapidly effective. In a number of instances with patients apparently dead, this method has produced striking resuscitations. It is a puzzle to me that this mode of resuscitation is not mentioned in the treatise of Haldane or in the writings of Yandel Henderson on resuscitation. Waters and Bennet, on the contrary in a recent paper in which they had studied the respective merits of different methods of manual resuscitation concede that the best of them (Sylvester's) is second only to mouth to mouth insufflation. Physiologically this is a sound procedure because it allows the immediate administration of the correct mixture of carbon dioxide in oxygen under the correct conditions of temperature, moisture, pressure and at the proper intervals. Moreover it takes advantage of the powerful Hering Breuer reflex.

Such striking results have been obtained by this procedure that it has been routinely used in my services during the last 10 years in all patients with asphyxia. Patients have been revived in whom the heart beats could hardly be detected and only by the movements of intracardiac needle, and in whom

Fig 5 Action of intrapulmonary hyperpressure (20 cm. of water) and hypopressure (-20 cm of water) upon arterial and venous pressures. From up down, arterial pressure, intrapulmonary pressure, venous pressure and time in seconds. As the intrapulmonary pressure rises the arterial pressure drops and venous pressure rises (graph of Rost)

rapidly to 14 millimeters of mercury, 3, and falls almost vertically to minus 9 millimeters of mercury, 4, from which it rises to a slightly negative pressure, 5. If we neglect the intermediate oscillations due to the play of the valves and the "jumps" of the manometer (Fig. 3B) we can distinguish in the action of the apparatus two phases. (1) $1'$, $2'$, $3'$ of insufflation and a second, $3'$, $4'$, $5'$, of suction. Before the rise as before the fall, we find a period of slightly positive, $1-2$ and another of slightly negative, $0-1'$ pressures which constitute two-thirds of the cycle.

As the tempo of the cycle depends upon and is regulated by the pressure obtained, it becomes more rapid when the capacity of the lung (the bag here) is decreased and slower when the capacity is increased. Likewise it is influenced by the "volume" of gas allowed to enter the apparatus. Thus, obstruction of the air passages is immediately signaled by the rapid tempo of the apparatus.

On the contrary, the changes occurring in the pressure in the gas tank as it empties were shown to be without any marked influence upon the pressures and rhythm of the respiratory cycle. Tracings were taken with pressures in the tank decreasing from 1800 to

30 pounds. Figure 4 shows that there were no appreciable changes either in the height or in the frequency of the oscillation when the pressure of the tank has fallen to only 30 pounds.

The apparatus was tried in continuous function for 12 hours without showing any changes in the tracings.

It was concluded, therefore, that the mechanical construction of this apparatus insures a regular, accurate, and prolonged function which is maintained unchanged until the tank is practically empty (30 pounds' pressure).

Effects of prolonged action of the apparatus upon normal dogs (without previous operation). The problem to solve was whether prolonged use of the apparatus on normal dogs caused any organic lesion of the lung or any functional disturbances of respiration and circulation, and for how long the use of this apparatus could be prolonged without any untoward effects.

Before giving our experimental findings I think it is of interest to quote from the literature on the effects on intrapulmonary hyperpressures and hypopressures.

Chillingworth and Hopkins (1930) carried

Fig 3 Graphs taken with the outlay shown in Figure 2 A shows above the actual graphs of the chloroform manometer and below of the mercury manometer. Times are registered in seconds. 1, 2 and 3 show the building up of positive pressure (14 mm Hg) 4 and 5 the negative pressure. B shows the same graph when the parts of the curve representing opening and closing of the valves had been eliminated in order to show more clearly the function of the apparatus.

5 What are the results if any obtained from asphyxiated and apneic animals, the lungs of which have been maintained ventilated by this apparatus, when direct massage of the heart is applied several minutes after complete arrest of cardiac action?

6 What is the action of this apparatus on humans who have developed apnea in the course of, or following thoracic operations?

EXPERIMENTAL INVESTIGATION

It is obvious that the points raised above could not be answered satisfactorily by superficial inquiry or with preconceived ideas for or against the principle upon which this apparatus is based. Therefore these problems were submitted to a long experimental investigation which was carried out in the laboratory of Surgical Research of Cornell Medical College, with the collaboration of Dr G L Birnbaum. Forty-two dogs were used. A number of clinical observations and experi-

Fig 4 Tracing taken while the tank was almost empty and pressure in it was of 30 pounds only (initial pressure 2,000 pounds). A comparison of this graph with Figure 3 shows no changes in the shape of the curve.

mental results gathered during previous experimental and clinical work on submersion (to appear shortly) have been used in this investigation.

1 Mechanical efficiency of the apparatus. The function of the apparatus was first checked by graphs taken with mercury and chloroform manometers. For this purpose the mask of the apparatus was connected with a rubber bag representing the lung (Fig 2). In the two tubes leading from the apparatus to the mask were interposed two T tubes, 1, 2 the vertical branches of which were connected with a Y tube 3 which was connected with two manometers, one chloroform and the other mercury. Thus the tubes of the apparatus, 4, 5 were connected with the bag and the manometers.

The study of the graphs taken with this arrangement (Fig 3) showed that the up and down strokes representing positive (upward) and negative pressures were perfectly regular, their heights above and below the basal line were equal and their spacing the same.

The graph of Figure 3 gives a clear idea of the functioning of the apparatus. At the start the pressure is slightly positive for a short while 1 to 2 (Fig 3A), then it rises

when instead of plain oxygen, this author used 4 and 6 per cent of carbon dioxide in oxygen mixtures all other conditions of the experiment being the same, the changes in venous and arterial pressures were much less marked. Figure 6, represents the results obtained by using, respectively: pure oxygen (right end of the curve), and 4 and 6 per cent mixture of carbon dioxide in oxygen (middle part of the curve *b* and *c*). The fall of arterial and the rise of venous pressures during hyperpressures, sharply marked when the dog was breathing pure oxygen, *a*, are hardly noticeable or absent when carbon dioxide in oxygen mixture was given, *b*, *c*. In all these experiments the dog was curarized and anesthetized with chloral.

Rost reports that animals anesthetized with ether or chloral did not present any untoward after-effects following prolonged application of hyperpressure or hypopressure. Application of the same technique on the human did not show any untoward effects. Electrocardiograms taken at the end of the experiment showed no changes.

In our experimental study 7 dogs, of 10 kilograms average weight, were submitted to the action of the apparatus. They were all anesthetized by sodium amytal (55 milligrams per kilogram intraperitoneally, 10 per cent solution) or with ether. The duration of the experiments varied from 1 to 8 hours without interruption. No intratracheal cannula or air-way was used.

When the action of the apparatus did not last over 1 hour and 30 minutes, there was no period of apnea when the mask was disconnected, and the animal immediately resumed normal breathing. On the contrary, when the action of the apparatus was prolonged for 6 hours and over, there was often a period of apnea. In one animal (dog 22, 7 hour experiment) apnea lasted 4 minutes and 11 seconds. In another animal (dog 23, 6 hour experiment) apnea lasted 1 minute and 40 seconds. In both, normal respiration resumed spontaneously and proceeded normally.

In dogs 26, 27, and 28, on the contrary, with duration of the experiment of, respectively, 3 hours and 20 minutes, 6 hours, and 4 hours, there was not the slightest apnea. In

Fig. 7 Heating of gases going from E & J apparatus to the dog (Exp 28)

dog 24 the apparatus was connected with a tank of compressed air; in the others with a tank of 5 per cent carbon dioxide in oxygen mixture.

However, an important complication developed in the course of this investigation. Dogs 22, 23, 24, and 25 died between 12 hours and 5 days after the experiment although blood pressure and pulse rate had come back to normal. At the autopsy relatively slight pulmonary or other lesions were found, which could not explain death. Figure 1 shows the lung of the most affected of these animals (dog 22). Suspecting chilling as a possible cause of these deaths because the rectal temperature in all these dogs had dropped to around 31 degrees C. at the end of the experiment, we endeavored to avoid loss of heat and to maintain the body temperature around 38 degrees C. rectally. Dogs 25, 27, and 28, in which such precautions were taken, did not show the slightest trouble following the experiment. Dog 25 especially in which a heating and humidifying device of the gas mixture was used (Fig. 7.) showed the most uneventful recovery.

I deem it of interest to give here a short résumé of the protocols of these animals.

Experiment 22 Male dog, 12½ kilograms. The action of the resuscitator was prolonged for 6 hours. Carbon dioxide in oxygen, 5 per cent was used. When the resuscitator was disconnected the animal presented apnea which lasted 4 minutes and 11 seconds. Respiration continued normal thereafter. However, the animal was deeply in shock, with corneal and light reflexes absent. This animal was

Fig. 6 Same experiment as in Figure 5 showing that the effects of intrapulmonary hyperpressure and hypopressure upon arterial and venous blood pressure are much less marked when instead of pure oxygen a mixture of oxygen carbon dioxide was used

out experimental work on dogs in order to test whether positive intrapulmonary pressures were likely to cause abnormal resistance to circulation and heart failure. They found that when the lung was inflated with air under pressure to or above 80 millimeters of mercury and this pressure was sustained for 10 seconds, there was considerable fall of the systemic arterial pressure while the venous pressure increased. In one experiment, in which the intrapulmonary pressure was brought to 80 millimeters of mercury the arterial pressure fell from 150 millimeters of mercury to 26 millimeters of mercury and the venous pressure rose to 120 centimeters of water. On releasing the intrapulmonary pressure the arterial pressure gradually returned to 128 millimeters of mercury, reaching this level within one minute. Haldane commenting on these findings says "It is obvious that high intrapulmonary pressure could not cause heart failure in consequence of an abnormal strain thrown on the right ventricle owing to excessive resistance to the outflow of blood from it, because there was little or no blood entering the ventricle to be pumped out ward."

A thorough experimental work was carried out by Rost (1932) on the effects of intrapul-

monary hyperpressure and hypopressure in dogs. In Figure 5, representing a graph of this author, are registered the results of hyperpressure (20 centimeters of water) and hypopressure (-20 centimeters of water) on a dog anesthetized with chloral and curarized. In this graph are recorded from up down, arterial pressure (femoral artery), intrapulmonary pressures (tracheal cannula), venous pressure (jugular vein), venous blood flow and time in seconds. It is clearly shown in this graph that as the intrapulmonary pressure is raised venous pressure rises and arterial pressure falls. The fall of the former being proportionate to the duration of the intrapulmonary hyperpressure. When the intrapulmonary pressure was decreased to -20 millimeters of water the arterial rose and the venous pressure dropped. The second period of hyperpressure in this curve was prolonged for 60 seconds. The arterial pressure showed a much greater drop even then, however, immediately after release of the intrapulmonary pressure both arterial and venous pressures were restored to normal. Continuation of this experiment for over an hour did not produce any damage to the lung or to the circulation nor was the flow of the venous blood influenced. It is of importance to note that

when instead of plain oxygen, this author used 4 and 6 per cent of carbon dioxide in oxygen mixtures all other conditions of the experiment being the same, the changes in venous and arterial pressures were much less marked. Figure 6, represents the results obtained by using, respectively, pure oxygen (right end of the curve), and 4 and 6 per cent mixture of carbon dioxide in oxygen (middle part of the curve *b* and *c*). The fall of arterial and the rise of venous pressures during hyperpressures, sharply marked when the dog was breathing pure oxygen, *a*, are hardly noticeable or absent when carbon dioxide in oxygen mixture was given, *b*, *c*. In all these experiments the dog was curarized and anesthetized with chloral.

Rost reports that animals anesthetized with ether or chloral did not present any untoward after-effects following prolonged application of hyperpressure or hypopressure. Application of the same technique on the human did not show any untoward effects. Electrocardiograms taken at the end of the experiment showed no changes.

In our experimental study 7 dogs, of 10 kilograms average weight, were submitted to the action of the apparatus. They were all anesthetized by sodium amytal (55 milligrams per kilogram intraperitoneally, 10 per cent solution) or with ether. The duration of the experiments varied from 1 to 8 hours without interruption. No intratracheal cannula or air-way was used.

When the action of the apparatus did not last over 1 hour and 30 minutes, there was no period of apnea when the mask was disconnected, and the animal immediately resumed normal breathing. On the contrary, when the action of the apparatus was prolonged for 6 hours and over, there was often a period of apnea. In one animal (dog 22, 7 hour experiment) apnea lasted 4 minutes and 11 seconds. In another animal (dog 23, 6 hour experiment) apnea lasted 1 minute and 40 seconds. In both, normal respiration resumed spontaneously and proceeded normally.

In dogs 26, 27, and 28, on the contrary, with duration of the experiment of, respectively, 3 hours and 20 minutes, 6 hours, and 4 hours, there was not the slightest apnea. In

Fig 7 Heating of gases going from E & J apparatus to the dog (Exp 28)

dog 24 the apparatus was connected with a tank of compressed air; in the others with a tank of 5 per cent carbon dioxide in oxygen mixture.

However, an important complication developed in the course of this investigation. Dogs 22, 23, 24, and 25 died between 12 hours and 5 days after the experiment although blood pressure and pulse rate had come back to normal. At the autopsy relatively slight pulmonary or other lesions were found, which could not explain death. Figure 1 shows the lung of the most affected of these animals (dog 22). Suspecting chilling as a possible cause of these deaths because the rectal temperature in all these dogs had dropped to around 31 degrees C. at the end of the experiment, we endeavored to avoid loss of heat and to maintain the body temperature around 38 degrees C. rectally. Dogs 25, 27, and 28, in which such precautions were taken, did not show the slightest trouble following the experiment. Dog 25 especially in which a heating and humidifying device of the gas mixture was used (Fig 7.) showed the most uneventful recovery.

I deem it of interest to give here a short résumé of the protocols of these animals.

Experiment 22. Male dog, 12½ kilograms. The action of the resuscitator was prolonged for 6 hours. Carbon dioxide in oxygen, 5 per cent was used. When the resuscitator was disconnected the animal presented apnea which lasted 4 minutes and 11 seconds. Respiration continued normal thereafter. However, the animal was deeply in shock, with corneal and light reflexes absent. This animal was

Fig. 8 Technique of experimental study in asphyxia submersion. The head of the dog previously anesthetized, was introduced into a metallic cylinder the hood. One base of this cylinder was closed by a rubber membrane perforated in its center. To the other base of the cylinder was soldered a funnel like device through which water could be poured into the hood. The neck of the animal was shaved and anointed with petrolatum. The hole in the rubber membrane was slightly stretched and the head of the animal passed through it. Thus the base of the hood was closed watertight and the head of the animal could be submerged by filling the hood with water. No undue structure was exerted upon the neck of the animal. A pneumograph was applied on the chest of the animal and a cannula was introduced into the femoral artery. This technique allowed continuous recording of respiratory movements and blood pressure.

found dead the next morning about 10 to 12 hours after the experiment. Autopsy showed light consolidation in the left lower and partial consolidation of the left upper lobe and right leaf of the accessory lobes as shown in the photograph of the specimen (Fig. 1).

It was thought that the animal probably died from oxygen pneumonia since he was breathing in an atmosphere of 95 per cent oxygen and in this instance the partial tension of oxygen in the mixture was 722 millimeters of mercury instead of 149 millimeters of mercury as in atmospheric air.

Histological section showed pulmonary congestion with moderate edema in the areas of consolidation.

However, the rectal temperature of this animal at the end of this experiment was 31 degrees C instead of 39 degrees C which is normal for the dog. This subnormal temperature was attributed to the rapid evaporation taking place in the lung to the low tempera-

ture of the gases, and the immobility of the anesthetized animal. Moreover, since the gases were dry, they might have caused pulmonary irritation by their dehydrating effect.

For the solution of this problem the following experiments were carried out.

Oxygen carbon dioxide mixture was replaced by plain compressed air in order to confirm or rule out oxygen pneumonia.

Experiment 23. Male dog 10½ kilograms. Sodium amytal was given intraperitoneally 55 milligrams per kilogram. The apparatus was connected with a tank of compressed air.

This experiment was carried out for 6 hours, all other conditions being the same as for experiment 22. The animal's temperature at the end of the experiment was again 31 degrees C. The animal presented apnea when the resuscitator was disconnected. Its duration was 1 minute and 40 seconds. This animal died 11 hours after the experiment.

Fig 9 Graph of submersion in water (dog, technique of Fig 8) showing the four phases of asphyxia in submersion. Upper curve, respiration, lower, blood pressure. W, Water was poured into the hood. It is followed by reflex arrest of respiration (initial apnea) and elevation of blood pressure. 1-2, first phase, duration 1 minute. 2-3, Respiration becomes irregular and blood pressure continues to rise—second phase, of dyspnea, duration 1 minute. From 3-4 respiration gradually stops and blood pressure drops rapidly—third phase of terminal apnea, duration 1 minute. 4-5, Drop of blood pressure continuous and at the end the heart stops—fourth phase of arrest of the heart.

Autopsy showed again slight marginal consolidation which could not be the cause determining death.

Thus the cause of death in the previous experiment (dog 22) was not necessarily oxygen pneumonia.

The above findings were further verified by two additional experiments:

Experiment 24. The action of the apparatus was prolonged for 1 hour, using carbon dioxide in oxygen (95-5 per cent). Dog, 9½ kilograms, anesthesia with amytal 50 milligrams per kilogram. The rate of the apparatus was 15 per minute. Gas pressure in tank was 1700 pounds. Other conditions were the same as in experiments 22 and 23. The rectal temperature at the end of the experiment was 32 degrees C. These animals presented no apnea. Ocular and corneal reflexes were normal, anus only slightly patent. The last day of life the dog appeared rather sick. He died 5 days later. Postmortem examination revealed no appreciable pulmonary lesions.

Experiment 25. Dog, 9 kilograms. Sodium amytal anesthesia, 50 milligrams per kilogram body weight. The apparatus was connected with a tank of carbon dioxide in oxygen (95-5 per cent), initial pressure in tank was 1800 pounds. This experiment lasted 3½ hours. Again, at the end of the experiment the temperature had dropped to 31 degrees C. The animal died within 10 hours. At autopsy no sizable lesions of the lung were found.

These experiments suggested that the cause of death might have been related to an excessive chilling of the animals. It was therefore

interesting to prevent chilling, eliminate drop of temperature, and see whether death could be prevented, all other conditions remaining the same.

Three experiments were carried out:

Experiment 26. Dog, 18 pounds. Amytal, 55 milligrams per kilogram of body weight. This experiment was conducted exactly as experiments 22, 23, 24, and 25, the only differences being that measures were taken to prevent a drop of temperature by covering the animal with several blankets between which an electrically heated pad was placed. Rectal temperature was maintained constant between 38.5 and 39 degrees C. (readings taken every 5 minutes). Rate of the resuscitator was 20 per minute. Initial pressure in the tank was 1300 pounds. Carbon dioxide in oxygen mixture 5 per cent. Action of the apparatus was prolonged for 3 hours and 20 minutes. At the end of the experiment there was no apnea. Corneal reflex was active. Reflexes to light normal; anus contracted. Animal was out of anesthesia 2 hours after the end of the experiment, up on his feet, and he ate and drank. This dog remained in perfect condition.

Experiment 27. Apparatus was connected with a tank of compressed air as in experiment 25. Duration of experiment 6 hours. Dog, 8 kilograms: anesthesia with sodium amytal, 55 milligrams per kilogram body weight. Rate of apparatus 18 per minute. This rate was obtained by turning down clockwise the regulating valve of the apparatus so that the gases were turned off more than half. The animal's own respiration rate before the mask was applied was 14 per minute. Rectal temperature was main-

Fig 20 Similar experiment as in Figure 9 As in that graph the four phases are clearly shown

tained at 38.5 degrees C. Pressure in the tank at the start of the experiment was 2000 pounds. At the end of the experiment it was 450 pounds. No apnea occurred and the animal was up and about 3 hours after the end of the experiment. He remained in perfect condition.

The above experiments (26 and 27) have shown conclusively that the death of dogs 22, 23, 24, and 25 was not due to oxygen pneumonia and the hypothesis of death caused by excessive chilling was corroborated. In fact, when the loss of heat was prevented the dogs were able to stand 6 hours of continuous action of the resuscitator, using a 95-5 per cent carbon dioxide in oxygen mixture or compressed air without any evil after effect.

This question of death due to the lowering of the temperature of the animal was of particular interest. Therefore, in order to eliminate any possible error, in the following experiment (dog 28) the gases were heated and humidified before being led into the mask, by passing through a two-tubed bottle containing water heated to about 100 degrees C (Fig 7). The animal was not covered with blankets and electric pad. The protocol of this experiment follows.

Experiment 28. Male dog weight 25 pounds. Sodium amytal was given intraperitoneally 55 milligrams per kilogram body weight. Apparatus connected with carbon dioxide in oxygen (95-5 per cent). Layout of experiment as in drawing (Fig 7).

A large bottle containing water which could be heated was interposed in the insufflation tube of the E & J resuscitator and a similar bottle containing calcium chloride was interposed in the suction tube going from the mask to the machine. Thus the gases going to the mask were heated and humidified while the moisture in the gases coming from the mask was intercepted in bottle B in order to avoid possible damage to the apparatus. The temperature of the gases in the mask was checked by a thermometer tipped under the mask. The temperature of the body was recorded by another thermometer in the rectum. The duration of this experiment was exactly 4 hours 21 cubic centimeters more of 10 per cent solution of amytal was given during this time to maintain the animal under anesthesia. The temperature in the mask varied from 37 to 30 degrees C and was regulated by turning the heater on or off. Rectal temperature stayed 38 degrees C throughout the experiment. Pressure in the gas tank was 1500 pounds at the start and 100 pounds at the end of the experiment. The rate of the apparatus was 12 at the beginning, 14 in the middle of the experiment and 24 during the last 5 minutes of the experiment. There was no apnea at the end of the experiment.

The stomach of the animal was slightly distended at the end of the experiment. Corneal and light reflexes were present and very active. Three hours later the animal was on his legs and able to eat and drink. The next day the animal was normal and remained in good condition.

MECHANICAL RESUSCITATION

All students of asphyxia and resuscitation agree that the general term of "asphyxia" is a vague, confusing and often misleading term. In fact, as it will be presently shown,

Fig. 11 Failure of attempt at resuscitation in submersion. The hood was removed at the end of the third phase. Blood pressure continued to drop. Bronchoscopic aspiration of fluid was applied 30 seconds after removal of hood, and intratracheal insufflation 30 seconds later without any result.

asphyxia, whatever its origin may be, is composed of four distinct phases which follow one another but they present different symptoms and different prognoses. Thus, for example, while resuscitation is very easy at the first and second phase, it becomes difficult at the beginning of the third phase, very difficult at the middle of this phase, and quite impossible at its end, and in the fourth phase. Therefore when the question of resuscitation is discussed and especially when the merits of the different procedures are appraised and compared, it is absolutely necessary to indicate with the greatest accuracy not only the phase but also the period of the phase of asphyxia in which the reported results were obtained. Reports and conclusions in which this point has not been strictly observed are deprived of any scientific value. I believe that is because this point has not been sufficiently stressed so far that so many contradictory opinions are held today upon the different methods of resuscitation. This contention is backed by our experimental data which are reported here.

The most commonly encountered forms of asphyxia belong to one of the following three groups: (1) Resistance to respiration, such as submersion in water, bronchial obstruction or combination of both as when the lung drowns in its own exudate; (2) vitiation of the respired air, such as oxygen want, or in breath-

ing of anesthetic or neutral gas, or carbon monoxide poisoning, (3) disturbances of the respiratory center as in electric shock and possibly traumatic or postoperative shock.

It is not in the scope of this paper to enter into the details of resuscitation in all these forms of asphyxia. Thus resuscitation in carbon monoxide poisoning and of the newborn shall not be considered. I shall study asphyxia and resuscitation only as regards submersion, bronchial obstruction, and anesthesia—the forms of asphyxia of the greatest interest both to the thoracic surgeon and to the anesthetist.

Asphyxia by submersion. Asphyxia by submersion has been studied experimentally by means of a special technique which has rendered possible accurate and continuous recording of respiration and blood pressure throughout the entire duration of submersion. Flagg, Birnbaum, and I have devised a method during our studies on submersion which gave us valuable information. Our experimental findings were checked upon human cases of submersion which we had the opportunity to study on the beach of Coney Island during the summer of 1933.

Technique. Thirty-two dogs were used for these experiments, weighing around 10 pounds. The animals were anesthetized with sodium amytal, 10 per cent solution, injected intraperitoneally. Fifty-five milligrams per

Fig. 12 Spontaneous resuscitation in submerison. The hood was removed 15 seconds before the end of the third phase.

kilogram of body weight was given. In a small number of dogs ether anesthesia was used instead.

The neck of the animal was shaved and anointed with petrolatum. A special hood had been constructed, of light metal, representing a cylinder 10 inches long and 6 inches in diameter. One base of this cylinder was closed with a diaphragm of rubber tissue in which a central opening was made. On the other base, a smaller and funnel like cylinder was soldered. In the middle of the hood a hole was made which was closed, and kept water tight by a sheet of celluloid and served as an observation window. A pneumograph was applied on the chest of the animal and was connected with a recording tambour. The femoral artery was cannulated and the

cannula was connected with a recording mercury manometer (Fig. 8).

By slightly stretching the opening of the diaphragm of the hood it was easy to pass through it the head of the animal down to its neck. Thus the head was contained in a cylinder the bottom of which was water tightly fitted around the neck without exerting any undue pressure upon it.

Thus during the experiment it was possible to register on the smoked drum respiration, blood pressure, times in seconds and the oscillations of the resuscitation apparatus.

For producing asphyxia by submersion water was poured into the cylinder which was filled up until mouth and nostrils of the animal were completely under water. This technique rendered also possible the study of submersion in different medias. Interesting differences were noted when the animals were submerged in tap water, isotonic, or hypertonic salt solution. Moreover it was possible to interrupt instantly submersion or even to administer oxygen or carbon dioxide in oxygen by means of an intratracheal catheter while the mouth and nostrils of the animal were under water.

We shall report here the more interesting points of our findings.

Figures 9, 10, and 11 show the course of asphyxia by submersion in tap water. The whole phenomenon from its beginning to the death of the animal presented a remarkably constant duration of 4 to 5 minutes. This

A.R.

Fig. 13 Attempt at resuscitation in submersion with F & J apparatus. End of third phase. Successful. The hood was removed at the end of the third phase. Manual

artificial respiration was applied. A.R. without result. F & J apparatus was then used for 90 seconds with success. Blood pressure rose, spontaneous respiration resumed.

course was clearly divided into 4 distinct phases, each of 1 minute duration. These phases can be described as follows (Fig 9).

The first phase is characterized by apnea and rise of blood pressure. This apnea is due to the reflex closure of the glottis. I shall call it the phase of initial apnea. Rise of blood pressure at the beginning of asphyxia is a constant phenomenon in all forms of asphyxia. The duration of this phase is of about 1 minute.

The second phase is characterized by labored respiratory movements and continuation of the rise of blood pressure. The animal fights for breath; the non-anesthetized animal is perfectly conscious until the end of this phase and fights vigorously to liberate itself of the hood. At the end of this phase, which lasts also 1 minute, consciousness disappears and tonic and clonic convulsions appear. This phase can be called the "phase of dyspnea."

The third phase is characterized by arrest of respiration, drop of the blood pressure, and disappearance of reflexes and muscular tonus. The duration of this phase is also of 1 minute. The animal which presented clonic and tonic convulsions at the end of the second phase, gradually relaxes and becomes limp, its jaw drops, the sphincters relax and the corneal and glottis reflexes disappear. I shall designate this phase as the phase of "terminal apnea."

The fourth phase is characterized by rapidly progressing weakness of cardiac contraction and arrest of the heart. I shall indicate this phase as phase of arrest of the heart. The same phases are seen in Figures 10 and 11.

The prognosis is very different in each of these phases; in fact when submersion is interrupted anywhere before the middle of the third phase immediate and spontaneous resuscitation always follows (Fig. 12); on the contrary, in the third phase (phase of terminal apnea) resuscitation which is still easy when submersion is interrupted at the beginning of this phase becomes increasingly difficult as we approach the end of this phase. Figure 11 illustrates this point. Although the hood was removed at the end of the third phase asphyxia progressed to the fourth phase and the heart stopped. Neither artificial respiration nor bronchoscopic intratracheal insufflation succeeded in resuscitating this animal.

The graph, Figure 13, is of considerable interest because it shows that resuscitation can be obtained in this phase by the use of the E & J apparatus when it is applied without any delay. The hood was removed at this experiment, as in experiment of Figure 11, at the end of third phase. Artificial respiration was without any response. On the contrary within 20 seconds after the application of E & J apparatus blood pressure rose almost vertically and the animal was brought back to life.

This experimental evidence shows clearly, I believe, the importance of dividing asphyxia by submersion into four phases. Moreover, it shows the futility of artificial respiration and carbon dioxide in oxygen inhalation beyond the third phase and the necessity of avoiding any loss of time by the immediate application of procedures which insure insufflation of oxygen.

Fig 14 Graph of asphyxia by obstruction of trachea in the dog, upper curve, blood pressure, lower respiration. In 1 the trachea was only partially obstructed, blood pressure was very slightly affected. At 2 obstruction was made complete. Blood pressure rose for 1 minute while

respiratory movements became irregular—second phase. Then blood pressure began to drop and respiration ceased—third phase. Gradually heart stopped—fourth phase. Resuscitation was attempted without success at the fourth phase.

Fig 15 Asphyxia by tracheal obstruction. Spontaneous resuscitation. Obstruction was removed at the end of third phase before the beginning of the fourth phase. It

was found that the blood pressure rose immediately and that spontaneous respiration was resumed 20 seconds later.

into the lung. The fact that resuscitation is still easy at the beginning of the third phase while it is very difficult and often impossible at the end of the same phase and that the duration of this phase is of 1 minute only, shows clearly the paramount importance of time. Seconds count in asphyxia and often determine the life or death of the patient. This experimental evidence illustrates the statement previously made that unless the phase of asphyxia is accurately indicated in the results obtained with different procedures of resuscitation, no reliance can be placed upon the results reported.

The division of asphyxia into four phases is also evident in bronchial obstruction and in breathing of neutral or anesthetic gases (oxygen want).

Asphyxia by bronchial obstruction. Eighteen dogs were used for these experiments. Bronchial obstruction was obtained by introducing into the trachea, through the bronchoscope a small balloon attached to a fine brass tube. This balloon could be inflated from the outside and thus produced obstruction either of the trachea or of a common bronchus. The advantages of this technique are that complete obstruction can be obtained without any traumatism to the animal, that the degree of obstruction can be regulated at will and that it can be established or interrupted instantly.

The curve of asphyxia by complete obstruction of the trachea is very similar to the curve of submersion (Fig 14). The four phases are clearly shown namely initial apnea, dyspnea, terminal apnea, and arrest of the heart. Again the duration of each phase is of

about 1 minute and death occurs within 4 to 5 minutes.

Removal of the obstructing agent before the end of the third phase is followed as a rule by immediate spontaneous resuscitation (Fig 15). On the contrary, when obstruction is released later artificial resuscitation is generally necessary in order to obtain resuscitation (Fig 16). In a general way, however, resuscitation is easier in bronchial obstruction than submersion. The reason is obvious, removal of the obstructing agent instantly establishes the patency of the air passages in uncomplicated bronchial obstruction while in submersion alveoli, smaller bronchi, and even larger bronchi may be filled with water. On the other hand, it should not be forgotten that there are cases of submersion in which very little water has penetrated into the lung, while, there are cases of bronchial obstruction in which the lung is filled up with bronchial secretions representing the "drowned lung" of Leopold. These little known details explain the peculiar variations in resuscitation; they must be borne in mind in the appreciation of the causes of success or failure and of the therapeutic indications in each individual case.

Partial obstruction causes little changes in the curves of respiration and blood pressure (beginning of curve Fig 14). It is surprising how little air is often sufficient to prolong life. This point is of paramount practical importance because it shows the necessity of insuring at once even partial patency of the upper respiratory ways. Suction of exudate present in the larynx, traction of the tongue and especially introduction of intratracheal catheter

↑ E & J app

Fig 16 Asphyxia by bronchial obstruction. Resuscitation by the E & J apparatus applied at the end of the third phase. From up down, times in $\frac{1}{2}$ minutes, blood pressure and respiration. Obstruction of trachea was released at the

end of the third phase. E & J apparatus was applied 20 seconds later. Blood pressure continued to drop for 30 seconds, it remained low for 30 more seconds, and then rose to slightly above normal.

when performed timely and skillfully, increase considerably the chances of resuscitation.

It is obvious that in asphyxia by tracheal obstruction or submersion, artificial respiration by the Shaeffer or Sylvester methods combined with carbon dioxide in oxygen inhalation will be successful as long as they are applied on patients with patent respiratory ways and before the end of the third phase. After this phase rhythmic insufflation and suction of air into the lung are incomparably more efficient. Figure 16 shows resuscitation obtained by the application of E & J apparatus, 1 minute after complete drop of the blood pressure, with heart beats hardly visible, that is almost at the fourth phase.

These two forms of asphyxia, by submersion and bronchial obstruction, are of great practical importance to the anesthetist and the thoracic surgeon. In fact, the great majority of deaths following thoracic operations for pulmonary suppuration are due to their combination. In these cases the patients die because of restriction of the respiratory field, with or without bronchial obstruction, by the bronchial exudate retained in the bronchial tree. From the evidence herein offered it becomes obvious that the only rational treatment in these cases consists in the rapid suction of this exudate by means of intratracheal catheter followed by rhythmic insufflation of carbon dioxide in oxygen, either by mouth-to-mouth insufflation or better by means of an apparatus. Moreover, preventive measures in

these cases are of the greatest importance. Careful pre-operative removal of bronchial secretion by cough and postural drainage, and the use of intratracheal catheter during operation in all patients who expectorate over 30 cubic centimeters in 24 hours are lifesaving measures. It was shown elsewhere that aspiration of bronchial secretion before and after thoracoplasties in pulmonary tuberculosis have considerably decreased both morbidity and mortality in these cases.

Asphyxia by respiration of neutral or anesthetic gases. Asphyxia was produced experimentally by breathing of hydrogen, nitrogen, and helium. Seven dogs were used in these experiments, 2 with hydrogen, 2 with nitrogen, and 3 with helium.

The curves of these forms of asphyxia are identical with the curves of submersion and bronchial obstruction, with the only difference that the phase of initial apnea is less marked in them and occasionally absent. Figures 17 and 18 represent respectively the curves of asphyxia by overdose of ether and breathing of helium. Again we found in these curves as in the previous ones, the characteristic drop of blood pressure at the third phase followed by arrest of the heart within 5 minutes after the beginning of the experiment.

These two curves (Figs 17 and 18) should be studied more closely because they show in a remarkable way, and for the first time as far as I know, the importance and efficiency of massage of the heart in resuscitation even

Fig 17 Resuscitation in asphyxia by overdose of ether Combined action of E & J apparatus and direct massage of the heart 1 fourth phase arrest of the heart—0 minute after respiratory arrest 2 E & J apparatus was put in action (2 minutes after arrest of the heart) Manual

artificial respiration was without any effect M, Direct massage of the heart repeated at M and M' followed by resuscitation about 9 minutes and 50 seconds after complete arrest of respiration and 0½ minutes after arrest of the heart (See text)

over 10 minutes after complete arrest of the heart provided that the lung had been maintained adequately ventilated

Resuscitation obtained after the fourth phase by combined mechanical pulmonary ventilation and massage of the heart Two of these experiments are reported here

Dog 18 Male 13 kilograms (Fig 17) This dog was given ether until drop of blood pressure (third phase) had occurred and the heart stopped (fourth phase) E & J apparatus was applied 6 minutes after respiratory arrest and 2 minutes after arrest of the heart For 4 minutes no changes were noticed in the heart or the blood pressure Nine minutes and 50 seconds after the onset of apnea and 6½ minutes after arrest of the heart the abdominal wall was incised and the hand was introduced into the chest cavity through the diaphragm the heart was grasped and massaged slowly On the graph the massage was distinctly visible and is indicated by the letter M Following the second massage of the heart a few cardiac contractions were felt which are seen on the graph Following a third attempt the heart started beating regularly and vigorously The animal was brought back to life

Dog 10 Male, 18 kilograms Anesthesia was effected with amylal 10 per cent intraperitoneally 55 milligrams of amylal per kilogram body weight

This animal was given pure helium to breathe (curve Fig 18 A and B 18B being the continuation of 18A) The animal entered the third phase 3½ minutes after the onset of the experiment and 1 minute later (4½ minutes after the onset of this experiment) there was terminal apnea and arrest of the heart E & J apparatus was applied at the sixth minute Rhythmic compression of the chest was

used at same time without any effect upon heart At the eleventh minute (6 minutes after apnea and 5 minutes after arrest of the heart) a long abdominal incision was made and the hand was introduced into the chest through an opening made in the diaphragm Seven times the heart was massaged once every minute at the eleventh, twelfth, thirteenth, fourteenth, sixteenth, seventeenth and eighteenth minute Each time there was a response of the heart which was becoming progressively stronger and longer, as it is clearly shown in the graph At the twentieth minute (15 minutes after arrest of the heart) the heart started beating again blood pressure rose and spontaneous respiratory movements were re established

These two experiments show that massage of the heart as a method of resuscitation in desperate cases of asphyxia may be successful, provided that the pulmonary blood had been maintained adequately ventilated It is my contention that pulmonary ventilation is a compulsory factor for the success of massage of the heart It is reasonable to admit that unless the blood pumped into the heart and forced into its coronary vessels by massage of this organ be adequately oxygenated, no resuscitation of this organ can take place

These experiments are of considerable practical importance They prove that massage of the heart should be accepted as a legitimate procedure for resuscitation, more over that immediate application and continuation of mouth to mouth or mechanical

Fig 18 A and B. B, the continuation of B. Resuscitation in asphyxia by helium. Combined action of E & J respirator and direct massage of the heart. Arrest of the heart at the fifth minute, 1. Respirator was put in action

at the sixth minute. 2. M M, massage of the heart, each massage being followed by a faint response of the heart. At 3, 15 minutes after arrest of the heart spontaneous beats had resumed and blood pressure rose (See text.)

insufflation gives enough time to surgeon to enter into the chest either through the abdominal cavity or through the fourth intercostal space, with all aseptic precautions. If my interpretation of data presented is correct, massage of the heart should be recognized not only as a legitimate procedure but as a compulsory one in advanced cases of asphyxia.

Action of E & J apparatus in open chest operations. The behavior of dogs, with wide open chest, in which respiration was insured by the resuscitator was investigated in 13 animals. On these animals were performed ligations of the pulmonary vessels, lobectomies, pneumonectomies, wrapping of lobes in rubber bags for the production of compressive atelectasis and ligation of the coronary vessels. All these animals resumed normal respiration after closure of the chest.

It must be noted that these operations were carried out in the dog with greater ease than with ordinary intratracheal insufflation because relatively slight expansion and retraction of the lungs were sufficient to insure adequate ventilation, thus the chest was not crowded by over expanded lungs and there was more room for the performance of the operations.

The following experiment illustrates that by using the E & J apparatus dogs can remain for a long time with the chest widely open without showing any marked disturbances of respiration and circulation; when the chest was closed the animal immediately resumed normal respiration.

Experiment 33 Dog weighed 8 kilograms. Anesthesia given was amylal intraperitoneally. Chest was opened by section in the middle of the sternum,

ligation of bleeding vessels and wide retraction of the edges of the sternum by means of self retaining retractor. Mask connected with resuscitator. Resection of the right lung. After 2 hours the chest was closed in an air tight manner by means of clamps and resuscitation was discontinued. Spontaneous respiration was immediately resumed and the blood pressure rose.

Possibility of injury to the lung by positive intrapulmonary pressures. In order to investigate this point we used lungs of dogs removed immediately after death with care to prevent any injury to them. Manual handling of the lung was avoided. The lungs were separated from the heart after ligation of the pulmonary arteries and veins. The two tubes of the resuscitator were connected with a Y tube the vertical branch of which was solidly tight to the trachea as was the rubber bag in Figure 2. Under the action of the resuscitator the lung expanded and retracted rhythmically, with positive pressure of 14 millimeters of mercury it became only moderately distended. In order to produce rupture to the lung it has been necessary to connect the trachea directly with the faucet of compressed air of the laboratory, the lung was placed and maintained under water by a metallic net placed above the lung. Rupture of the lung and bubbling of air appeared only when the pressures reached between 52 to 58 millimeters of mercury. It is therefore impossible that a positive pressure of 14 millimeters of mercury can cause even the slightest traumatic lesion of the lung. On the contrary, when there is an advanced degree of collapse, as there is 5 to 10 hours after death of the animal, the lung can be only partially inflated by the positive pressure built by this apparatus. Therefore, it is reasonable to believe that clinically we may encounter collapsed lungs resisting adequate expansion with 14 millimeters of mercury positive pressure. For this reason we have advised the manufacturer to add a fool proof valve which could allow when and if necessary intermittent insufflations under a positive pressure of 20 to 30 millimeters of mercury.

It is true, however, that high positive intrapulmonary pressures above 50 millimeters can produce rupture of pulmonary alveoli often complicated by mediastinal and subcutaneous emphysema, pneumothorax, and even pneu-

moperitoneum. Intrapulmonary hemorrhage and cardiac or cerebral air embolism may also be produced by high intrapulmonary pressures.

Ewald and Robert (1883) had found that in rabbits when the pressure in the lung reached 40 millimeters of mercury, air could be detected in the abdominal cavity. Joannides (1931) produced pneumothorax, pneumoperitoneum, and even air embolism with intrapulmonary pressures of from 50 to 100 millimeters of mercury.

Polak and Adams (1932) have carried out a series of interesting experiments in dogs, in which arterial and venous pressures were recorded. They have introduced air under pressure into the trachea through a tracheal cannula. A special cannula was interposed in the carotid artery filled with normal saline which was arranged to act as a trap for any air bubbles which might be present in the blood or the artery. When they raised the intrapulmonary pressure to 60 millimeters of mercury for 10 seconds they observed the typical fall of arterial pressure and rise of venous pressure already described (Figs 4 and 5). No air bubbles appeared in the carotid trap with 60 millimeters of mercury pressure. Only when the intrapulmonary pressure was brought to 80 millimeters of mercury and maintained at this level for 10 seconds, numerous air bubbles appeared in the carotid trap. With 100 millimeters of mercury for 10 seconds still more air appeared in the carotid trap and the animal ceased to breathe though the heart continued to beat for 2 more minutes. At autopsy, besides extensive mediastinal and subcutaneous emphysema, interstitial emphysema was present around the pulmonary vessels and hemorrhagic areas were seen extending into the lung substance. Microscopically, vascular hemorrhages were found in the lung and air emboli were present in the coronary and mesenteric arteries and in vessels of the brain. Air was present in both ventricles. From their numerous experiments these authors concluded that no harm can be caused as long as the intrapulmonary pressure remains below 80 millimeters of mercury. But from 90 millimeters of mercury or more traumatic air embolism is likely to occur.

These experiments of Polak and Adams were carried out in order to explain embolism occurring in sailors carrying the submarine escape respiratory apparatus and rapidly rising from a depth of 15 feet or more. Haldane, commenting on their work said: "When a man comes up rapidly from a depth of even as little as 15 feet, with his mouth closed and without breathing, excess of intrapulmonary pressure over external pressure is built and it rises rapidly to a high figure. As soon as this pressure exceeds about 80 millimeters of mercury there is stretching and tearing of alveoli and their capillaries with the result that air is forced into these vessels; nothing of the kind occurs if the man is instructed to breathe during the ascension."

Therefore, we can conclude that no traumatism to the lung is possible even when positive pressures of 30 and 40 millimeters of mercury are used. It is fortunate that there is such a large margin of safety between the pressures necessary and sufficient for resuscitation and the pressures which are liable to cause rupture of alveoli, thus the lung may be forcibly expanded if it presents an advanced degree of collapse without any danger of injury.

In the light of the experimental evidence presented here I was forced to revise my previous unfavorable opinion of the automatic pulmotor principle. This opinion was based upon the conclusions of the reports in 1913 of the Commission of Resuscitation from Electric Shock (17) and of the Committee on Resuscitation from Mine Gases (18) in 1914. These conclusions were both edited by the secretary of this committee, Yandel Henderson. This author in numerous papers which have appeared since the publication of these reports has repeatedly and insistently expressed his distrust for all procedures of resuscitation based upon the principle of the automatic pulmotor of Draeger. I cannot agree with this author. The experimental work, only partially reported in this paper, has convinced me that the E & J apparatus is harmless and of great help in resuscitation. Therefore I thought that I was authorized to apply it to patients. This trial has justified my favorable opinion, as it is shown in the reports of a small number of human cases.

HUMAN CASES

This apparatus was used on 12 patients during or following operations for pulmonary suppuration. All had shown advanced asphyxia with apnea. The histories of 3 cases, 2 successful and 1 failure, are given here. A more extensive study of all cases will be given later in a special paper.

CASE 1. S. M., aged 28 years, white, female, was admitted to Sea View Hospital, January 15, 1935; readmitted June 9, 1936 No 11466-36. Diagnosis: right mixed infection tuberculous empyema; drained, left pneumothorax with adhesions. Sputum, Gaffky No 3.

November 24, 1936. Pneumonolysis of left apex. Successful Sputum turned negative for 2 months.

December 29, 1936. First stage thoracoplasty on right side. Total resection of three ribs. Cyclopropane anesthesia. Good recovery.

April 6, 1937. Second stage thoracoplasty, resection of fourth, fifth, and sixth ribs. Cyclopropane anesthesia. Patient strongly anoxicemic. Vital capacity 950 cubic centimeters. Intratracheal catheter was used.

Twenty minutes after beginning of operation patient became extremely cyanotic with shallow, rapid, and periodic breathing. Patient was given carbon dioxide in oxygen inhalation which improved her condition. At the end of the operation condition became worse—gray cyanosis, with shallow, irregular, and gasping breathing, fall of blood pressure—pressure could not be recorded in the sphygmomanometer. Heart was irregular. Stimulants and carbon dioxide in oxygen inhalation were without any effect. Suddenly respiration stopped, eyes were glassy, pupils half dilated and jaw relaxing.

Resuscitator was applied and kept on for 15 minutes. Immediate and striking improvement was noticed. Within 5 minutes heart beats became regular, pulse could be felt in the radial artery (140 per minute) and cyanosis cleared up considerably. Spontaneous breathing was re-established within 12 minutes. Resuscitation was stopped after 14 minutes. Patient made uneventful recovery.

CASE 2. H. L., white, female, aged 23 years, with bilateral thoracoplasty was admitted at Sea View Hospital June 4, 1936 No 1316-36. Bilateral ulcerative pulmonary tuberculosis. Sputum, Gaffky No 6.

Pneumothorax was attempted on both sides without success. Vital capacity 1200 cubic centimeters. Marked chronic anoxemia.

December 22, 1936. First stage thoracoplasty was done on left side, with cyclopropane anesthesia, resection of five ribs. During operation patient had repeated attacks of apnea but recovered with inhalation of carbon dioxide in oxygen and rhythmic pressures on the chest.

At the end of the operation respiration became very shallow and hardly noticeable; marked cyano-

sis, blood pressure fell rapidly and could not be recorded respiration ceased. Patient was in profound shock and complete relaxation. Heart beats could not be detected.

Mouth to mouth insufflation was instituted and resuscitator was applied. Within 7 minutes, color improved, blood pressure rose to 85 millimeters systolic and spontaneous respiratory movements were resumed. Inhalation of carbon dioxide in oxygen was then continued for 40 minutes until patient was awakened. Recovery was uneventful.

February 23, 1937. First stage thoracoplasty on right side with cyclopropane anesthesia. resection of four ribs. No shock. Course uneventful.

CASE 3. W. A. white aged 34 years. Patient was admitted at Sea View Hospital July 31, 1936. No 13941-36. Diagnosis: bilateral ulcerative pulmonary tuberculosis.

January 22, 1937. First stage thoracoplasty with resection of three ribs and apicolysis. Cyclopropane anesthesia was used. Postoperative course was smooth.

January 28, 1937. Sixth postoperative day spontaneous pneumothorax on right side. Deflation of 1100 cubic centimeters of air with marked relief. Patient was placed on continuous deflation.

February 1, 1937. Right lung partially re-expanded. The patient who had been comfortable for the last 3 days suddenly developed pain in left chest and extreme dyspnea with cyanosis. Diagnosis of obstruction of the left lower lobe was made in the x-ray film. An intratracheal catheter was introduced and the right lower bronchus was aspirated. Patient was improved immediately.

February 4, acute episode similar to that on February 1 occurred. An intratracheal catheter was introduced in the left bronchus and 20 cubic centimeters of thick mucus was aspirated. Patient was immediately improved. However 1 hour later a new attack of extreme dyspnea occurred, and when the resident physician arrived a few minutes later (no more than 5 to 7) patient was in apnea. Heart beats could not be elicited, pupils were dilated and lower jaw relaxed. Intracardiac adrenalin was given and mouth to mouth insufflation was instituted until the apparatus was brought in. Within 2 minutes after application of apparatus heart beats could be heard again but they were very rapid and faint. Bronchial suction was repeated but during action heart stopped again. Apparatus was re-applied and heart beats were established again. Occasional spontaneous respiratory movements were produced. After 30 minutes heart went into fibrillation and patient died. Direct massage of the heart through abdominal incision could not be resorted to because of lack of authorization. Patient died 1 hour and 40 minutes after last attack. At the autopsy no other cause of death was found outside of advanced atheroma of aorta. Right auricle and ventricle were moderately dilated and left heart hypertrophied.

These cases are typical examples of ad-

vanced forms of asphyxia with apnea in the presence of marked chronic anoxemia. In all these cases resuscitation began after the third phase. The results obtained show the importance, in such cases of immediate and energetic resuscitation, and the futility of simple inhalation with manual artificial respiration. In these cases the insufflation—suction apparatus and mouth to mouth insufflation—are the only methods which have given me satisfactory and often striking results.

SUMMARY AND CONCLUSIONS

The relatively frequent development of acute asphyxia complicating chronic anoxemia always present in cases with chronic pulmonary suppuration either during operations upon these cases or during the post-operative period, has rendered necessary the perfection of our procedures of resuscitation.

A long study clinical and experimental was carried out on dogs on humans drowned at Coney Island beach and on our patients operated upon for chronic suppurations of the lung, especially with advanced pulmonary tuberculosis and bronchiectasis.

Ample experimental evidence has shown that acute asphyxia should be divided into 4 phases. It was shown that during the first 2 phases and the beginning of the third resuscitation can be easily obtained with manual artificial respiration and inhalation of oxygen carbon dioxide 5 to 10 per cent as shown by Vandel Henderson. On the contrary in the third phase which is characterized by rapidly falling blood pressure ending in arrest of the heart (fourth phase) inhalation and manual methods are inadequate to insure resuscitation. Suppression of muscular tonus and apnea prevent any adequate ventilation of the blood by these methods.

Experience had shown that in these cases mouth to mouth insufflation has given by far the best results. Therefore, it was thought that an apparatus based on the automatic pulmotor principle, with constant pressure and variable volumes, could be useful in cases in which mouth to mouth insufflation was not applicable as in tuberculous or bronchiectatic patients.

An apparatus based on this principle was

selected (E & J apparatus) and submitted to exhausting experimental investigation. The results of this inquiry having been favorable, this apparatus was used upon human cases with satisfactory results.

It seems, therefore, that previously prevailing opinions against the principle of a rhythmic insufflation-aspiration must be revised. At any rate these opinions were not based, at least in the reports and papers published up to this date, upon any thorough experimental or even clinical evidence. On the other hand, it is peculiar that even in the papers of Henderson in which the principle of insufflation-suction is definitely condemned, intratracheal insufflation (procedure of Meltzer) is recommended for the resuscitation of stillborn infants.

The evidence presented in this paper has convinced me that while manual artificial respiration with oxygen-carbon dioxide inhalation are efficient procedures for non-advanced degrees of asphyxia (first to third phase) they become useless and even dangerous, because of loss of time, when asphyxia has reached the third and especially the fourth phase. In the presence of apnea and beginning relaxation of the muscular system, only methods insuring forcible insufflation of oxygen into the lungs can still produce resuscitation.

It should be understood that these two procedures should not be opposed to each other. They have their special indications and they complete one another. The automatic pulmotor principle, complements manual artificial respiration with inhalation in advanced asphyxia as the principle of passive expansion-contraction of the chest, utilized in the machines of Drinker and Emerson, is the only one suitable in cases of paralysis of the respiratory muscles.

In a general way mouth-to-mouth insufflation or mechanical insufflation-suction need be applied for a relatively short time and until spontaneous respiratory movements have been resumed. Resuscitation should be continued thereafter by the inhalation method until complete recovery. In cases of asphyxia with carbon monoxide, inhalation should be continued for a relatively long time.

Thus we come to the conclusion that the ideal mechanical contraption for resuscitation is an apparatus which combines an inhalator and a resuscitator. A simple inhalator represents only one half of such an apparatus. Therefore I am satisfied that the E & J apparatus is of a great help in mechanical resuscitation.

It is also my contention that this apparatus can cause no harm in the hands of non-medical but trained rescue squads. The fear of causing pulmonary, cardiac, or respiratory complications by rhythmic rise and fall of intrapulmonary pressure had not been corroborated either by my experimental and clinical investigation or by the studies of other authors.

Moreover, it was shown in the course of this work that in cases of asphyxia with apnea and arrested heart, resuscitation is possible by direct massage of the heart within 10 minutes from the time of arrest of the heart, provided that the lungs have been maintained actively ventilated.

Yandel Henderson has said recently that much still remains to be learned about asphyxia. It can be added to this wise remark that in order to learn it is necessary to free ourselves from cumbersome dogmatism and preconceived ideas. Only thoroughly checked experimental evidence and equally thoroughly controlled clinical facts must guide us in our statements and conclusions. Asphyxia has entered today the domain of everyday practice and its fundamentals should be well understood by anesthetist, surgeons and physicians, and adequate equipment for resuscitation should be made available for timely use.

THE FERTILE PERIOD IN PRACTICE

A Five-Year Clinical Study

ARTHUR G. MILLER, B S, A.M., M.D., Hobart, Indiana

IT is not my purpose in this article to enlarge the ever-increasing amount of technical data that are constantly broadening and changing our viewpoint of the phenomena of ovulation, conception, and pregnancy. But the avenues of thought, study, and research opened by work already accomplished are fascinating in the extreme, and the dimly seen possibilities of outstanding service to humanity urge every scientifically minded physician to add his bit to the still obscure phases of the problem.

Most of us cannot carry on the necessary research or laboratory and clinical procedure and I am, therefore, encouraged to note my own experience in actual practice, in the belief that every doctor can use some of the results of my more-or-less pioneering clinical efforts with the assurance of a successful outcome in practically all cases.

My interest in the fertile period and the physiological and biological discoveries that pointed to its existence began during a period of study in the Vienna clinics in 1931. There I first became acquainted with the work of Aschheim and Zondek, Ogino, Knaus, and others. Upon my return I began the regular use of the Aschheim-Zondek test for pregnancy, and developed a single injection method, using rabbits for test animals. This work was described in an article in *Medical World*, August, 1933. These efforts led to consideration of the fertility-sterility theory, which I hesitated to accept fully because I could not satisfy myself that the observed phenomena were based on a rational thesis.

INVESTIGATION OF THE SCIENTIFIC BASIS

In this quandary I began a thorough study of existing literature, including the latest and most pertinent data on the sperm cell, the egg cell, the ovary and the corpus luteum,

From the Miller Clinic

and the uterus and the pituitary hormones. The work of many investigators on the lower mammals, from the mouse to the monkey, was reviewed and verified. Nothing was taken for granted.

With the aid of Professor Thomas of the department of physics, Valparaiso University, hormones were extracted from female urine, and their action tested upon laboratory animals. Also with the technical aid of Professor Thruen of the chemistry department and Professor Elliot of the biology department, Valparaiso University, and the very generous help of the Methodist Episcopal Hospital, Gary, Indiana, the work of both Drs. Ogino and Knaus was repeated and checked.

There gradually appeared a rational premise for the existence of a fertile period in the menstrual cycle, and this was supported by all of the carefully verified evidence. It seemed advisable, therefore, to make actual tests and I commenced the application of the theory in a few cases, using the time intervals suggested by Knaus. The results of these efforts were most encouraging and were described by my associates and myself in *SURGERY, GYNECOLOGY AND OBSTETRICS*, June, 1933.

FIVE HUNDRED INDIVIDUAL CASES TESTED

From these early beginnings to the present time I have utilized the fertile period procedure in 500 private cases with excellent results. From time to time I have instituted such corollary procedures and changes as seemed necessary, and have tested various calendars and time interval indicators, by which the patient may locate her own fertile periods under my supervision. The procedure has been used in some instances to avoid pregnancy; in others to bring about pregnancy; and in many to space pregnancies properly.

Of these 500 women, 20 were considered unfit to apply the fertile period knowledge.

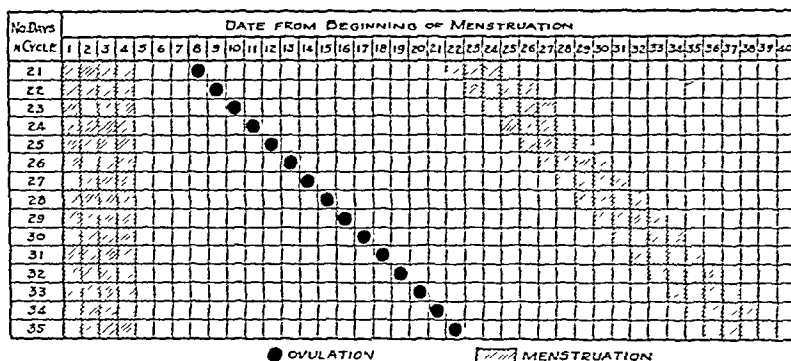

Fig 1 Ovulation date for various cycles

the day of ovulation in various cycles ranging from 21 to 35 days in length. In all of my work I have used a 5 day fertile period for a given cycle. This includes the day of ovulation as the fertility period of the egg cell, and 2 days preceding the day of ovulation as the fertilizing life span of the sperm cell. A day is then added at the beginning and end of this 3 day period to allow for the variation of a fraction of a day in the actual time of ovulation. The fertile periods for a number of cycles are shown in Figure 2, the day of ovulation being the next to the last day of the fertile period in each case.

In the present state of our knowledge the only exact measure of the length of the menstrual cycle is its termination, the onset of the next menstruation, and the beginning of the next cycle. If it were necessary to wait for this occurrence the information would be just 2 weeks late, and the only woman who could apply the fertile period knowledge would be one with the uniform cycle, having the same number of days each month. Such women are apparently very rare indeed.

THE LAW OF CYCLE VARIATION

Accurate study of the menstrual cycles of many women has revealed, however, that there is a law of recurrence in their cycles. This law may be expressed as follows: *Barring accident or disease, the menstrual cycle of a normal woman varies in length continually between a certain maximum and minimum number of days.* Here is the key that opens the door to the location of the ovulation date

within a certain period, thus pointing out the location of a period of possible fertility in the cycle of a normal woman.

The longest and shortest cycles shown by the written record, kept for 6 months or more, determine the length of the period of possible fertility. For instance, if the shortest cycle is 26 days and the longest cycle is 30 days, ovulation may occur on the thirteenth, fourteenth, fifteenth, sixteenth, or seventeenth day of the cycle, as shown in Figure 1. Allowing 3 days before the first ovulation date and 1 day after the last ovulation date, the period of possible fertility is from the tenth to the eighteenth day, inclusive. All the remaining days of the cycle are sterile. Figure 3 shows the periods in the 26 to 30 day cycle graphically.

NORMAL CYCLE LENGTH AND VARIATION

In the 480 normal patients who form the basis of this study the first thing of interest is the cycle length and its variation. Table II shows that these women had individual cycle variations of from 1 to 9 days. The numbers of cases for each variation follow the "normal distribution" type of curve, as would be expected, the variation norm probably lying between 4 and 6 days. The rarity of the uniform, unvarying cycle, as well as the variation of 10 days or more, is definitely indicated. The fact that about 85 per cent of these women had a variation of not more than 6 days (11 day fertile period) is also of interest.

The lower limits of the cycle lengths are listed in Table III. It will be noted here that

TABLE I—LOCATION OF OVULATION BY SYMPTOMS

Previous menstruation	Ovulation symptoms		Following menstruation at on	Interval—days	Length of cycle—days
	Location	Date			
12-1-15	Right ovary	Dec 14	Dec 29	14	37
12-18-25	Left ovary	Jan 13	Jan 27	14	30
1-27-36	Both ovaries More on right	Feb 13	Feb 27	14	31
2-27-36	Left ovary	Mar 16	Mar 30	14	31
3-10-36	Right ovary	Apr 24	Apr 8	14	29
4-18-36	Left ovary	May 14	May 28	14	30
5-26-36	Right ovary	June 11	June 25	14	28
6-25-36	Left ovary	July 8	July 22	14	27
7-22-36	Both ovaries More on right	Aug 7	Aug 21	14	30
8-21-36	Left ovary	Sept 7	Sept 21	14	31
9-21-36	Right ovary	Oct 9	Oct 23	14	32
10-23-36	Left ovary	Nov 7	Nov 21	14	29
11-21-36	Right ovary	Dec 8	Dec 22	14	3

their condition being determined by a simple procedure which is followed in each case (1) each woman is required to present a written record of the beginning dates of the last six menstruations, (2) each woman is given a thorough physical examination which includes a pelvic search for pathology

IMPORTANCE OF PHYSICAL EXAMINATION

The physical examination is just as important as the menstrual record, because a woman may have a seemingly normal cycle variation and yet be afflicted with some systemic or pelvic condition which will soon make it impossible for her to use the fertile period law successfully. This careful weeding out of the abnormal cases accounts in a large measure for the very gratifying results obtained in this study as compared with the many failures reported by other women who have attempted to apply the new knowledge without the advice and guidance of their physicians.

The 20 abnormal women showed the following conditions: 3 had well advanced pulmonary tuberculosis, 4 had a fibroid uterus, 1 had an ovarian carcinoma, 4 had cervical carcinoma, 2 had occluded fallopian tubes, 4 had large ovarian cysts, 1 had a uterine polyp, and 1 had pernicious anemia.

PHYSIOLOGICAL FACTS LOCATE FERTILE PERIOD

The existence of definite fertile and sterile periods in the menstrual cycle is based on just three facts: (1) Ovulation occurs 14 days before the following menstruation. (2) The egg cell can be fertilized only during the 12 hour period immediately following its emergence from the follicle. (3) The fertilizing ability of the sperm cell in the female genital tract is maintained for not more than 24 to 36 hours.

Much research remains to be done to determine these intervals exactly under all kinds of conditions. For example, no free fertilized human egg has ever been removed from the uterus of a woman, the youngest embryo yet described being 11 days old.

However, if the intervals herein noted are assumed to be the maximum, it is possible to calculate the location of supposedly sterile periods, which can then be tested for various cycles. This has been the basis of my 5 year study.

OVULATION INDICATED BY SYMPTOMS IN SOME CASES

Many women observe a painful sensation over one or both ovaries for an hour or more at the time of ovulation. Late in 1935 I asked one of my patients who always recognizes the *mittelschmerz* to keep a record of the date and location of these pains, as well as the menstruation dates. Her record is shown in Table I. This woman is in normal health, 32 years old, and has two children. She knows nothing about the time when ovulation is supposed to occur. She describes her symptoms on the dates shown as similar to those at the onset of menstruation. The record is valuable as corroborating evidence that ovulation occurs 14 days before the following menstruation. We have found, however, that most women cannot locate the day of ovulation accurately from symptoms.

FERTILE PERIOD LOCATED BY OVULATION

For the location of the fertile period the day of ovulation is the basis. As already stated, ovulation occurs 14 days before the following menstruation. Figure 1 shows the position of

Research along this line is now being conducted in this clinic.

Fig. 4. Graphic presentation of Tables II, III, and IV

period, although 7 of them used contraceptive methods. It is, of course, impossible for a doctor to enforce continence during the fertile period, but in all cases in which the patient's health had depended on the avoidance of pregnancy I have instructed them carefully and no failures have resulted.

During this study 27 women have used the fertile period procedure to space their pregnancies properly. In other words, they first avoided pregnancy and later conceived at the desired time through cohabitation during the fertile period. Fifteen women came seeking advice for the relief of sterility of one or more years' standing, and for the sole purpose of becoming pregnant. Six of them became pregnant after a single cohabitation during the fertile period. Two of the 6 afterward avoided conception for several months and then attained a second desired pregnancy through a single cohabitation during the fertile period. They are now using the procedure to avoid further conception.

RELIEF OF SUPPOSED STERILITY

The case of Mrs. G. H., age 32, married 8 years, is a good example of the relief of supposed sterility (Fig. 5).

She came to us complaining of sterility, but examination showed no essential reason why she could not become pregnant. Her menstruation record for 6 months revealed a 27 to 32 day cycle, the last menstruation date being July 26. During the month of August she cohabited just once, on August 13. No menstruation having occurred on August 30, a rabbit test for pregnancy was made and showed positive. In 280 days from the beginning of the last menstrual period she gave birth to a 9½ pound baby girl. Menstruation again occurred 4½ months after delivery and the menstrual record for the next

TABLE II.—CYCLE VARIATIONS OF 480 NORMAL WOMEN

Cycle variation in days	Number of cases	Per cent of cases	Cumulative percentage
1	2	0.4	0.4
2	24	5.0	5.4
3	68	14.2	19.6

Fig 2 Fertile period for various cycles

Fig 3 Various periods, in 26 to 30 day cycles

the numbers of cases do not follow the "normal distribution" curve since a majority of these women had a minimum cycle length of 26 days

Table IV lists the maximum cycle lengths. Here the numbers of cases again seem to follow the normal distribution with the maximum cycle length normally lying between 30 and 32 days. The data listed in Tables II, III, and IV are shown graphically in Figure 4 which gives a fairly definite picture of what the physician can expect among his normal healthy patients. It shows that the old, time honored 28 day cycle has been largely a figment of the imagination and that the average healthy woman will have a cycle which varies between a minimum of 26 or 27 days and a maximum of 30 to 32 days.

The implications of these figures are extremely fascinating because they point to the possibility of using the accurate record as an indicator of abnormal female condition. I have explored this possibility and in a number of cases have been able through careful study of the menstrual record and a subsequent examination, to detect incipient disorders of which the patients were entirely unaware.

IMPORTANCE OF MENSTRUAL RECORD IN DIAGNOSIS

It is my belief that an accurate menstrual record is a definite indicator of normal or abnormal function and that a more concerted effort should be made by members of the medical profession to secure accurate, authentic menstrual histories. Heretofore most of the published records have come from the inmates of hospitals and other institutions and were based entirely on memory. Little attention has been paid to the physiological and pathological conditions of the women in relation to the menstrual flow. What we need is a great mass of data from women in all walks of life, from the normal, healthy ones, as well as those who suffer from incipient or advanced abnormal conditions.

CONCEPTION CONTROLLED SUCCESSFULLY

A most significant fact about this 5 year use of the fertile period procedure is that not a single pregnancy has resulted from cohabitation outside the fertile periods established for the various patients. A total of 12 women who desired to avoid pregnancy have become pregnant through cohabitation during the fertile

		FIVE - YEAR COHABITATION RECORD																														28 TO 33 DAY CYCLE

		STERILE PERIOD										PERIOD OF POSSIBLE FERTILITY 28-33 DAY CYCLE										STERILE PERIOD															
/////// - FERTILE PERIOD FOR GIVEN CYCLE. X - COHABITATION DATES. O - OVULATION DATES. A - ABORTION DATES																																					

Fig. 6 Five year cohabitation record

Mrs F G, aged 35 years, married at the age of 20, had 3 children, the youngest aged 10 and an incurable idiot. Because of the great burden her youngest child has been to her family she did not desire more children for fear that they too might be feeble minded. In spite of the fact that she earnestly sought contraceptive advice and had used various types of vaginal suppositories, jellies, and cones;

also a combination of jellies and rubber diaphragms; a gold stem pessary; also lemon juice lysol, potassium permanganate, boiled milk and iodine as douches, nevertheless, during the following years she became pregnant six times and underwent six self-induced abortions. Having heard of the fertile period theory she came with an 8 months' record of her menstruation dates and volunteered the infor-

Fig. 5. Relief of supposed sterility

6 months revealed a 28 to 32 day cycle. For the next 11 months she avoided pregnancy and, during the twelfth month a single cohabitation during the fertile period resulted in a desired pregnancy. She gave birth to a 10 pound boy, 281 days after the beginning of the last menstruation. Four months later menstruation again commenced and a 6 month record showed a 28 to 31 day cycle. She is now using the fertile period procedure to avoid further conception.

A 5 YEAR COHABITATION RECORD

I am fortunate in being able to present the cohabitation record of Mrs. E. J., who has been noting the dates of her cohabitations and menstruations since 1931.

This woman first attempted to utilize the fertile period law after reading a lay book on the subject and became pregnant twice. She was later instructed by me and has avoided pregnancy for several years. The cycle variation has been from 28 to 33 days and the location of the various cohabitations with respect

to the period of possible fertility, the actual fertile periods and the ovulation dates is shown in Figure 6. It is interesting to note that although the first day of the possible fertile period was violated in 5 instances during 1932 and 1933 no conception resulted.

TIME INTERVALS AMPLE AND PRACTICAL

That the time allotted for the life of the sperm cell and the fertility period of the egg cell is ample there can be no doubt, because many women have reported violations of the first and last days of the period of possible fertility. Still no pregnancy resulted and a careful examination of their records show that they missed the actual fertile period for the current cycle by only one day. A case in point is reported in brief as follows:

TABLE IV—MAXIMUM CYCLE LENGTHS OF 480 NORMAL WOMEN

Maximum cycle in days	Number of cases	Per cent of case
25	1	2
26	4	8
27	9	19
28	23	48
29	3	25
30	110	24.8
31	1	25.1
32	91	19.0
33	44	9.2
34	5	5
35	35	7.3
36	8	4
37	4	8
	480	100.0

TABLE III—MINIMUM CYCLE LENGTHS OF 480 NORMAL WOMEN

Minimum cycle in days	Number of case	Per cent of cases
23	14	8
24	16	3.3

	480	100.0

nostic aid of abnormal female sex organ function. It also shows that ovulation has a definite time relationship to the next succeeding menstruation, and indicates that the time between ovulation and the next menstruation is a matter of 14 days.

1. The regularity, duration, and character of the menstrual periods are the chief signs indicating normal or abnormal female sex organ function.

2. Barring accident or disease the menstrual cycle of a normal woman varies continually between a certain maximum and minimum number of days.

3. Ovulation has a definite time relationship to the next succeeding menstruation and, regardless of the rhythm in the menstrual cycle, this relationship does not change.

4. That there are definite periods of physiological fertility and sterility in the menstrual cycles of normal women appears to be a definitely established biological law.

5. The fundamental scientific basis of the fertile period procedure is sound and reliable. The procedure offers to mankind, when it is supervised by a physician, a simple, dependable, and physiological method for conception control.

mation that her cycle was exactly 26 days. A careful check showed it to have a 24 to 26 day variation. A suitable calendar was furnished to her with specific instruction for its use. A year later she returned with the calendar properly marked to show menstruation dates and cohabitations. This time she informed me that the device had certainly been a God send to her that she had had 66 cohabitations and had not become pregnant. Careful study of the calendar revealed some startling facts which nevertheless show that there is a considerable safety factor in the time intervals used. She had coitus five times on the first day of the possible fertile period, five times on the last day of the possible fertile period, and three times she violated both the first and last days of the same period. Still no pregnancy resulted because she missed the actual fertile period by exactly one day in each instance.

TEDIOUS CALCULATIONS ELIMINATED

For most doctors and their patients calculations of the various periods are tedious and subject to error. Fortunately, accurate charts have been published giving the required information instantly when the cycle has been determined from the patient's written record.

In my practice I use a chart which shows the fertile periods, the sterile periods, and the time of ovulation for about 90 different cycle variations. It also indicates, by means of an accessory aid, the actual calendar dates in any period and the number of days between any two consecutive menstruation dates. This chart is very much worth while because it obviates counting on the calendar, saves time and eliminates the chance of error.

TIME INDICATORS FOR PATIENT'S USE

The last necessity for the doctor who utilizes the fertile period procedure for his patients is a means for getting the information to them in some usable form which will eliminate as far as possible the chances of error on their part. There are available a variety of indicating devices and many lay books have been published on the subject. The lay books are all very interesting to read, but our experience has been that most women are not able to apply the published information in a practical manner, their calculations being about 90 per cent wrong.

During this 5 year study 7 different styles of indicating devices or individual calendars have been investigated. Although elaborately

constructed, one was applicable only to women with a cycle variation of 26 to 31 days. Three others were discarded as being much too complicated, even for most physicians. A fifth one was found to locate ovulation 15 days before the following menstruation, and investigation showed that 5 pregnancies had resulted from coitus on the first indicated non fertile day after ovulation. A sixth was found to be thoroughly reliable, but indicated what seemed to us an unusually long fertile period. The seventh is now being generally used by our patients. It is made up to suit any one cycle variation only, incorporates a standard continuous calendar, and is therefore less liable to error. Unlike all others, it is distributed only through the medical profession. During the past 3 years it has had no recorded failures in more than 30,000 cohabitations.

PRACTICAL AND SIMPLE ROUTINE PROCEDURE

Beyond these indicating devices the doctor needs no further equipment to put the fertile period procedure into practice. In this clinic every menstruating woman is told of the importance of an accurate menstrual record and is given a suitable card on which to record the dates. Every recently confined woman is instructed as to the importance of spacing pregnancies. A regular, completely effective routine has been developed, in which there are only four comparatively simple steps.

1. Get from the patient a list written down at the time of the last 6 or 8 menstruation dates.
2. Determine the cycle variation from the longest and shortest cycles in the list.
3. Examine the patient for abnormal pelvic conditions and correct those found, if necessary.
4. Furnish to the patient an indicator or individual calendar that is as nearly fool proof as possible.

SUMMARY AND CONCLUSIONS

A 5 year clinical study of the fertile and sterile periods of women has been made. This study quite definitely points out the value of accurate menstrual records as an early diag-

lier papers on the subject reported that corpus luteum extracts failed to inhibit ovulation in rodents. The present view universally held by all students of the subject, however, is that corpus luteum is directly concerned with the course of pregnancy. Corner (12) sums up the matter in this way: Broadly speaking, the endocrine function of the corpus luteum is a part of the mechanism of pregnancy. Its action is exerted on the uterus to prepare that organ for the reception and nutriment of the embryo. When the ovum begins its journey through the fallopian tubes, the follicle whence it took its origin gives place to the corpus luteum, and this newly formed corpus luteum begins to deliver into the blood stream a substance causing extensive development of the uterine glands and changing the histological structure of the uterine mucosa or endometrium. By the time the fertilized ovum reaches the uterus, the endometrium through this action upon it of corpus luteum hormone is in a state of heightened secretory activity by which nutritive substances are provided for the embryo. Furthermore, through the action of the corpus luteum secretion, the endometrium is sensitized so that it responds to the presence of the embryo by forming the maternal part of the placenta. It has been shown experimentally that removal of corpus luteum from an animal during the early part of pregnancy results in failure to implant the embryo or, if the embryo is already implanted, effects a deterioration of the pregnancy. Corner found that injection of corpus luteum extract in castrated rabbits produced pregnancy changes in the uterus. In rabbits castrated during early pregnancy, injection of progestin protected the embryos against the loss of their mothers' corpora lutea and maintained the pregnancy to full term. In guinea pigs progestin was found to sensitize the uterus to produce the maternal placenta or so called Loeb's *deciduoma*.

2. RELATION OF CORPUS LUTEUM TO MENSTRUATION

It is now generally known that menstruation is not identical with ovulation although it bears a definite relation to the estrus cycle of various animals, including human beings.

Physiologically speaking, menstruation is the last effort made in the sex cycle of higher animals after there has been failure to conceive. It has been shown in women (100) and in monkeys (80) that menstruation, disappearing as a result of ovariectomy, may be induced experimentally by treatment with estrogenic substances. On the other hand, Pratt claims that excision of corpora lutea in adult primates will precipitate menstruation. It has been demonstrated that the injections of corpus luteum extract may delay or postpone menstrual periods experimentally produced in monkeys. It is now generally agreed that, in the normal menstrual cycle, both the estrogenic or follicular hormone and corpus luteum play rôles. Typical progestatized endometrium has been produced in ovariectomized monkeys by successive folliculin and corpus luteum injections (35). Similar experiments have been reported by Smith and Engle (89), and Kaufmann has actually produced premenstrual endometrium in castrated women by first administering large doses of estrogenic substance to bring the uterus back to its normal interval stage and then injecting corpus luteum extract to effect the premenstrual changes. A proper balance between the follicular and corpus luteum hormones is essential for normal menstruation, as estrogenic substance has been demonstrated in the human corpus luteum during the premenstrual stage (2, 4). These studies on menstruation point unequivocally to an important endocrinological function of the corpus luteum in primates but the methods employed are too complicated for practical routine assay of the hormone.

3. HISTOLOGICAL CHANGES INDUCED BY CORPUS LUTEUM EXTRACTS

Various investigators have found that progestin or corpus luteum hormone produces histological changes in different lower animals and also in human beings. Corner states that administration of progestin produces pregnancy changes in uterus of castrated rabbits. Corpus luteum extracts, administered to rabbits castrated during early pregnancy, as has already been stated, protect the embryos against loss of the mothers' corpora lutea and

METHODS OF DEMONSTRATING THE ACTIVITY OF CORPUS LUTEUM

DAVID I MACHT, M D, F A C P Baltimore Maryland

THE exact number of ovarian hormones present in the body of higher animals is still in dispute. Many think there are at least three such internal secretions—the follicular hormone, the corpus luteum hormone, and the hormone of interstitial tissue, others, a larger number. Fraenkel's early researches stressed corpus luteum as the most important internal secretion of the ovary, a view which prevailed for some years although slightly modified by Marshall and others. Later, studies on the effect of x rays on the female gonads brought the function of the so called interstitial ovarian tissue into prominence and pointed to the endocrinological action of that tissue, elucidated by the work of Bounin, Ancel and Villemin, and of Steinach and Holzkehn. Following the interesting researches of Stockard and Papanicolaou (93) concerning the histological changes in the gonads and accessory organs produced at various periods of the estrus cycle, an enormous amount of work was done on the cellular structure of the vaginal epithelium which culminated in the study of the estrogenic or follicular hormone by means of vaginal smears. These researches, popularized by the writings of Allen and Doisy (3), S. Loewe, and others directed the attention of physiologists to the function of the follicular fluid and stressed the hormones contained therein as the principal endocrine product of the ovary. While the exact number of ovarian hormones is still unsettled and their chemical nature occasions even more dispute among those investigators who have been working on the biochemistry of the gonads, it is the general consensus that the female gonad elaborates at least two different hormones quite distinct in their physiological function. One of these is the follicular hormone, often known by other names such as estrogen, folliculin, amniotin, menformon etc., the other is an internal secretion elaborated by corpus lu-

teum particularly when fully developed. The physiological action of the follicular hormone can be demonstrated in several ways and especially by the study of the vaginal epithelium obtained from smears or scrapings of castrated female rats, mice, and guinea pigs. The character of the cells thus obtained changes after such castrated animals have been injected with estrogenic hormone. Demonstration of the physiological function of corpus luteum, although effected in any one of a number of ways, is much more difficult. The purpose of the writer is to offer a brief resumé of the physiological procedures employed for detecting and demonstrating the activity of corpus luteum either *in vivo* or by pharmacological use of corpus luteum extracts and further more to describe and present his experiences with some of the newer methods of approach more recently employed in that connection.

Experimental data pointing to physiological action of corpus luteum hormones may be classified as those pertaining to (1) the relation of corpus luteum to pregnancy, (2) the relation of corpus luteum to menstrual cycle of monkeys and human beings, (3) histological changes produced by corpus luteum in sexual apparatus, (4) changes effected by corpus luteum in vaginal epithelium, (5) gross anatomical changes produced by corpus luteum hormone in uterus etc., (6) influence of corpus luteum on contractions of smooth muscle, and (7) miscellaneous physiological effects produced by corpus luteum.

I. RELATION OF CORPUS LUTEUM TO PREGNANCY

Pearl and Surface have described an inhibition of ovulation following intraperitoneal administration of a fat free preparation of corpus luteum substance. Haberlandt, Knaus (47) and Kennedy noted that temporary sterility of females was produced by injections of corpus luteum extracts. On the other hand, Loeb, and Corner and Hurns (14) in their ear-

the results of which indicate that such corpus luteum injections, as compared with those of the follicular hormone, exert an antagonistic action. The experiments were made on various series of guinea pigs. For a long time the normal cycle of each animal was determined by vaginal smears. After the duration of the respective animals' estrus cycles had been established, guinea pigs were given repeated daily injections of water-soluble corpus luteum extracts (prepared by various methods); and their effect on the duration of the cycle was observed. It was found that the corpus luteum injections markedly prolonged the *diestrus* or interestrus interval. Table I reveals the findings obtained in experiments with 27 such animals. While the average diestrus of normal or untreated animals was 11.9 days, that of the guinea pigs thus treated with corpus luteum extracts was 44.7 days. These figures demonstrate decisively that corpus luteum greatly prolonged the interestrus interval. Of further interest was a supplementary study made by Macht and Stickels (62) in which corpus luteum was not injected but fed to guinea pigs for long periods. Table II shows the results obtained in these tests.

5. CHANGES IN GROSS ANATOMY

Besides the histological or microscopic changes produced by female sex hormones injected under specified conditions, marked changes in the *gross* appearance of various organs have also been observed after such treatment. Indeed, the most important criterion of the activity of extracts used in earlier work on this subject was the gross appearance of the uterus and gonads. Many such changes were noted after injection of follicular extracts in one form or other. The aim of some of the early injection experiments was to "maintain uterine nutrition," inasmuch as removal of both ovaries was invariably followed by atrophy of the uterus. Such administration of some of the extracts was followed by most striking results (1, 11, 22, 24, 31, 38, 39, 71, 83, 84, 85). Another criterion was the *swelling* and *hyperemia* produced by ovarian extracts in area surrounding the external genitalia of rabbits, pigs, dogs, and monkeys (91). Changes in size of the uterus in the smaller rodents were

TABLE I—EFFECT OF INJECTIONS OF CORPUS LUTEUM ON ESTRUS CYCLE OF THE GUINEA PIG

of special interest. Zondek and Aschheim (102) noted an increase in size of uterus of mice injected with follicular extracts. Similar observations were made by Kochmann. Other changes were noted in the mammary glands (7, 55) of both males and females but especially of the latter. Frank and Rosenbloom noted that certain ovarian extracts injected in rabbits stimulated the growth of not only the uterus but also the vagina, breasts, and accessory organs, while Courrier observed that they accelerated development of the uterus and other genitalia in newly born animals. After continued treatment of rats with

induce characteristic pregnancy changes in the uterus, and corpus luteum hormone administered to guinea pigs, sensitizes the uterus and produces the maternal placenta or so called Loeb's *deciduoma*. Later work by Hisaw, Meyer and Fevold, by Smith and Engle, and by Corner revealed that progesterin, administered to monkeys, produces a picture characteristic of premenstrual endometrium. So characteristic is the change produced by progesterin in rabbits according to Corner and Allen (13), that they have advocated as a standard for assaying it the so called *rabbit unit*, which is the amount of the hormone (divided into 5 equal daily doses) that will produce on the sixth day a microscopic condition of the uterus equal to that of the eighth day of normal pregnancy. Injections of corpus luteum hormone have also produced physiological changes in other and more remote organs.

Herrmann and Stein (32) reported that when injected in young male rats and rabbits, the estrogenic hormone delayed attainment of sexual maturity and furthermore that large quantities of corpus luteum hormone injected in adult rats and rabbits, produced in the testes degenerative changes not unlike those produced by x rays. Fellner (20, 21) repeated and extended this work and discovered that degeneration of testes was produced by injections of placental or corpus luteum lipoids. This so called "antimale" property of corpus luteum is of interest in connection with the peculiar reaction of the vas deferens and seminal vesicles described by Macht and Matsumoto. The latest study on histological changes is that made by Pincus and Werthessen, who have correlated the activity of corpus luteum preparations with microscopic measurements of the actual size of the ovum. All such studies as those mentioned, however require very complicated technique and are not suitable for practical bioassay of corpus luteum preparations. One special method of histological character however, is adapted to the assay of estrogenic substances and has been employed by the present writer also in testing corpus luteum extracts and preparations. It is the study of the vaginal epithelium.

4 EFFECT OF CORPUS LUTEUM HORMONE ON VAGINAL EPITHELIUM

The most popular method for studying female hormones, derived from the follicles and spoken of as the follicular or estrogenic hormones or theelin may be described as follows. Vaginal smears obtained from normal intact rats or mice present periodic variations in the number and character of epithelial blood, and other cells in relation to their estrus cycles. In castrated or ovariectomized animals a typical and constant picture of the diestral stage is maintained. When injections of estrogenic hormone are given to such animals however, the character of the vaginal cells changes and repeated injections produce a picture of estrus. Accordingly use has been made of such changes in vaginal cells in assaying preparations of that type.

Can any change in character of the cells obtained from vaginal smears be effected by administration of corpus luteum hormone? Corpus luteum in contrast to estrogenic substance, can obviously not be expected to stimulate estrus. On the other hand, there is a possibility of its acting synergistically or antagonistically to follicular hormone. A number of investigators have attacked this problem. The most satisfactory experiments with corpus luteum on the estrus cycle of animals were obtained not with mice or rats (because of the short duration of their cycles) but with guinea pigs, the estrus cycle of which is considerably longer (10 to 12 days). Thus, Papanicolaou, who injected extracts from the corpus luteum in guinea pigs reported inhibition of estrus, determined by the smear method over extended periods while negative results were obtained in control tests on follicular fluid, placenta and other tissue. Papanicolaou considers this the proper luteal hormone. Parkes and Belferby obtained vaginal reactions in mice by injecting small doses of follicular fluid after ovariectomy and attributed such results to removal of corpus luteum inhibition. Voss has also effected an inhibition in guinea pigs by administering corpus luteum extracts.

The present writer in collaboration with Stickels and Seckinger (65) has for several years carried on studies along these lines,

Fig 1. Stimulation of uterus of virgin rabbit effected by 0.02 cubic centimeter of pituitrin (surgical, P D).

6. RELATION OF FEMALE GONADS TO ACTIVITY OF UTERINE AND OTHER SMOOTH MUSCLE ORGANS

A. Relation to posterior pituitary hormone

In recent years studies on the contractions and tonicity of the smooth muscle from the uterus, fallopian tubes, seminal vesicles, vasa deferentia, etc., have thrown considerable light on the intricate physiology of the sex hormones and yielded useful criteria for evaluating their activity, particularly that of the corpus luteum. Knaus (48, 49, 50) established the fact that the excised uterus of a rabbit under the influence of a functioning corpus luteum did not respond to treatment with the posterior pituitary hormone *in vitro* as did the

virgin uterus, whereas even minute doses of pituitrin effected a powerful contraction in the control, taken from a virgin rabbit.

While it is generally accepted that the estrogenic hormone stimulates the contractions of the uterus, as shown by the work of Parkes, Kelly, Zondek and Aschheim (103), Brouha, and others, accumulated evidence reveals that in normal higher animals and the human being, the corpus luteum hormone inhibits or quiets contractions of the uterus. Thus Knaus (51) and Manzi maintain that the uterus is kept in a state of quiescence during pregnancy by the influence of the corpus luteum and when, toward the end of pregnancy that effect diminishes, the organ becomes more

TABLE III—EFFECT OF INJECTIONS OF ESTRIN ALONE AND ESTRIN PLUS LUTEIN ON WEIGHT OF MOUSE UTERUS

anterior lobe of the pituitary Long and Evans found that the ovaries were enlarged as the result of formation of many corpora lutea

Have any gross anatomical changes been noted after administration of corpus luteum? As late as 1927 Allen and Dowsy stated that they knew of "no successful attempts to

inhibit the action of injected follicular hormone by injection of corpus luteum extract." More recently, the present writer, collaborating with Stickels has obtained some interesting results in studies on synergistic effects of combinations of estrogen and corpus luteum hormones. This work was stimulated by the interesting finding of Siddall who developed a novel test for pregnancy. It was found that the usual ratio of the uterus weight of a mature non pregnant white mouse to its body weight is over 1.400. Normal mature mice were injected with follicular estrogenic extracts for 7 to 10 days, at the end of which period they were killed and the weight of the uterus determined. Such injections markedly increased the size of the uterus so that the ratio of its weight to that of the body fell far below 1.400.

Macht and Stickels (63) undertook similar studies with both the estrogenic hormone of the ovary and with corpus luteum extracts. A series of mice, injected daily for 2 weeks with a standard estrogenic extract, were then killed, and the ratio of the uterus weight to that of the whole body was determined. A marked hypertrophy, shown by increase in the weight of the uterus, was noted. In a second series, mice injected with corpus luteum extract alone revealed no change in size or weight of the uterus. A third series of mice was injected for the same length of time with a mixture of the same estrogenic preparation and a water soluble corpus luteum extract prepared in this laboratory. The most striking discovery made was that no hypertrophy such as had succeeded injection of estrogenic extract alone followed administration of a combination of estrogenic and corpus luteum extracts. These experiments clearly revealed that lutein antagonized or inhibited the stimulating action of the follicular hormone. Table III strikingly illustrates these findings. This antagonism between corpus luteum and follicular extracts was noted not only in injection experiments but also after feeding experiments, prolonged for several weeks in which the two hormones were administered in combination to mice. The findings in these experiments are shown in Table IV.

Fig. 3 Effect of 0.01 cubic centimeter of pituitrin (surgical, P D) on uterus of normal virgin rabbit

and recurrent abortion uterine contractions were inhibited by such an extract. Halban advocated the employment of corpus luteum in the treatment of abortion, and the successful use of such preparations has been reported by Glismann, Antecki and Zwolinski, Wolfson, Weinzierl, Bracht, Wagner, and Knab Krohn, Falls and Lachner employed corpus luteum for the treatment of threatened and habitual abortion and have recently (by a balloon method) demonstrated that corpus luteum inhibited the contractions of the uterus (19). More recently, Robson and Illingworth, and de Fremery, Luchs, and Tausk have studied various fractions obtained from corpus luteum extracts and found that one of these, which they called "desensin," thus inhibits the action of pituitrin on the uterus. Similar findings were made by Foster, and especially by Reynolds Corner (66) and his associates used such uterine preparations in assaying a corpus luteum hormone which they prepared and named "progestin."

The present writer has been experimenting on rabbits for over a year in order to study these remarkable variations in contractions of uterine muscle in relation to the influence of corpus luteum hormone and that of the posterior lobe of the pituitary gland. In these studies the writer employed an aqueous solu-

tion of the corpus luteum (prepared in these laboratories) of which numerous physicians have made wide clinical use with allegedly favorable therapeutic results. Healthy normal virgin rabbits were selected. In some, ovariectomy was performed, in others, the ovaries were left intact. A standard preparation of pituitrin (P D.) was used for testing the oxytocic response of uterine muscle. In most of the experiments one horn of the virgin uterus was removed under aseptic conditions and the animal was allowed to recover. The contractions with which the excised tissue in oxygenated Locke solution responded to small doses of pituitrin were carefully recorded. The rabbit operated upon was then given repeated intravenous injections of corpus luteum extract for 10 days, after which the other horn of the uterus was studied in similar fashion. It was found that injections of lutein (H W & D.) effected in behavior of the muscle such a change as that described by Corner and other previous writers. Uterine preparations (from mature rabbits) previously treated with lutein gave a much weaker response to pituitrin and, after very large doses of lutein, did not react to pituitrin at all although other oxytocic agents effected a contraction of the muscle. The subjoined curves show the type of response obtained in control animals, on

Fig. 2 Effect of repeated injections of lutein (HWD) totaling 30 cubic centimeters on uterus of virgin rabbit

sensitive to the influence of the posterior lobe of the pituitary. The work of the Smiths (90) indicates that during pregnancy a physiological balance is maintained between estrogenic and corpus luteum hormones. As pregnancy progresses the estrogenic principle, becoming more dominant sensitizes the uterus to the oxytocic influence of the posterior lobe of the pituitary, and thus labor follows. Allan and Dodds (5) expanded this theory of labor onset. Inasmuch as corpus luteum vitally affects

the normal course of pregnancy, on the one hand and inhibits the motility of the uterus, on the other numerous investigators have successfully employed extracts of corpus luteum to prevent abortion and maintain the normal course of pregnancy. Miklos prolonged pregnancy in rats with aqueous extracts of corpus luteum. Clinically Hirst injected aqueous extracts of corpus luteum from pregnant cats to prevent habitual abortion. Hofbauer reported that in threatened

Fig 5 Relaxation of uterus of virgin cat effected by injection of 0.1 cubic centimeter of a 1:1000 solution of adrenalin, followed by stimulation produced by 0.025 cubic centimeter of pituitrin (surgical, P.D.) and, finally, by relaxation on addition of 5 milligrams of bromsalizol

alteration of character of the sex hormone set free in the cat's circulation during pregnancy. Accordingly, those authors, experimenting with injections of progestin or corpus luteum extract in cats, found that a reversal of epinephrin action took place in virgin cats under such conditions. Similar experiments were made by Kennard, and recently on guinea pigs by Holtz. The present writer, desiring to duplicate the experiments made by the American investigators, carried out a series of such studies

on virgin and pregnant animals. The results obtained fully agreed with those described. It was found that uterine preparations obtained from normal virgin cats and studied *in vitro* responded to adrenalin with relaxation of the tonus and inhibition of contractions. On the other hand, it was found that the uteri of virgin cats, injected intravenously for 2 weeks daily with extracts of corpus luteum, reacted paradoxically when treated with adrenalin and responded with much less relaxation and sometimes none at all although a positive pressor effect or contraction was noted rarely. The subjoined curves illustrate these findings (Figs 5, 6, and 7)

C. Physiological responses of the vas deferens

Some years ago Macht and Matsumoto described a third phenomenon in regard to the contractility of smooth muscle organs in relation to the sex hormones. Those findings have more significance at the present time than they conveyed 18 years ago. The authors undertook a study of the physiological effects of all kinds of glandular extracts on the motility of the genito-urinary organs or, more specifically, on the contractions of the smooth muscle they contain. The effects of various

Fig 6 Stimulation adrenalin produces in uterus of cat in early pregnancy (1 to 2 weeks).

Fig. 4. Small effect produced by the administration of pituitrin (surgical P.D.) on horn of uterus of virgin rabbit which had been fed desiccated lutein (1 gm. a day) for a period of 5 weeks.

the one hand, and in rabbits treated with corpus luteum extract, on the other (Figs. 1 and 2). A comparison of the writer's curves with those of other investigators revealed that a cubic centimeter of the corpus luteum solution exerted an action similar to that effected by 0.1 milligram of progesterone.

Although, generally speaking, considerable skepticism exists regarding the effectiveness of the female sex hormone products administered *per os*, the writer is inclined to believe that the feeding of such preparations, when continued for a sufficient length of time, does have a definite physiological action. The writer has performed experiments in which instead of injecting extracts of corpus luteum, the desiccated gland was fed by stomach to rabbits for several weeks. In control experiments other rabbits were given the same food minus the powdered corpus luteum. The corpus luteum powder used in these experiments was prepared from fresh glands desiccated at low temperature. Figures 3 and 4 illustrate the results obtained with uterine muscle preparations from controls and from rabbits fed with such powder. It was found that just as injections of corpus luteum weakened the response of the muscle preparation to subsequent treatment with pituitrin or completely

suppressed it, so the continued feeding of desiccated corpus luteum rendered responses of uterine muscle from rabbits very feeble. The difference between the results obtained in the injection and feeding experiments were quantitative rather than qualitative. Of course, the feeding experiments had to be continued for a considerably longer time before the physiological effect mentioned could be obtained.

B. Relation to epinephrin. Of great physiological interest as well as of practical value is another remarkable phenomenon noted recently in studies on the rhythmic contractions of uterine muscle, i.e. the response of such muscle to epinephrin in relation to the influence of female sex hormones. It has been known for a long time that the uterus of the virgin cat responds differently to stimulation of the hypogastric nerves *in vivo* or to treatment with epinephrin both *in vivo* and *in vitro* from that of the animal in pregnancy. The normal virgin uterus of the cat is relaxed by epinephrin but the uterus of the pregnant cat *in vitro* contracts when treated with the same drug. This remarkable reversal of the usual response of the cat's uterus to epinephrin suggested to Van Dyke and Gustafson that the explanation of the phenomenon might lie in an

the corpus luteum in particular may be noted in this place to complete an exposition of the various reactions given by that hormone Hisaw (34), who has done a great deal of work on female hormones, described a relaxant effect which corpus luteum extract exerted on the symphysis pubis of guinea pigs and rabbits, a relaxation similar to that occurring in all these animals during pregnancy. This reaction Hisaw found to be so characteristic that he ascribed it to the specific hormone contained in corpus luteum, which he named "relaxin"

Studies on spontaneous or voluntary activity of skeletal muscles of rats placed in rotary cages were made by Slonaker, Wang (97, 98) and associates. The latter authors first established the normal cycle of activity in rats and then studied the effects of ovariectomy and the influence of subsequent injection of various solutions of female hormones on the same animals. The results obtained were not especially significant.

A different kind of psychological study on the ovarian and corpus luteum hormones was published by Macht and Seago (61). The behavior of white rats trained in a circular maze was carefully established and their running time was measured. Ovariectomy was performed and after the rats had recovered from such an operation their muscular activity and general behavior were again observed. Small doses of ovarian and corpus luteum extracts were then injected. The results of these experiments indicated that ovarian extract in general and extract of corpus luteum definitely improved the running time and cerebral responses of both normal and ovariectomized rats.

A third reaction obtained by Macht and Matsumoto (60) with ovarian and corpus luteum extracts on the pupils of frogs' eyes may also be mentioned. These writers tested the action of 10 per cent solutions of corpus luteum and ovarian substances on frogs' eyes and noted that corpus luteum produced dilatation and the ovarian extract no effect whatever.

Finally, mention should also be made of the interesting findings reported by Kanter, Bauer, and Klawans. These writers discovered that

the growth of the ovipositors of Japanese bitterlings was stimulated by feeding them with estrogenic preparations of the ovary. In this connection the present writer made some tests in which a desiccated corpus luteum preparation was fed to bitterlings by a method described elsewhere. Bitterlings placed in water containing preparations of follicular hormone showed marked elongation of the ovipositors in from 24 to 48 hours. In a series of experiments in which corpus luteum and follicular extracts, in suitable proportions, were administered simultaneously to these fish, a definite inhibition resulted; i.e., the elongation which the follicular hormone would have effected was antagonized by the corpus luteum extract and no stimulation to growth was consequently observed. Such experimentation, while not extensive, is mentioned briefly in this place (59). Kleiner and his associates have recently expressed some doubt as to the reliability of the bitterling reaction to the follicular hormone, on the one hand, and claimed, on the other, that the female bitterling is a specific physiological test animal for the male hormone.

EVALUATION

The abundant data, physiological and pharmacological, assembled in this paper (which, if space permitted, could be extended) afford sufficient evidence, beyond reasonable doubt, of the important endocrine function of the corpus luteum. Whether one or more hormones contained in that gland are responsible for the various physiological effects noted by different observers is not yet definitely established. Unquestionably the corpus luteum through its internal secretion plays an important rôle with regard to the course of pregnancy and in primates exerts an influence on the menstrual cycle as indicated by gross anatomical and histological changes in gonads and accessory organs. Of particular interest from the standpoint of practical therapeutics are those experiments in which corpus luteum preparations or extracts have been injected into animals, normal and castrated, for the purpose of influencing their physiological function. These indicated the close relationship and interdependence of the corpus luteum and estrogenic or follicular hormones. It

Fig 7 Effect of adrenalin on uterus of virgin cat which had been daily injected intraperitoneally with lutein (H W & D) for 8 days the total amount injected being 18 cubic centimeters. Note inhibition of contractions but no relaxation of muscle.

glandular extracts on the uterus, fallopian tubes, seminal vesicles vas deferens bladder, and ureters of various kinds of animals were carefully studied.

It was found that while aqueous or saline extracts of all sorts of glands (with the exception of the suprarenal) effected but a mild stimulation of smooth muscle preparations, corpus luteum extracts produced an extraordinary stimulation of vasa deferentia of rodents, particularly of white rats. Even minute quantities of such corpus luteum extracts produced powerful contractions of the vas which, within biological limits were proportional to the amount of the extracts used.

Extracts of whole ovary also stimulated the vas deferens of the rat to some extent but it was demonstrated that such contraction was effected by the corpus luteum present in the preparations. When ovarian or follicular extracts free from corpus luteum were examined in this way, the response was very weak. These observations of Macht and Matsumoto (69) suggested a simple and ready method of comparing the activity of corpus luteum preparations. Such a method, used by the writer and his associates (64) yielded data in remarkable agreement with results reported by clinicians employing the same preparations.

The curious anomaly of a male genital organ exhibiting specific sensitivity for a female sex hormone, namely corpus luteum, puzzled the writer working originally on this subject. At the present time such a phenomenon is by no means an unusual one. Reference has already been made to certain "antimale" reactions elicited by estrogenic hormones. Again,

the extensive studies on the effect of estrogenic female hormone on the estrus cycle of rats and mice reported by numerous investigators, have eventually led to the discovery that this so called female hormone is widely distributed in nature not only among animals but also among plants and that it can be extracted in large quantities from the urine of men as well as that of pregnant women.

D Response of fallopian tubes. The relation of the female sex hormones to the movements of the genital organs is of interest in another respect, namely in regard to the rhythmic contractions these hormones produce in the fallopian tubes. Some of the most interesting studies reported on the subject have been those which Seckinger published from this laboratory. The effect of ovarian and corpus luteum extracts on the normal rhythmic contractions of the fallopian tubes of the pig *in vitro* was carefully observed. It was found that there was a distinct difference in the type of contractions produced by corpus luteum and whole ovary extracts, respectively. Here again earlier experiments take on a new significance in the light of the results herein cited with regard to the relation between corpus luteum and the pharmacodynamic properties of pituitrin and epinephrin. Thus we have described at least four different smooth muscle reactions which distinguish between the follicular hormone and the hormone of corpus luteum.

7 MISCELLANEOUS EFFECTS OF CORPUS LUTEUM

A number of other physiological effects produced by female hormones in general and by

and lower animals The isolation of the various active principles of ergot scored another triumph for modern pharmacology, nevertheless, few are the skilled obstetricians who would administer small quantities of the same in preference to the well standardized galenical preparations of the drug. The chemistry of digitalis leaf, the most important heart drug at the service of the medical man, has not been entirely established Some twenty different glucosides and other chemical bodies have been isolated from this plant and the pharmacological action of each has been carefully studied but neither digitoxin nor any other powerful pure digitaloid principle, administered separately, is as satisfactory therapeutically as the leaf itself or the official tincture and infusion of the plant

In their search for active principles those who are interested in practical therapeutics must not lose sight of the important fact that two or more drugs may profoundly modify the action of each other in not only the pharmacological but also the physicochemical sense of the word Thus, pharmacologically, one chemical may antagonize or potentiate the effect of another. Again, in a purely physical way, the combination or mixture of two or more bodies may serve to keep all in solution as, for instance, in case of the digitalis glucosides The *total ensemble* or combination of medicinal principles in the proportion in which they occur in nature is often much more effective for clinical purposes than any artificial mixture of pure principles. Such possibilities should be borne in mind when the efficiency of the female sex hormones and their preparations is considered, especially by those medical men who are interested in their practical therapeutic use. As our knowledge of the subject accumulates, we begin to doubt even such phenomena as those heretofore considered absolutely reliable criteria Thus, for instance, in a recent paper Freed and Soskin suggest that the potency of an estrogenic substance as regards cornification bears no constant relationship to its potency as regards other important physiological properties, and therefore in their opinion an assay of estrogenic substance by the vaginal smear method alone is no absolutely reliable

indicator of its potency as regards other physiological properties or as regards its possible value in therapeutics. We have not yet solved the physiological puzzle of the sexual cycle in higher animals, much less that of primates. This cycle is controlled by such an intricate and delicate system of checks and balances, depending not only on the hormones of the ovarian follicle and corpus luteum but also upon the internal secretions of the pituitary, thyroid, and suprarenal glands, that any attempt at rational substitution therapy with isolated, so called chemically pure hormones may well be considered hazardous until the whole subject of internal secretions and their physiological function is thoroughly understood. It may be much wiser for the clinical practitioner to employ carefully prepared extracts of the whole ovary or of the corpus luteum, approximating as closely as possible the normal content of the gland in its natural state unmixed with products of disintegration, rather than to experiment with combinations of allegedly "pure principles," the physiology, chemistry, and even posology of which are still unsettled.

SUMMARY

1. A résumé of all kinds of experimental data found in scientific literature regarding the physiological function of the corpus luteum is presented.
2. Three lines of investigation by the writer and his collaborators with water-soluble corpus luteum preparations are described.
3. A study of vaginal smears revealed that injections of corpus luteum extracts distinctly inhibited the estrus cycle of guinea pigs.
4. Injection of corpus luteum extracts in mice inhibited a tendency to hypertrophy of the uterus induced by injections of estrogenic follicular extracts
5. Corpus luteum extracts elicited characteristic responses from uterine muscle of guinea pigs and cats, fallopian tubes of pigs, and vasa deferentia of white rats.
6. In the three classes of experiments the same extracts induced parallel and comparable results, thus demonstrating that the activity of corpus luteum preparations may be shown by several convenient methods

appears that these two groups of hormones in some respects exert diametrically opposite physiological effects. This antagonism is only apparent, however, and should be regarded as a *synergism promoting the normal functioning of the sexual apparatus*. Experimentally there is no longer any doubt as to the inhibitory effect of corpus luteum on the estrus of small animals. The most recent work on the subject corroborates this view. Thus, Dessau notes that "daily injections of estrone, estrinol, or estradiol into mature guinea pigs (castrated or normal) cause proliferation and metaplastic changes of the uterine epithelium. These changes are inhibited by corpus luteum hormone." These findings are in complete agreement with the results obtained by Macht, Stickels, and Seckinger.

A discussion of the chemical nature of the various extracts or "active principles" obtained from the corpus luteum by different investigators does not come within the scope of this paper. However, although almost every investigator studying biochemical phases of the subject is inclined to regard the particular extract or preparation that he has been using as the most efficient, an impartial examination of the literature reveals that physiological effects have certainly been obtained with both the lipid soluble and the aqueous extracts of corpus luteum.

The writer and his co workers have experimented with all kinds of extracts prepared from corpus luteum substance. Some of these were prepared with ether, others with petroleum ether, acetone, chloroform or ethyl acetate, and still others with alcohol. All the extracts prepared though they were in different ways exhibited more or less activity when tested by various methods. The authors obtained the most satisfactory clinical results however, with a water soluble extract made by treating desiccated corpus luteum substance with alcohol for a prolonged period, deproteinizing it with lead acetate, filtering and removing the lead and adjusting the hydrogen ion concentration of the resultant solution. It was found that preparations so obtained prolonged the interestrual interval in guinea pigs and rats and were also quite active in producing the peculiar and specific

reactions of smooth muscle preparations from the uterus and vas deferens previously described. When the curves obtained by the writer with uterine preparations in response to posterior pituitary hormone were compared with those of other investigators, it was found that the effect produced by 1 milligram of crystalline progesterone was approximately equivalent to that resulting from repeated injections of 10 cubic centimeters of lutein solution (H.W. & D.). The author and his co workers found furthermore that the activity of corpus luteum preparations in guinea pigs tested by the vaginal smear method ran parallel to their effects on the vas deferens of the rat, on the one hand, and on the uterus of the rabbit with respect to its response to posterior pituitary hormone, on the other. The potency of such preparations in clinical practice has been attested by reports from a host of physicians who have made carefully controlled studies on patients with all kinds of female hormone products. In the experience of the writer and his co workers, the various physiological effects of corpus luteum were obtained not only by injection of extracts but also by prolonged feeding of desiccated corpus luteum.

Whether a single active principle or a mixture of active principles occurs in the various extracts of female gonads employed in these studies has not yet been ascertained. From the standpoint of practical therapeutics, however, the value of isolated active principles separated from the synergistic bodies which the various glands contain in their natural state, is still debatable. Thus for instance, the discovery and isolation of the chemically pure thyroxin, active principle of the thyroid gland, marked a great advance in biochemical science, yet in clinical practice this principle administered alone has proved less effective than many of the ordinary thyroid preparations on the market. The isolation and chemical identification of various vitamins marked similar progress in biological science but the value of administering minute quantities of pure vitamins separately in cases of defective nutrition is still disputed. In fact such treatment has already been reported to produce dangerous pathological changes in man.

and lower animals The isolation of the various active principles of ergot scored another triumph for modern pharmacology; nevertheless, few are the skilled obstetricians who would administer small quantities of the same in preference to the well standardized galenical preparations of the drug. The chemistry of digitalis leaf, the most important heart drug at the service of the medical man, has not been entirely established. Some twenty different glucosides and other chemical bodies have been isolated from this plant and the pharmacological action of each has been carefully studied but neither digitoxin nor any other powerful pure digitaloid principle, administered separately, is as satisfactory therapeutically as the leaf itself or the official tincture and infusion of the plant

In their search for active principles those who are interested in practical therapeutics must not lose sight of the important fact that two or more drugs may profoundly modify the action of each other in not only the pharmacological but also the physicochemical sense of the word. Thus, pharmacologically, one chemical may antagonize or potentiate the effect of another. Again, in a purely physical way, the combination or mixture of two or more bodies may serve to keep all in solution as, for instance, in case of the digitalis glucosides. The *tout ensemble* or combination of medicinal principles in the proportion in which they occur in nature is often much more effective for clinical purposes than any artificial mixture of pure principles. Such possibilities should be borne in mind when the efficiency of the female sex hormones and their preparations is considered, especially by those medical men who are interested in their practical therapeutic use. As our knowledge of the subject accumulates, we begin to doubt even such phenomena as those heretofore considered absolutely reliable criteria. Thus, for instance, in a recent paper Freed and Soskin suggest that the potency of an estrogenic substance as regards cornification bears no constant relationship to its potency as regards other important physiological properties, and therefore in their opinion an assay of estrogenic substance by the vaginal smear method alone is no absolutely reliable

indicator of its potency as regards other physiological properties or as regards its possible value in therapeutics. We have not yet solved the physiological puzzle of the sexual cycle in higher animals, much less that of primates. This cycle is controlled by such an intricate and delicate system of checks and balances, depending not only on the hormones of the ovarian follicle and corpus luteum but also upon the internal secretions of the pituitary, thyroid, and suprarenal glands, that any attempt at rational substitution therapy with isolated, so called chemically pure hormones may well be considered hazardous until the whole subject of internal secretions and their physiological function is thoroughly understood. It may be much wiser for the clinical practitioner to employ carefully prepared extracts of the whole ovary or of the corpus luteum, approximating as closely as possible the normal content of the gland in its natural state unmixd with products of disintegration, rather than to experiment with combinations of allegedly "pure principles," the physiology, chemistry, and even posology of which are still unsettled.

SUMMARY

1. A résumé of all kinds of experimental data found in scientific literature regarding the physiological function of the corpus luteum is presented.
2. Three lines of investigation by the writer and his collaborators with water-soluble corpus luteum preparations are described.

factor in producing cholecystitis. Many authors have inoculated the bacteria directly into the wall and cavity of the gall bladder. The results obtained in these cases are even more contradictory. Cushing, using typhoid bacilli injected into the rabbit's gall bladder, and Italia, using *Bacillus coli* and *Bacillus typhosus* in both rabbits and dogs, obtained inflamed gall bladders with stone formation. Rosenow, working on his idea of the "selective affinity" of bacteria (especially streptococcus and *Bacillus coli*) to certain organs and tissues, tried to establish a connection between "foci of infection" and gall-bladder disease. He used both the intravenous and the direct inoculation methods, and obtained contradictory results, as in certain cases in which the intravenous route produced marked cholecystitis, direct inoculation into the gall bladder was ineffective. Schoebl was more successful in producing cholera carriers by direct inoculation than by intravenous injection. Meyer and coworkers, using typhoid bacilli, obtained positive results with both methods.

Doerr observed that excretion of typhoid bacilli into the bile, which occurred regularly after the injection of the former into the systemic veins, could be prevented by ligation of the cystic duct. Koch and Chiarolanza, however, arrived at opposite conclusions. They found typhoid bacilli in the gall bladder after intravenous injection even after a preceding cystic duct ligation.

Nichols produced "lesions of the gall bladder" in a high percentage of cases by injecting typhoid bacilli into the mesenteric or ear veins. Emmerich and Wagner obtained similar lesions by direct inoculation of typhoid bacilli into the rabbit's gall bladder. Venema's experiments, however, performed under similar conditions, revealed no changes in the gall bladder.

In connection with the "specific affinity" idea of Rosenow we ought to mention the work of Brown, who found mainly streptococci in the emulsified gall-bladder tissue from cases of human cholecystitis. He demonstrated serologically the direct etiological importance of these streptococci and proved their specific affinity for the gall bladder by intravenous injection in rabbits.

Staphylococci are used in the experimental work of Magner and Hutcheson. These authors produced a change in the gall bladder wall by injecting these organisms under the serous layer, while this change occurred in only a limited number of cases following injection into the lumen.

More recently Rehfuess and Nelson studied the problem of gall-bladder infection in the experimental animal and concluded that a variety of organisms when injected intravenously in the rabbit, can produce lesions of the gall bladder.

Evidence other than infection in the literature. Much doubt has been expressed on different occasions on the accuracy of the theory that infection plays the primary rôle in the etiology of gall-bladder lesions. Clinical observations caused various authors to search for some other cause.

On the basis of his clinical observations, Denton was not able to accept the theory of infection and suggested mechanical and circulatory disturbances as the causes of the gall-bladder pathology. Similarly Feinblatt concludes from his pathological studies that mechanical and metabolic factors are important parts in the production of cholecystitis.

One metabolic disturbance in particular has found a prominent place in the literature in this connection, i.e., the cholesterol metabolism. The "strawberry gall bladder," first described by Moynihan, occurs under certain pathological conditions of cholesterol metabolism. Boyd considers infection to be the cause of this metabolic disturbance. Wilkie and Rosenow obtained positive cultures from the wall, the gall-bladder contents and stones of such cases. The importance of cholesterol in stone formation is well known and need not be taken up here. There is no evidence, however, in the literature, of acute inflammatory changes in the gall-bladder wall in connection with a disturbance in cholesterol metabolism.

As compared to the enormous amount of literature on cholecystitis brought about experimentally by bacterial infection, relatively little is known about chemical cholecystitis.

Well known is the work of Mann who produced acute changes in the gall-bladder

EXPERIMENTAL CHOLECYSTITIS

HANS G. ARONSOHN, M.D., and EDMUND ANDREWS, M.D., F.A.C.S. Chicago, Illinois

A REVIEW of the literature on the etiology of gall bladder diseases reveals that 9 of 10 publications consider bacterial infection to be the most likely agent. Some uncertainty as to the accuracy of this view is evident, however.

The first to associate gall bladder inflammation with infection was John Hunter, who first observed cholecystitis in typhoid fever patients. Gilbert and Girode proved this relationship bacteriologically, while Chiari added clinical evidence in support of this view. The idea was quick to take and was soon confirmed by many authors. Doubt, however, was early expressed. Rolleston emphasizing the need for an additional factor than infection, basing his idea on the clinical fact that cases of cholecystitis were increasing coincident with a marked decrease in the occurrence of typhoid fever. This is confirmed by Osler's report of 19 cases of cholecystitis in a series of 1,500 cases of typhoid fever while it is well known that most cases of typhoid fever have a large number of organisms in the bile. Furthermore the theory of the relationship between typhoid fever and gall bladder disease was an intimate one and received its death blow in the fact that the former has practically disappeared from all civilized communities without any appreciable lessening in the evidence of gall bladder disease.

Organisms other than typhoid bacilli have also been incriminated. Much valuable information was obtained by culturing the bile and the walls of gall bladders obtained at post mortem examinations and at operation. Table I is taken from the article by Rehfuess and Nelson (43) and needs little comment. Both Andrews (3) and Wagner, studying the content of human gall bladders removed at operation, have found 65 per cent of cases to contain sterile bile. Osler places this figure at

52 per cent. According to the study of Wagner and Hutcherson, *Bacillus coli* is the most common organism in the cavity of the gall bladder, while streptococci are found more often in the gall bladder wall. Drennan emphasizes the anti bacterial activity of bile on account of his small percentage of positive cultures. Scarcity of clinical signs of infection the low fever, the mild leucocytosis and the rareness of leucocytes in the bile convinced Denton that infection does not play a primary role in the production of cholecystitis. Feinblatt concurs in this opinion on the basis of the slight inflammatory changes he observed in the gall bladder wall and the small amount of leucocytes in the bile. In contrast to this idea, Huntemueller found positive bacterial cultures in 100 per cent of cases when he included both the gall bladder wall and the liver. The finding by Koch and Chiarolanza of emboli in the folds of the mucous membrane led to the conclusion that a transverse infection of the wall is the usual route.

EXPERIMENTAL LITERATURE

The amount of experimental work done to prove the theory of infection as playing the leading part in the etiology of cholecystitis is enormous. Most authors have tried to confirm their clinical observations by animal experimentation. The various techniques employed are emphasized in the following discussion, as differences in results might be due in some cases to variations in the methods employed.

Intravenous injection of bacteria has been a popular method. *Bacillus typhosus* was found in the bile fairly regularly by Blackstein several days or weeks following intravenous injection of this organism. Sherrington using *Bacillus anthracis*, *Bacillus pyocyaneus* and staphylococci recovered the organisms in the bile in only 18 out of 49 cases. The condition of the walls of the gall bladders was not mentioned in these experiments. Gilbert (23) considered *Bacillus coli* the most important

From the Department of Surgery, University of Chicago. This work has been aided by a grant from the Douglas Smith Foundation for Medical Research of the University of Chicago.

present opinion on the subject. The theory of infection is questioned, but while other theories are suggested, none is actually proved.

Experimental results vary considerably, and often are even contradictory. This may be due to differences in the technique employed by various investigators.

The disadvantage of the most commonly used method, *i.e.*, introduction of bacteria by means of a needle puncture through the gall-bladder wall, was recognized by many early workers. Rosenow found damage to the gall-bladder wall, in many instances, at the point of injection. Venema found this damage to be severe in extent, an observation which is confirmed by Wilkie.

Venema then tried to improve the needle puncture technique by cauterizing the wall at the point of injection. He obtained normal gall bladders in this way, while Emmerch and Wagner had produced changes of the wall. Hospers performed the injection through the liver surface of the gall bladder, a method which leaves the free surface unharmed but may cause occasional bleeding in the liver tissue.

Intravenous injection of bacteria as practiced by Rosenow and others is a much more satisfactory method. Positive reactions in the gall bladder after such injection seem to indicate a specific affinity of these bacteria for the biliary system. Negative results, however, are of lesser value, since we have no way of proving that the organisms actually reached the gall bladder. They might still possess some definite affinity for the gall bladder if brought there in some other way. Another disadvantage of the intravenous method is the bacteriemia which is produced, and which is usually not present in human cholecystitis.

In the production of experimental cholecystitis the dosage used in most cases has been so extreme that it can hardly be compared to any possibility offered by focal infection in man. Several observers have stated that the liver was a rather efficient filter for bacteria in the blood and that only when overwhelming doses were given did any appear in the bile. Furthermore some state that trauma must be added to cause infection to spread from bile to gall bladder if injection be made locally.

We have often made the observation in sampling the gall bladders of dogs that the needle punctures were seen to react sharply. The next day there is usually an area about a centimeter in diameter which histologically closely resembles acute cholecystitis. For these reasons the development of a special technique was important. Needle puncture is, of course, ruled out. Closure of the ducts alone has previously been shown to cause severe damage to the gall-bladder wall. Therefore the following technique was adopted.

A NON-TRAUMATIZING TECHNIQUE

Experimental cholecystitis from which conclusions can be drawn concerning human cholecystitis requires 3 basic postulates: (1) the cholecystitis must be a direct result of the material used; (2) the material introduced must be such as is normally found either in the body fluid or in the ingested food and should not be artificial and foreign to the body; (3) the reaction produced in the experimental animal must be similar in appearance to human cholecystitis.

We have found a technique which fulfills the third requirement in a satisfactory manner. The principle of our technique is the retrograde introduction of a fine ureter catheter into the gall bladder through an opening in the common duct and the subsequent plastic repair of the duct by insertion of a glass cannula.

A detailed description of this technique, which was applied in dogs only, follows.

The dog's abdomen is opened under ether anesthesia by an incision in the upper midline. The duodenum is lifted aside and the common duct is freed by blunt dissection from the surrounding tissue. A longitudinal incision, about 1 centimeter long is made in the duct about 1.5 centimeters distant from its entrance into the duodenum, and the margins of this opening are clamped by a mosquito forceps. A soft French rubber catheter, 25 to 35 millimeters in diameter is then introduced through this opening into the gall bladder. Bile is aspirated and the particular material we are testing is injected into the gall bladder through this catheter. Before the catheter is withdrawn and the glass cannula is inserted,

wall by the intravenous injection of Dakin's solution. Dilatation of the lymphatics, breaking down by blood are the typical microscopic changes. In another series of experiments, changes of the gall bladder wall were brought about by the direct introduction of chemically or mechanically irritating substances, as for instance mustard oil, used by Darnbacher and Sacks.

The effect of x ray radiation was shown by Brans and Darnbacher to consist of an acute inflammatory change in the gall bladder wall.

PHYSIOLOGY OF THE GALL BLADDER

Any discussion of the problem of gall bladder diseases requires first a precise knowledge of the function of liver cells as well as the chemical and biological characteristics of bile. The gall bladder is more than a container to store bile. We know from the extensive investigations of Peyton Rous, and McMaster that the gall bladder concentrates liver bile to a great extent. Andrews (2) has shown that the function which the human gall bladder performs has been greatly underestimated. This fact is of importance for the proper understanding of the disorders of function which are often found after cholecystectomy. The gall bladder ought not to be considered as just a useless appendix to the liver which can be removed without any risk. Bile itself offers many biochemical problems. The extensive use of bile as a medium for culturing bacteria is well known. However there is no uniform behavior for while bile favors the growth of certain organisms it has an inhibitory effect on others.

The greatest difficulty arises in studying the chemical composition of bile. Cholesterol, bilirubin and calcium have been studied by many authors in connection with stone formation and pregnancy.

Modern investigation has shown that cholesterol is kept in solution by bile acids and that precipitation of cholesterol occurs when the bile acids are diminished.

While biochemists are studying the various fractions and chemical formulas of bile salts very little is known about their biological importance. The modern conception is that the bile salts are produced in the reticulo-

endothelial system, excreted by the liver concentrated in the gall bladder, excreted into the intestines, and reabsorbed by way of the portal system. Their function in emulsifying fats is well known but very little else about their normal functions is known. It is therefore, not surprising that still less is known about the rôle they play under pathological conditions.

PATHOLOGICAL ANATOMY

Little information is added from anatomical studies as to the etiology of cholecystitis.

Gall bladders, removed at operation for acute gall bladder disease, often prove to be either perfectly normal at microscopic examination or show changes which are in no way sufficiently characteristic to classify them into one pathological group.

However in a great number of cases a definite anatomical picture is found. We will give a short description of these lesions to serve as a comparison with the results obtained in experimental work.

Henke and Lubarsch compare the findings in acute cholecystitis with those found in acute appendicitis, the purulent infiltration of the wall however being less pronounced in the former case. The character of the exudate is seropurulent. The process begins in the intramuscular pits of the mucous membrane the so called *Luschkaschen Gaenge*. Later the entire wall especially the serosa becomes involved. Thickening of the gall bladder is due mainly to edema in the outer layers.

The description given by modern American authors such as Graham Boyd, Andrews, Fenblatt and others differs in that the presence of pus cells in acute cholecystitis is practically denied. Edematous thickening of the serosa with round cell infiltration, dilatation of the lymphatics and deposition of a fibrinous exudate on the serosa are the common findings. The mucosa is very often normal while some round cell infiltration is often found in the muscularis.

REASONS FOR A NEW APPROACH TO THE PROBLEM

From this review of the literature on cholecystitis one can see the confused status of

tion Mononuclear cells are prevalent, while pus cells are rarely found, not even in cases of so called "empyema," in which the gall bladder content usually consists of amorphous debris or cholesterol crystals rather than of true pus

2 Bacteria are seldom found in stained sections of the gall-bladder wall and the bile is found to be sterile in a high percentage of diseased gall bladders

3 Finally there is the clinical observation that sepsis is a rare complication of cholecystitis and that the gall bladder is rarely involved in cases of pyemia

To prove or disprove the infectious theory, the following series of experiments were carried out:

Bacteria obtained from human sources, such as acute and chronic mastoiditis, sinusitis, adenitis, etc., were introduced into the gall bladders of dogs by means of the catheter-cannula technique. The cultures were of recent isolation. The bacteria used for the injection were suspended in saline solution in a concentration of approximately 500 million bacteria per cubic centimeter, the criterion used being the cloudiness of the suspension as compared with one of known bacterial content. One cubic centimeter of this suspension was the amount generally injected. Wherever the reaction obtained was especially severe, the experiments were repeated with smaller amounts, while 2 or 3 cubic centimeters were injected in cases in which no reaction occurred.

Tables I, II, and III give detailed description of the 26 experiments.

Cholecystitis 1 indicates a gall bladder with only few changes, slight edema, and congestion in the serosa being the only pathological findings.

In cholecystitis 2, the gall-bladder wall was thickened up to 4 millimeters, the acute inflammatory signs were more definite, and a thin fibrinous membrane covered the serosa.

Cholecystitis 3 includes all those cases in which the changes exceed those in group 2 as to thickness of the wall and the extent of inflammatory signs. Whenever the introduction of the catheter or the insertion of the cannula was attended with difficulty, the term "traumatization" was included in the column label-

Fig 2 Microscopic appearance 20 minutes following the intravenous injection of commercial bile salts. Marked edema of serosa about four times normal thickness.

ed "complications." Wherever this happened, or in those experiments in which the common or cystic duct was tied, results are of value only when the gall bladder remained normal in spite of the bacterial injection or duct ligation or traumatization.

RESULTS

Special emphasis is laid in our experiments upon the studying of *Streptococcus hemolyticus*, which has been accused of being the main causative agent in the production of cholecystitis in both animal experimentation and in man. Four different strains of *Streptococcus hemolyticus* were used in 12 injection experiments. Although three of the four strains were taken from acute human infectious processes, changes of the gall-bladder wall occurred in only one of these.

These changes, however, occurred in all 3 of the cases, in which this particular strain

Fig 1a Microscopic appearance 48 hours following the introduction into the gall bladder of commercial bile salts 15 per cent. Note edematous thickening of the serosa five times normal with fibropurulent exudate on serosal surface.

Fig 1b Microscopic appearance 48 hours following the introduction into the gall bladder of sodium desoxycholate 8 per cent. Diffuse leucocytic infiltration of all three layers.

a rubber protected clamp is placed around the common duct as close to the gall bladder as possible. This is necessary to prevent a back flow of bile.

The cannula which is 3 centimeters in length and 4 millimeters in diameter tapering at the ends and grooved transversely a short distance from the tips on each side is inserted into the common duct and kept in place tightly by 2 ligatures around the grooved surfaces. After the duct is unclamped and a rather normal bile flow is observed the edges of the opening are sutured together above the cannula.

Since during the whole procedure which takes about 20 minutes the gall bladder is not even brought into view we feel sure that the factor of traumatization is practically negligible.

That this is actually the case has been proved by a great number of control experi-

ments. In some cases bile was aspirated and nothing injected while in others the gall bladder was thoroughly washed with normal saline solution. The animals were electrocuted 24 or 48 hours after operation and the gall bladders were found to be perfectly normal on gross and microscopic examination.

Absence of reaction in the gall bladder shows that by use of the technique described experimental manipulation of the gall bladder is possible without any traumatization.

THE THEORY OF INFECTION AND THE OBJECTIONS TO IT

The main arguments against the infectious theory of cholecystitis based on anatomical and clinical observations are summarized as follows:

1. Pathological studies of diseased gall bladders reveal few signs of bacterial infec-

tion Mononuclear cells are prevalent, while pus cells are rarely found, not even in cases of so called "empyema," in which the gall bladder content usually consists of amorphous debris or cholesterol crystals rather than of true pus.

2 Bacteria are seldom found in stained sections of the gall-bladder wall and the bile is found to be sterile in a high percentage of diseased gall bladders

3 Finally there is the clinical observation that sepsis is a rare complication of cholecystitis and that the gall bladder is rarely involved in cases of pyemia

To prove or disprove the infectious theory, the following series of experiments were carried out:

Bacteria obtained from human sources, such as acute and chronic mastoiditis, sinusitis, adenitis, etc, were introduced into the gall bladders of dogs by means of the catheter-cannula technique. The cultures were of recent isolation. The bacteria used for the injection were suspended in saline solution in a concentration of approximately 500 million bacteria per cubic centimeter, the criterion used being the cloudiness of the suspension as compared with one of known bacterial content. One cubic centimeter of this suspension was the amount generally injected. Wherever the reaction obtained was especially severe, the experiments were repeated with smaller amounts, while 2 or 3 cubic centimeters were injected in cases in which no reaction occurred.

Tables I, II, and III give detailed description of the 26 experiments

Cholecystitis 1 indicates a gall bladder with only few changes, slight edema, and congestion in the serosa being the only pathological findings

In cholecystitis 2, the gall-bladder wall was thickened up to 4 millimeters, the acute inflammatory signs were more definite, and a thin fibrinous membrane covered the serosa

Cholecystitis 3 includes all those cases in which the changes exceed those in group 2 as to thickness of the wall and the extent of inflammatory signs. Whenever the introduction of the catheter or the insertion of the cannula was attended with difficulty, the term "traumatization" was included in the column label-

Fig 2 Microscopic appearance 20 minutes following the intravenous injection of commercial bile salts. Marked edema of serosa about four times normal thickness

ed "complications." Wherever this happened, or in those experiments in which the common or cystic duct was tied, results are of value only when the gall bladder remained normal in spite of the bacterial injection or duct ligation or traumatization.

RESULTS

Special emphasis is laid in our experiments upon the studying of *Streptococcus hemolyticus*, which has been accused of being the main causative agent in the production of cholecystitis in both animal experimentation and in man. Four different strains of *Streptococcus hemolyticus* were used in 12 injection experiments. Although three of the four strains were taken from acute human infectious processes, changes of the gall-bladder wall occurred in only one of these.

These changes, however, occurred in all 3 of the cases, in which this particular strain

had been injected. Death of the animal within 15 hours after injection resulted in one instance, while another animal was moribund in 24 hours, and the third one in very poor condition when killed.

In contrast to these experiments the dogs into which the other three strains of Streptococcus hemolyticus were injected, showed no signs of illness. Postmortem examination after electrocution revealed either normal gall bladders or changes which were very slight and not of an inflammatory character.

Table II shows that Bacillus coli has no effect on the gall-bladder wall. This chart demonstrates clearly the value of a proper technique. In two animals where traumatization occurred or duct ligation had been performed, severe reactions were produced, which cannot be attributed to the action of the bacteria, since bacterial injection by means of the catheter-cannula technique revealed definitely negative results.

Similarly we conclude from Table III that none of the organisms used in this series can produce cholecystitis.

On microscopic examination, we find in the gall bladders, where the strain of Streptococcus hemolyticus from acute mastoiditis had been injected, an enormous thickening of the serous layer, which is mainly due to edema and hyperemia. The serosa is infiltrated with

leucocytes and covered with a fibrinous exudate. Those gall bladders, however, into which had been injected another strain of Streptococcus hemolyticus or any of the other bacteria named in the charts either proved to be normal or revealed only very slight changes.

In summarizing these experimental results we may conclude that there is little tendency for acute bacterial infection of the gall-bladder wall to result from any of the contents of the organ. Bacteria, although present in bile in

overwhelming numbers, do not cause any change in the gall bladder wall unless they are of unusually great virulence.

These results concur with the observations of Rosenow and of Magner and Hutcheson, who stressed the varying activity within the Streptococcus hemolyticus group on the basis of differences in virulence. The negative results, however, which we obtained in using Bacillus coli stand in direct disagreement both with the clinical data reported by Gilbert and the experimental work done with this organism by Italia. The negative results after the injection of Staphylococcus albus and aureus, Streptococcus viridans and Bacillus welchii agree with results reported in the literature.

CHEMICAL CHOLECYSTITIS

Mechanical factors can produce lesions in a gall bladder containing stones. There is little doubt that the presence of one or more stones in the gall bladder or the impaction of a stone in the cystic or common duct can

lead to marked changes in the gall bladder wall. However, at postmortem examination stones are often found in patients who, during life, never had any gall bladder symptoms, and many stones containing gall bladders reveal no anatomical changes in their walls. This would suggest that mechanical interference as represented by the presence of stones can be considered an aggravating, but not a primary factor in the production of gall bladder lesions.

There is even less support for the theory of mechanical cholecystitis in a gall bladder without stones. Cases of gall bladder disease after external injury are as rare as traumatic appendicitis. The gall bladder is deeply imbedded in the liver and well protected against injuries from the outside, hence cholecystitis on a purely mechanical basis in the stoneless gall bladder cannot be accepted.

In considering the possible chemical agents as etiological factors, there are as many possibilities as there are constituents in bile. Thorough investigation, however, meets with the

greatest difficulties, since we know very little about the quantitative composition of bile. Elaborate chemical studies of the composition of bile by Ravdin have shown wide variations, the studies of which offer but little hope of drawing definite conclusions. Our own similar chemical studies have likewise defied any logical interpretations. The acidification of bile during its concentration in the gall bladder was first recorded by Okada and later confirmed by several authors. The mechanism, however, by which this process takes place, has never been clearly demonstrated.

We therefore attempted to make parallel analyses of both liver and gall-bladder bile in dogs, estimating the main factors which affect the acid-base equilibrium. Since a number of experiments indicated that different anesthetics and drugs affect the quality of the bile, special precautions were taken in obtaining the bile.

First, we performed a laminectomy in the middorsal region under local anesthesia and transected the spinal cord. About 1 hour later when the dog had recovered from the shock, the abdomen was opened, the cystic duct clamped, and a glass cannula inserted into the common duct. This cannula was connected with a rubber tube leading to a glass container in which the bile was collected under oil. The carbon dioxide and hydrogen-ion concentration values were determined immediately.

Standard methods for blood and urine were used for the bile analyses, which were rendered difficult because of the mucus and color content. Tables IIIA and IIIB show the average

TABLE III B

Anions and cations in M eq/L

results of the analyses of 7 liver and 12 gall-bladder biles of other dogs electrocuted. It is obvious from the study of these charts that our analyses as well as those of previous workers fail to explain entirely the acidification of the bile in the gall bladder. It is quite surprising to note that in spite of the acidification there is a rapid absorption of calcium and carbon dioxide ions. The only acid which seems to increase to any extent is the phosphate and even this, as is shown on the table, accounts for only part of the change. The \times anion of Ravdin remains a mystery.

NITROGEN CONTENT OF THE BILE OF NORMAL AND DISEASED GALL BLADDERS

Since the total nitrogen in bile seems to maintain a fairly constant level, deviations from this level might be of importance for understanding the pathology of this organ. Pathological processes in the gall-bladder wall might merely be associated with changes in nitrogen content of the bile, or these changes might be the primary cause for gall-bladder reactions.

Little work has been done on the nitrogen content of bile. Gunderman found that the

CHEMICAL CHOLECYSTITIS

Mechanical factors can produce lesions in a gall bladder containing stones. There is little doubt that the presence of one or more stones in the gall bladder or the impaction of a stone in the cystic or common duct can

lead to marked changes in the gall bladder wall. However, at postmortem examination, stones are often found in patients who during life, never had any gall bladder symptoms and many stone containing gall bladders reveal no anatomical changes in their walls. This would suggest that mechanical interference as represented by the presence of stones can be considered an aggravating, but not a primary, factor in the production of gall bladder lesions.

There is even less support for the theory of mechanical cholecystitis in a gall bladder without stones. Cases of gall bladder disease after external injury are as rare as traumatic appendicitis. The gall bladder is deeply imbedded in the liver and well protected against injuries from the outside hence cholecystitis on a purely mechanical basis in the stoneless gall bladder cannot be accepted.

In considering the possible chemical agents as etiological factors, there are as many possibilities as there are constituents in bile. Thorough investigation, however, meets with the

THE TOXIC EFFECT OF BILE

Having obtained marked reactions in the gall bladder of dogs after the injection of foreign protein, the next procedure in our studies was to examine the constituents of bile itself for any possible toxic effect.

Bile as a whole cannot be considered toxic to the gall-bladder wall if present in normal concentration. As seen from our control experiments, removal of bile from a dog's gall bladder by means of a catheter and replacing it by bile from another dog leaves the gall-bladder wall unchanged. Similarly ox bile introduced into the dog's gall bladder gives negative results.

It has long been known, however, that bile has a marked toxic effect outside of the gall bladder, a subject upon which a large amount of literature has been written. The local destructive power of bile in contact with living tissue has been demonstrated repeatedly. Flexner, and Meltzer and Salant showed that bile causes necrosis of living cells and hemolysis of blood cells. Pancreatic necrosis has been produced by many authors with gall-bladder bile. Dragstedt (17) demonstrated an acute necrosis of the pancreas which had been brought in contact with bile through a window in the gall-bladder wall. Necrosis of muscle and subcutaneous tissue results from the injection of sterile bile or a solution of bile salts, as demonstrated by Andrews in the experimental animal. Similarly, lesions in the stomach wall and in the salivary glands have been produced by Sellards.

Flexner demonstrated that it is bile salts which constitute the toxic element in bile, and expressed the opinion that gall-bladder bile, in which bile salts are relatively concentrated, is more toxic than liver bile.

In addition to the local toxic effect, there is a well known systemic toxic action of bile. Many investigators have found that animals die within a short period of time from intravenous injection of bile or bile salts. Dragstedt (18) demonstrated that animals died within 2 or 3 days when the common bile duct was anastomosed to the vena cava or portal vein. In discussing the toxic action of bile and bile salts, we ought to mention briefly a mechanism which is supposed to compensate

*Material obtained at postmortem—41 human postmortem bile

nitrogen content in stone containing gall bladders was variable, while it was usually higher in cholecystitis. Boekelman arrived at similar conclusions by aspirating bile from the duodenum in man.

We conducted a series of observations to confirm those conclusions.

First, we examined 41 human gall bladders obtained at postmortem. We tried to make a gross diagnosis of the gall bladders in each instance, using as a basis only the most obvious signs, which were little influenced by postmortem changes. The diagnoses of stones, adhesions, hypertrophy of the wall and obliteration of the cavity could be made with assurance, but we did not try to make any finer diagnoses, or to conduct microscopic examinations in this series, since postmortem changes do not permit such precise study.

In our second series which consisted of 13 fresh specimens obtained at human operations a more definite pathological diagnosis was made. This was confirmed by the clinical history of the patient and by microscopic examination. Fresh bile was available in this series for chemical studies. For the sake of comparison the same classification was applied here as in the postmortem series, the similarity in the results showing that postmortem changes had not influenced the figures of the postmortem bile to a great extent.

In addition, determinations of the protein phosphorus were made using the colorimetric method of Fiske and Subbarow.

A glance at Tables IV and V shows that no definite correlation exists between the nitrogen and phosphorus content of bile and diseases of the gall bladder. While there is no marked difference in the average figures in stone containing normal and chronically diseased gall bladders, there is a great variation in the individual figures of each group. Total nitrogen, for instance, in the group with chronic changes varies from 55 to 924 milligrams per cent.

Animal experimentation yielded similar results. We found in dogs where the common duct was ligated, that the total nitrogen rose in some cases, while it fell in others. The average figure in 8 normal dogs was 340 milligrams per cent.

PROTEIN INJECTION INTO THE GALL BLADDER

We learn from the last series of experiments that no conclusions can be drawn about the pathology of the gall bladder from the nitrogen content of bile.

However, there still remains the question as to whether increase in the nitrogen content can set up a reaction in the gall bladder wall.

We tried to approach the matter experimentally by increasing the nitrogen content and observing the effects. This was done by the rough method of injecting egg albumen into the dog's gall bladder. Six cubic centimeters of undiluted white of egg or 6 cubic centimeters of a 6 per cent solution of crystal line purified egg albumen in Pinger's solution were injected into the gall bladder cavity of the dog either by means of needle puncture or with the catheter technique. In some experiments the material was injected into the wall of the gall bladder at 6 or 8 different points. Where the material was introduced into the gall bladder cavity, the gall bladder was usually allowed to remain patent, but in some instances the common or cystic duct was ligated.

Fifteen dogs were operated upon none of which died or showed clinical signs of severe illness as a result of the injections. However, when the dogs were electrocuted 48 hours after the operation 13 of the 15 gall bladders showed active recent inflammation. No difference in reaction was found regardless of which technique had been used.

The reaction was characterized by edema, hemorrhage and a fibrinous exudate. Histologically, the most constant finding was edematous thickening of the serosa with round cell infiltration and dilatation of the lymphatics. Fibrinous deposits over the serosa were a frequent finding.

We can rule out traumatization as a cause for this reaction since the same results were obtained on the free surface of the gall bladder when the injection was made through the liver surface or when the material had been introduced through a catheter.

We can say in summary that egg albumen introduced into the wall or cavity of the dog's gall bladder by various techniques almost regularly sets up a reaction in the gall bladder wall.

salts were somewhat stronger than those with commercial bile salts, suggesting that the protein of the latter preparation had exerted a slight protective action against the toxicity. This possible protective action of bile protein will be discussed in more detail in later experiments.

To elucidate still further the toxic action of bile salts, we conducted a more thorough investigation by making use of different bile salt fractions.

Table VI shows the results obtained from the injections in 71 experiments.

For the sake of comparison the 16 experiments using commercial and purified bile salts discussed, have been included in this table. The groups are arranged in the order of decreasing toxicity.

We find that the bile salt mixtures are not the most effective preparations, but that the most severe reactions are obtained with isolated fractions, as desoxycholic, apocholic, and cholic acid which often cause gangrene of the gall bladder and death of the animal. Sodium desoxycholate proved to be the most powerful fraction and in a concentration as low as 7.5 per cent gave a marked reaction. Positive results were obtained with 7 per cent apocholic acid, while higher concentrations were necessary to produce similar changes with cholic acid.

Severe cholecystitis resulted from the injection of concentrated dog bile, which was obtained by evaporation of dog bile by means of a fan to about $\frac{1}{3}$ of its volume and which is known to contain mainly taurocholic acid.

The effectiveness of bile salts is increased rather than decreased by the process of hydrolysis, which consists of alcohol precipitation of the bile salts, sodium hydroxide extraction, precipitation with hydrochloric acid and finally dissolving them with alcohol and sodium hydroxide. We obtained marked reactions with an 8.7 per cent solution and very severe changes, often accompanied by death, with a 20 per cent solution.

Glycocholic acid, on the other hand, proved to be much less effective and produced changes in the gall-bladder wall only in higher concentrations. A study of decholin (dehydrocholic acid) which is used in the medical

TABLE VI—RELATIVE TOXICITY OF DIFFERENT BILE SALTS

Fraction and concentration used	Number of experiments	Final concentration in gall bladder %	Reaction
1. Desoxycholic acid 8 to 13%	13	7.5 to 13	Severe reaction. Gangrene of gall bladder, bile peritonitis, and death
2. Apocholic and cholic acid 7 to 12%	17	7.4 to 11.2	Same
3. Concentrated dog bile (mostly taurocholic acid)	4		Severe cholecystitis, bile peritonitis, and death
4. Hydrolyzed bile salts 10 to 20%	6	8.75 to 20	Severe cholecystitis and death
5. Purified bile salts 10 to 20%	4	8.7 to 15	Same
6. Commercial bile salts 10 to 20%	12	8.5 to 20	No death. Bile peritonitis and cholecystitis
7. Glycocholic acid 8 to 13%	9	7.5 to 11.1	Cholecystitis—occasionally on high concentration, mostly normal gall bladder
8. Decholin (dehydrocholic acid) 20%	6	9.4 to 15	Normal gall bladder

The final concentration of bile salts in the gall bladder in each experiment was calculated in the following manner:

The size of the gall bladder was estimated according to the weight of the dog and the gall bladder in the starving dog considered to be nearly well filled with bile. The bile salt concentration of normal gall-bladder bile in the dog was thought to be 7.5 per cent.

management of human cholecystitis, was added for the sake of completeness. No appreciable reaction is obtained with any concentration.

The gross and microscopic changes in most of these gall bladders are similar to those described in the commercial bile salt group. We might add the frequent occurrence of bile peritonitis, the pathogenesis of which is still only little understood. Bile peritonitis, either localized around the gall bladder or in a diffuse form was often seen without visible perforation of the gall bladder or bile ducts.

No qualitative differences were found in the appearance of the gall bladders after injection of the various fractions, the only differences being quantitative, with the exception of the desoxycholic group. In these cases apparently all of the layers were involved, leucocytic infiltration and hyperemia being found in the mucous membrane and the muscular layer as well as in the serosa. Whether this was due to a direct action of the desoxycholic acid on

*Material obtained at operation—13 human operation biles

for this toxic effect and which is said to be present in bile proteins

In a study of the hemolytic action of bile *in vitro*, Bayer found that serum protein exerts an inhibitory effect on this process while egg albumen has no such effect. These observations were controlled and confirmed by Sellards who demonstrated that these protective elements were present in serum even in high dilutions. Sellards as well as many other investigators claimed that this protective action of serum against the toxicity of bile plays an important part in acute hemorrhagic pancreatitis. This hemorrhage often found in necrosis of the pancreas, presumably tends to neutralize the action of the bile.

Similar protective action was attributed to mucus and other colloidal substances present in bile itself by Flexner, who assumed that bile protein diminishes the toxic action of bile if brought in contact with pancreatic tissue.

TOXIC EFFECT OF BILE IN THE GALL BLADDER WALL

It has been suggested recently by Andrews that bile may, under certain circumstances, acquire a destructive power in the gall bladder wall, in a manner similar to gastric juice in the stomach and pancreatic juice in the pancreas. The most obvious constituent of bile

which has a toxic and destructive effect on body tissues is the bile salts, which are present in gall bladder bile in rather high concentrations. Figures of 7 or 8 per cent are frequently found while the textbooks of Hawk and Hammersten give the normal concentration at about 10 per cent.

Whatever the normal concentration of bile salts in bile is, we attempted experimentally to increase the bile salt concentration in bile and to observe the effects of this on the gall bladder wall. The results were striking inasmuch as the reactions obtained in the gall bladder wall resembled human cholecystitis more closely than any reaction ever obtained previously.

Two forms of bile salts were used, commercial bile salts¹, and the same material freed by alcohol extraction from the large percentage of non alcohol soluble substances which it contains. The injections were all made by means of the non traumatizing technique.

The result of these injections was the production of acute cholecystitis with all the features of human cholecystitis. There was marked enlargement of the gall bladder with the cystic duct obviously shut by swelling of the mucous membrane. The color of the gall bladder was either grayish white or reddish, the serosa being covered with thick fibrous membranes, which in many instances caused the adjacent viscera to adhere to the gall bladder. The gall bladder wall was thickened up to 7 or 8 millimeters and was rigid in character. On microscopic examination the reaction was most marked in the serosa, which was 8 to 10 times its normal thickness and moderately infiltrated with round cells. There were marked hyperemia and punctate hemorrhages along with dilatation of the lymphatics.

A fibrinous exudate was found on the serosa and a slight leucocytic infiltration in certain places. The muscularis was moderately edematous and contained a considerable number of large and small mononuclear cells, with very few polymorphonuclear leucocytes. The mucosa in most instances was practically normal.

The reactions obtained with purified bile

salts were somewhat stronger than those with commercial bile salts, suggesting that the protein of the latter preparation had exerted a slight protective action against the toxicity. This possible protective action of bile protein will be discussed in more detail in later experiments.

To elucidate still further the toxic action of bile salts, we conducted a more thorough investigation by making use of different bile salt fractions.

Table VI shows the results obtained from the injections in 71 experiments.

For the sake of comparison the 16 experiments using commercial and purified bile salts discussed, have been included in this table. The groups are arranged in the order of decreasing toxicity.

In these cases apparently all of the layers were involved, leucocytic infiltration and hyperemia being found in the mucous membrane and the muscular layer as well as in the serosa. Whether this was due to a direct action of the desoxycholic acid on

the mucous membrane or to secondary involvement of the inner layers from the serosa, cannot be determined from the anatomical picture

IS BILE PROTEIN PROTECTIVE AGAINST THE TOXIC ACTION OF BILE SALTS?

Protein is said to have an inhibitory influence on the toxic action of bile salts, as aforementioned

In relation to our present work it is of special interest to determine whether such a protective mechanism is actually present in the mucus and protein of bile as claimed by Flexner and others. If this theory is correct, bile, deprived of its protein is thus converted into a toxic substance.

In regard to this point the following set of experiments was carried out:

Ox or dog bile was deproteinized either by boiling for 5 minutes and filtering or else by autoclaving for 15 minutes at 15 pounds and filtering. This was then injected into a dog's gall bladder in 13 experiments. In 9 instances in which this bile had been introduced by means of the catheter cannula technique normal or practically normal gall bladders were obtained. Two of 4 cases however in which the material had been introduced by means of needle puncture and followed by duct ligation, showed a severe reaction apparently due to the duct ligation. We might thus conclude that removal of the protein does not convert bile into a toxic substance.

STUDY OF THE TOXIC EFFECT OF BILE SALTS

From the previous studies it is seen that normal bile, which has a toxic action on tissues outside of the gall bladder is not toxic for the gall bladder wall itself if present in normal concentration even if it is deprived of its protein. An increase in concentration, however, converts the bile into a substance which is highly toxic to the gall bladder wall.

At this point we might inquire as to what extent bile has to be concentrated to bring about this reaction.

Possible means of concentrating the bile are as follows: (1) adding bile salts to whole gall bladder bile, (2) concentrating the dog's own bile within the gall bladder, (3) replacing

the gall bladder bile with another animal's bile which has been concentrated previous to the introduction.

The first method has been widely applied in studying the relative toxicity of various bile salt fractions. It is less useful for a quantitative analysis of the toxic action, in so far as the degree of concentration in the gall bladder to which the bile salts have been added is an unknown factor.

The concentration of the dog's own bile, without removal from the gall bladder, would be the ideal method. However such attempts have met with great difficulties. Since all water absorbing chemicals damage the gall bladder wall severely, we tried to accomplish this concentration by washing the gall bladder bile with dry, warm air for a certain length of time. Increase in the concentration of solids accompanied by a slight reaction in the gall bladder wall was obtained in some instances. However, the number of positive results and the degree of reactions obtained are too small from which to draw any conclusions.

More satisfactory results were obtained from the third method mentioned, namely, the replacement of gall bladder bile by bile concentrated previous to its introduction. Since the gall bladder was emptied before we introduced the known material, we excluded fairly well known factors in the analysis.

The bile, used for the experiments, was concentrated in the following manner:

Dishes each containing 200 cubic centimeters of fresh ox bile, were exposed to an electrical fan for varying periods of time, allowing evaporation and concentration down to 150, 110, 88, and 60 cubic centimeters. These different biles were injected by the catheter method into the dog's gall bladder, which was emptied previously by aspirating the entire bile content.

Table VII gives the results of these experiments and needs little additional comment. Concentration of ox bile to about half its volume has marked local and systemic effects in the dog while death frequently occurs from stronger concentrations.

To prove that the changes obtained were actually due to the toxic action of concentrated bile and not to accompanying bacterial

TABLE VII.—EFFECT OF VARIOUS CONCENTRATIONS OF OX BILE ON DOG'S GALL BLADDER

Ox bile	No of experiments	Results
Plain	3	Gall bladder practically normal in all instances
Concentrated 150	5	Gall bladder normal in 2 cases, slight reaction in 3 cases
Concentrated 110	6	Moderate degree of cholecystitis, 2 cases; moderate degree of cholecystitis plus bile peritonitis, 2 cases; severe cholecystitis, 2 cases
Concentrated 88	6	Severe cholecystitis, 1 case; severe cholecystitis plus bile peritonitis, 1 case; death and severe reaction, 4 cases
Concentrated 60	4	Severe cholecystitis, 1 case; severe cholecystitis plus bile peritonitis, 1 case; death plus severe reaction, 2 cases

infection, the following experiments were undertaken.

Since bacterial cultures revealed that the biles which had been exposed to air for any considerable time contained a great number of bacteria, we rediluted these concentrated biles to their original volumes and injected them into the dog's gall bladder.

No reaction was obtained, as seen from Table VIII, which proves that bacterial infection is not the cause of the changes obtained in the gall bladders.

EFFECT OF VARYING HYDROGEN-ION CONCENTRATION ON THE TOXICITY OF BILE SALTS FOR THE NORMAL GALL BLADDER

In subjecting the preceding findings to thorough criticism, there is still the possibility that the reactions produced might have been due to a change in the hydrogen-ion concentration of gall bladder bile. This change in hydrogen-ion concentration might convert the bile into a toxic substance. There are 2 ways of controlling this factor.

One method would be to produce a change in the hydrogen-ion concentration of gall bladder bile in the experimental animal by adding acid or alkali and observing the effect. The other method consists of the introduction of bile salt solution previously adjusted to the hydrogen-ion concentration of gall-bladder bile. Both methods have been applied.

The first method clearly demonstrates the

TABLE VIII.—CONTROL EXPERIMENTS WITH CONCENTRATED AND REDILUTED OX BILE

Ox bile	No of experiments	Results
Concentrated 150, rediluted	2	Gall bladder normal
Concentrated 110, rediluted	2	Gall bladder normal
Concentrated 88, rediluted	2	Normal, 1 case, slight reaction, 1 case
Concentrated 60, rediluted	2	Gall bladder normal

marked buffering action of bile. Injection of 5 cubic centimeters of glacial acetic acid into the dog's gall bladder was followed by total gangrene of the gall bladder and death of the animal. The hydrogen-ion concentration after adding this acid to the gall-bladder bile and thoroughly mixing, was about 2. Similarly, total gangrene of the gall bladder resulted from adding 10 cubic centimeters of 20 per cent sodium carbonate to the gall-bladder bile with a final hydrogen-ion concentration of 10.

More detailed information concerning the buffering potentialities of bile is yielded from the following experiments:

After aspiration of the total gall-bladder bile, the gall bladder was washed with a citric-phosphate buffer solution and was left filled with this solution. When the animals were electrocuted 48 hours later no changes in the gall-bladder wall were found. In other experiments, the same procedure was performed, a citric-phosphate solution of hydrogen-ion concentration of 3 being used. In one of these cases the gall bladder, containing a thin colorless fluid, showed a moderate degree of acute cholecystitis, but in the other it was refilled with dark bile and revealed a normal wall. It is obvious that the bile, which had re-entered the gall bladder through the hepatic ducts, by its buffering action, had kept the acid mixture from developing an irritating action on the wall of the gall bladder.

Various difficulties were encountered in performing the second series of experiments, namely, the introduction into the gall bladder of bile salts previously adjusted to the hydrogen-ion concentration of gall-bladder bile. In the first place, bile salts are easily pre-

TABLE IX—EFFECT OF VARYING HYDROGEN ION CONCENTRATION ON TOXIC EFFECT OF BILE SALTS ON THE NORMAL GALL BLADDER

Injected solution	Hydrogen ion concentration	Result
1 Sodium desoxychol 10%	pH after adjust with 0.1 mol citric acid 7.5	Severe cholecystitis
2 Sodium desoxychol 9%	7.5	Severe cholecystitis
3 Cholic acid 1 60%	7.8	Mild cholecystitis

8 Citric acid NaOH	7.4	Normal gall bladder

precipitated by adding acid to a bile salt solution. Furthermore, we have to consider that many acids, if brought in contact with the gall bladder wall themselves set up a reaction. We were able to overcome these difficulties by the use of a weak citric acid solution which as seen from controls, would not cause any change in the gall bladder wall even in a concentration higher than that used. As an example, the adjusting procedure for sodium desoxycholate is given as follows: 12 grams of sodium desoxycholate are dissolved in 100 cubic centimeters of distilled water. This solution which has a hydrogen ion concentration of 8.4 is heated to body temperature and 0.1 mol citric acid added one drop at a time. The precipitate which occurs is dissolved by shaking. After approximately the desired hydrogen ion concentration is reached (determined first roughly by a set of indicators) more exact determination is done with Hastings colorimeter. Table IX shows the results of experiments with adjusted bile salts, and the controls with citric acid. It is seen that the toxic effect of bile salts on the gall bladder wall is not changed when the hydrogen ion concentration is adjusted to that of gall bladder bile previous to injection. Citric acid solution, furthermore in concentrations even higher than that used for the adjustment does not in itself affect the gall bladder wall.

ALLERGIC GALL BLADDER REACTION

It is suggested by clinical observations that a reaction may occur in the biliary system in man which is based on an anaphylactoid condition. Many surgeons have seen flare ups of old gall bladder disease apparently due to an anaphylactic response against certain food stuffs such as chicken, egg, milk, cheese etc., omission of these foods affording relief. Alvarez and more recently Crouch reported several cases of this kind. The anaphylactic nature of this process, however, has only been suspected and no experimental proof has ever been given.

Hence the following experimental observations may be in place:

Each of 3 dogs received intravenous injections of crystallized egg albumen within a period of 3 days, each injection consisting of 5 cubic centimeters of a 6 per cent solution. No reactions were observed either during or after these injections. After an interval of 6 days similar injections of a 6 per cent solution of the same material were made, but this time in much larger quantities sufficient to produce visible toxic symptoms. In 2 of the animals the reaction consisted of vomiting, trembling, irregular respiration and passage of feces while in the third the response was much more pronounced, consisting of vomiting, loss of consciousness, cessation of respiration for 3 minutes and generalized convulsions. The quantity of the last injection was 15 to 20 cubic centimeters in the first 2 dogs and 25 cubic centimeters in the third. The animals were electrocuted $\frac{1}{2}$ hour following the last injection and postmortem examinations were made immediately. In all 3 cases there was found marked edema of the gall bladder wall, most marked in the serosa. Microscopic examination of the liver showed markedly constricted arterioles.

As a control egg albumen was injected in large amounts into 3 other dogs which had not received any previous injections. In 2 of these animals no symptoms were visible until 40 cubic centimeters had been injected. After 45 cubic centimeters however the reaction was marked but consisted only of vomiting and passage of feces. In the third dog the symptoms did not appear until 60 cubic centimeters

meters had been injected. Postmortem examination after electrocution revealed perfectly normal gall bladders.

A comparison of the results in the 2 series of animals suggests the conclusion that the reaction obtained after the last injection in the first series was an anaphylactic response, since it required much less albumen to produce a response in the previously sensitized dogs than in the control animals. Furthermore, the constriction of the arterioles in the liver in the first series of animals is suggestive of anaphylactic change.

BILE SALT INTRAVENOUS INJECTIONS

It is of great interest for the understanding of gall-bladder symptoms in man that it is possible to produce a condition of anaphylaxis experimentally.

Such an allergy might explain the gall-bladder symptoms which occur after the intake of certain foods. When we consider the frequency of gall-bladder disease, however, as contrasted to the comparatively rare observation of food allergy, we are inclined to believe that allergy, caused by exogenous food substances, is not of great practical importance.

Many possibilities present themselves, however, when we consider endogenous body substances. Many metabolic products may serve as sources of allergic states as well as any disturbance in the detoxifying action of the liver cells.

This consideration becomes of much more practical importance in view of experimental results which we obtained.

Having seen the powerful toxic action of bile salts in the gall-bladder wall, at a concentration which exceeds only slightly the normal values, we were tempted to suspect that an anaphylactic mechanism might be responsible for these effects.

The results which we obtained are striking, but since these studies are not as yet completed, we are not reporting the detailed work. We do not obtain positive results with such regularity that we can predict the conditions under which they will occur. There are still many factors the nature of which are unknown to us.

There follows a rough outline of the experiments:

Intravenous injections of commercial bile salts, purified bile salts or sodium desoxycholate were given to 26 dogs, concentrations of 5 or 10 per cent being used.

The number of injections given to each animal as well as the total amount injected varied considerably in the different experiments.

In one series we gave single injections, which we discontinued after toxic symptoms, such as vomiting, convulsions, etc., became visible. This stage was reached in our animals which had an average weight of 5 to 6 kilograms after 25 to 30 cubic centimeters of the 5 per cent solution had been injected. Those animals which did not die spontaneously, were electrocuted a few minutes after the injection.

Another group of dogs received 2 injections each, 20 minutes apart. We carefully avoided getting a marked toxic effect from the first injection, while the amount administered in the second injection was large enough to produce visible toxic signs or death of the animal.

A third group received 4 to 5 injections at hourly intervals, beginning with a comparatively small amount (10 to 12 c cm.) in the first injection and ending with 15 to 40 cubic centimeters in the last one. The last group received daily injections for about a week, and these animals were killed a few days after the last injection.

These experiments resulted in marked reaction of the gall-bladder wall in more than half of the cases, the positive results being found in the first 3 groups, while the fourth was completely negative.

No definite correlation, however, can be made between the different methods of administering the bile salts in the different groups and the reactions obtained. The number of positive results was greater in the first and second groups, where the 1 or 2 injections had been given within 3 to 20 minutes, than it was in the third. In the latter group the injections had extended over several hours.

The shortest time in which a reaction occurred was 3 minutes. Purified bile salts

TABLE IX—EFFECT OF VARYING HYDROGEN ION CONCENTRATION ON TOXIC EFFECT OF BILE SALTS ON THE NORMAL GALL BLADDER

Injected solution	Hydrogen ion concentration	Result
1 Sodium desoxy chole 10 3%	pH after adjust with 0.1 m l citric acid 7.3	Severe cholecystitis
2 Sodium desoxy chol 5	7.2	Severe cholecystitis
3 Cholecalciferol 5	7.8	Medium cholecystitis
4 Cholecalciferol 5	7.2	Medium cholecystitis

7 Citric acid NaOH 1 M citric acid adjust with NaOH 10% 7		Normal gall bladder
8 Citric acid NaOH	7.4	Normal gall bladder

precipitated by adding acid to a bile salt solution. Furthermore, we have to consider that many acids, if brought in contact with the gall bladder wall themselves set up a reaction. We were able to overcome these difficulties by the use of a weak citric acid solution, which, as seen from controls would not cause any change in the gall bladder wall even in a concentration higher than that used. As an example, the adjusting procedure for sodium desoxycholate is given as follows: 12 grams of sodium desoxycholate are dissolved in 100 cubic centimeters of distilled water. This solution, which has a hydrogen ion concentration of 8.4, is heated to body temperature and 0.1 mol citric acid added one drop at a time. The precipitate which occurs is dissolved by shaking. After approximately the desired hydrogen ion concentration is reached (determined first roughly by a set of indicators) more exact determination is done with Hastings colorimeter. Table IX shows the results of experiments with adjusted bile salts, and the controls with citric acid. It is seen that the toxic effect of bile salts on the gall bladder wall is not changed when the hydrogen ion concentration is adjusted to that of gall bladder bile previous to injection. Citric acid solution furthermore in concentrations even higher than that used for the adjustment does not in itself affect the gall bladder wall.

ALLERGIC GALL BLADDER REACTION

It is suggested by clinical observations that a reaction may occur in the biliary system in man which is based on an anaphylactoid condition. Many surgeons have seen flare ups of old gall bladder disease apparently due to an anaphylactic response against certain food stuffs such as chicken, egg, milk, cheese, etc., omission of these foods affording relief. Alvarez and more recently Crouch reported several cases of this kind. The anaphylactic nature of this process, however, has only been suspected and no experimental proof has ever been given.

Hence the following experimental observations may be in place:

Each of 3 dogs received intravenous injections of crystallized egg albumen within a period of 3 days each injection consisting of 5 cubic centimeters of a 6 per cent solution. No reactions were observed either during or after these injections. After an interval of 6 days similar injections of a 6 per cent solution of the same material were made but this time in much larger quantities sufficient to produce visible toxic symptoms. In 2 of the animals the reaction consisted of vomiting, trembling, irregular respiration and passage of feces while in the third the response was much more pronounced consisting of vomiting, loss of consciousness, cessation of respiration for 3 minutes and generalized convulsions. The quantity of the last injection was 15 to 20 cubic centimeters in the first 2 dogs and 25 cubic centimeters in the third. The animals were electrocuted 1½ hour following the last injection and postmortem examinations were made immediately. In all 3 cases there was found marked edema of the gall bladder wall most marked in the serosa. Microscopic examination of the liver showed markedly constricted arterioles.

As a control egg albumen was injected in large amounts into 3 other dogs which had not received any previous injections. In 2 of these animals no symptoms were visible until 40 cubic centimeters had been injected. After 45 cubic centimeters however the reaction was marked but consisted only of vomiting and passage of feces. In the third dog these symptoms did not appear until 60 cubic centimeters

human operations shows that there is no definite correlation between the nitrogen content of the bile and the changes of the gall-bladder wall, the fluctuations in nitrogen content being extreme in both

5 Injections of egg albumen into the dog's gall bladder set up an active acute inflammation

6. Changes of the gall-bladder wall of the dog which on gross and microscopic examination closely resemble those found in human cholecystitis, were produced in 72 experiments by the injection of bile salts. The differences in the activity of different fractions of bile are mainly quantitative in nature. Desoxycholic acid is the most effective fraction, causing gangrene of the gall bladder and death of the animal in many instances, while purified and hydrolyzed bile salts are somewhat weaker. Glycocholic acid causes a marked reaction only in higher concentration.

7 Injection of deproteinized dog or ox bile into the dog's gall bladder leaves the gall-bladder wall unchanged. No protective action of protein, as described in the literature, can be found.

8 A quantitative study of the toxic effect of bile salts was made by replacing gall-bladder bile in the dog by bile concentrated previous to the injection. Bile concentrated to about half its volume proved to have a marked effect.

9 Changes in the hydrogen-ion concentration of bile rarely bring about a reaction in the gall-bladder wall unless they are extreme, less than 3 and greater than 10. Such changes are not likely to arise in man. The toxic effect of bile salts is not due to a change in hydrogen-ion concentration since adjustment of the bile salts to the hydrogen-ion concentration of the gall-bladder bile previous to the introduction, did not diminish their toxic effect.

10 It is possible to produce experimentally an allergic condition in the gall bladder. Intravenous injection of egg albumen caused an edema in the gall-bladder wall of previously sensitized dogs, while no reaction occurred in control animals

11. A marked edema of the gall-bladder wall was produced by the intravenous injection of bile salts. The shortest time in

which this reaction took place was 3 minutes after the injection

It has been suggested that a temporary increase in bile salt concentration in the gall bladder brings about human cholecystitis.

seem to be more effective than any other fractions

Postmortem examination revealed a grayish white gall bladder with congestion of the serosa. Edema, most marked on the liver surface, was a prominent feature. No changes were found anywhere else in the body. Microscopic examination showed the serosa to be edematous, and swollen to 6 times its normal thickness.

EVALUATION OF STUDY

The gall bladder contains the strongest solution of any substance which the human body elaborates and this substance (bile acids) is an exceedingly toxic one. The normal gall bladder is a concentrating mechanism of high potency and our experiments show that only a slight overaction of its every day action may produce a concentration whose effect is damaging to the gall bladder and the surrounding tissues. This effect might be brought about in three different ways. First by the gall bladder itself from simple overaction, or second by the excretion of bile by the liver which is too concentrated in the first place, or third by the excretion of bile by the liver which contains substances which might become toxic on further concentration.

The first of these theories seems the least probable. The range of the normal liver bile in bile acid content is a wide one. The amounts may be very small but the gall bladder seems to tend to absorb water and to concentrate them all to about the same level. It has been shown in previous communications that the normal gall bladder in the course of its concentrating action absorbs but little bile salts during the period between emptyings but that if the action is prolonged, by stasis eventually all the bile salts will be absorbed. Such an action has been shown to be capable of precipitating the cholesterol in the bile which needs the bile salts to hold them in solution. This process apparently takes place without the patient going through an attack of cholecystitis, as the many specimens of such gall bladders show taken from individuals who have never had such an attack.

The second alternative, an increased secretion from the liver, also seems improbable,

as if such were the case values within the toxic range would certainly have been reported previously by some of the many who have worked in this field.

The third theory, a qualitative difference in the bile salts excreted by the liver, cannot be so easily disposed of. Our experiments indicate a far higher degree of toxicity for some of the unconjugated bile acids. We have previously reported the findings of large amounts of such bile acids in the liver bile of a diabetic, and it seems not unlikely that such may not be an uncommon occurrence. The present limitations of bile salt chemistry make it impossible to recognize even large amounts of such materials in the amount of bile recoverable from a gall bladder, but one may hope that progress in this field may soon make such analyses possible.

If some such theory of the origin of some cases of gall bladder disease is entertained, it fits in well with many of the observed facts which are thought by some to militate against bacterial theories. The frequent afebrile cases, failure to grow organisms in many cases, the pathological picture which Denton describes as resembling a hemorrhagic infarct are all consonant with such a chemical mechanism. The low values from bile acids found in most cases of closed acute gall bladders is explained on the assumption that the original high concentration causes an edema which permits the rapid leaking out of the contents by osmosis. Such can actually be seen in our experiments in the staining of the local peritoneum.

SUMMARY

1. A non-traumatic technique for introducing substances into the dog's gall bladder is described.

2. Most strains of bacteria even when injected in overwhelming numbers do not cause cholecystitis. If trauma is added these same strains do cause cholecystitis.

3. Carbon dioxide and chlorine are absorbed rapidly from the normal gall bladder, while phosphorus is excreted but an unknown amount for much of the acidification.

4. Chemical examination of 45 human postmortem biles and 13 biles obtained at

CARCINOMA OF THE RECTUM

A Plea for Group Study and Treatment

PAUL C MORTON, M.D., F.A.C.S., New York, New York

THIS analysis comprises all the cases of carcinoma of the rectum at St. Luke's Hospital, New York City, between the years 1924 and 1935 inclusive, both private and ward patients operated upon only by members of the hospital staff are included. It is important to understand early in the discussion that a comparison of these statistics with those of group clinics and clinics headed by one individual doing the great majority of work is of doubtful value. The reason for this statement will be made later. The general purpose of this paper is to present:

1. An analysis of these cases, with special reference to (a) the number of cases seen, divided into operable for cure cases, and inoperable cases, (b) a division of the operable for cure cases into groups in relation to their follow-up records.

2. A general discussion of the diagnosis, and of the pre-operative and postoperative management of cancer of the rectum, and suggestions for improving the care and the end-results, in general hospitals organized as St. Luke's Hospital.

Classification of these patients as to sex, age, pre-operative length of symptoms, and etiology, will not be given in this paper. This information, while available, corresponds in general to that given in all the recent papers. We have no hitherto unknown methods of diagnosis or new technique to offer. Our experience in very recent years has given us a better understanding of the management of these cases, and the adoption of those methods used in other clinics to shorten the length of operation, to protect the patient against peritonitis, and to improve the operative technique, has met with varying degrees of success.

DIAGNOSIS

Early diagnosis in this condition is the great hope for better therapeutic results. We believe in almost all cases of carcinoma of the anus, rectum, and rectosigmoid, that a proper digital examination will reveal the presence of the growth; this includes an examination, often with the patient in the stooping position and while they are bearing down. The great hope for the early diagnosis of this condition lies in periodic health examinations, including a digital and proctoscopic examination. The general use of the proctoscope will do much to improve the diagnosis and treatment of all rectal conditions. It is a simple procedure, given the proper instruments, a convenient arrangement, and gentleness on part of examiner. A proctoscopic examination should be part of every x-ray examination of the colon.

The question often arises as to how long a growth has been present. We have seen recently, and not included in this group, one patient who was proctoscoped by a competent observer 1 year prior to his admission, with a negative result. A well developed carcinoma within 2 inches of the anus was found at the end of this time.

Biopsy furnishes an accurate diagnosis as to the presence or absence of cancer, with minor exceptions, and should be done whenever possible. A negative diagnosis, however, must be judged together with the clinical findings. Included in this group is the case illustrated of an adenoma of the rectum, but with carcinomatous degeneration in one portion of the growth. Repeated biopsies failed to show carcinoma. Radical resection was performed. The converse is true, and inflammatory lesions, such as chronic ulcerative colitis and amebic dysentery, can be confusing. Every hard, friable, bleeding mass felt with the finger should not be called carcinoma without further examination.

the gland-bearing area for saving the sphincter. It is hoped additional progress in technique will bring results along this line.

ANESTHESIA

In the last 2 years, the use of spinal anesthesia has been of considerable help to us. With the use of pantocaine up to 2.5 cubic centimeters, introduced between the first and second lumbar vertebrae, we have gotten between 2 and 3 hours of anesthesia, and when the operation has been completed in this time the patients have shown less shock. Cyclo-

Fig 2 Specimen removed following three biopsy examinations with report of non-malignant adenoma. Carcinomatous degeneration in one portion only. Arrow at left, carcinoma, at right, adenoma.

propane and ether have come into favor when spinal anesthesia is not used. In the great majority of these cases reported the patients were operated upon with open ether anesthesia.

TRANSFUSIONS

We believe that the free use of transfusions before and after operations, regardless of the apparent condition of the patient, leads to fewer complications and a smoother convalescence. This applies to the first as well as the second stage of the multiple stage operation.

OTHER GENERAL CONSIDERATIONS

It has been our own experience in a comparatively small number of cases that the

Chart 1 The operability for cure in this series of 190 cases is 34 per cent. In this group this figure is low as compared to 73.6 per cent as reported by Cattell and 53.7 per cent as reported by D. F. Jones of Boston. Operability depends upon two main factors: (a) the class of patient admitted to the clinic. Group clinics depending upon referred patients for the greater number of their cases will have on the whole a better class of patient and an earlier diagnosed lesion than the general hospital in a large city receiving the charity patient from the ambulance in the street. (b) The skill of the operating surgeon. The more experienced the surgeon, the greater the number of cases he will operate upon.

PATHOLOGY

The one hundred cases reported in this series as operable for cure have had microscopic pathological diagnoses. The sections have not been graded according to Broder. Up to this time their relationship to the end results is, therefore, not available. Biopsies were performed in every case of the inoperable group in which a tumor could be reached.

OPERATIVE PROCEDURE

Multiple versus single stage operations. The discussion which is ever present as to whether multiple stage or single stage operations give the best results has been of some interest to

Chart 2 Inoperable cases total 180 from a total of 196. Seven cases with resection without hope for cure are excluded. Deaths following palliative procedures were as follows: 10 died following colostomy, 16 died in the hospital without operation, 5 died in the hospital following laparotomy but without colostomy, no deaths followed cecostomy.

us in examining this series. Fundamental physiological and operative principles should be borne in mind in the choice of operations for these patients, and should include: (a) as short an operation as possible which is consistent with a complete removal of the growth and gland bearing area, (b) the principle of self inoculation against peritonitis.

These two principles find their application in the advocacy of multiple stage procedures. Our own experience does not warrant any specific recommendation in this matter. We believe that any particular set of rules to be followed in every case is not to be accepted.

It has been our impression that the use of the multiple stage operation in the hands of younger surgeons, both as to years and experience, is a far safer maneuver in the majority of cases. To be dogmatic on this point, however, is to lose that fine sensitiveness to the patient's ability to withstand trauma which makes for a good surgeon and a cured and living postoperative patient.

Efforts should be made in judging these patients as to type of operation, to save the sphincter in as many cases as possible. In 8 patients, 2 of whom died, resections were performed saving the sphincter. Seven of these were true rectosigmoid lesions and the great temptation is to remove the growth by the abdominoperineal route. Undoubtedly a number of cases can be saved the inconvenience of a colostomy if experienced surgeons will attempt procedures such as these, but not sacrificing the principle of removing

Chart 3 Included in the 32 postoperative deaths are 4 cases in which only the first stage of a multiple stage procedure was carried out.

The 10 5 year arrests represent 31.5 per cent of 55 resections. Note that the figure at top of column indicates percentage as well as number of cases.

Fig 1 Specimen removed 1 year after a proctoscopic examination by a competent observer, who found abnormality in neither the rectum nor sigmoid

Fig 2 Illustration made at the operating table with the thyroid gland elevated out of its bed and inverted. The inferior thyroid artery is demonstrated and the typical relationship of the recurrent laryngeal nerve to the inferior thyroid artery is shown. Note the relationship of the lower parathyroid gland.

Fig 3 This illustration likewise was made at the operating table. Note that in this case the recurrent laryngeal nerve runs over the lower branch of the inferior thyroid artery and is buried beneath a tongue of thyroid tissue near the upper pole at which level it enters the larynx. Note the typical position of the lower parathyroid gland between the branches of the inferior thyroid; note the upper parathyroid which of all parathyroid glands is the

most constant in location most easily found in its position against the larynx. This thyroid gland has been elevated and inverted.

Fig 4 In this operative dissection the recurrent laryngeal nerve runs beneath both branches of the inferior thyroid artery in its typical relationship.

Fig 5 In this operative dissection as in the others the superior thyroid pole has been freed and cut; the gland has been elevated from its bed and inverted and the inferior thyroid artery has been cut between ties to permit complete exposure of the recurrent laryngeal nerve up to the point at which it enters the larynx. This extent of exposure will rarely be necessary. Note again the constant location of the superior parathyroid gland.

CLINICAL SURGERY

FROM THE DEPARTMENT OF SURGERY, THE LAHEY CLINIC

ROUTINE DISSECTION AND DEMONSTRATION RECURRENT LARYNGEAL NERVE IN SUBTOTAL THYROIDECTOMY

FRANK H. LAHEY, M D , F A C S , Boston, Massachusetts

UP to the present it has been the custom for surgeons operating upon the thyroid gland to take the position that they do not want to see the recurrent laryngeal nerve, that if the nerve is seen it is endangered, and that as the result of stretching and manipulation consequent to its exposure, recurrent laryngeal paralysis may result. It has been the custom of thyroid surgeons to avoid injury to the recurrent laryngeal nerve by leaving sections of thyroid tissue over the region where the nerve should be and by avoiding in the dissection the region in which the recurrent laryngeal nerve is presumably located. It has frequently been stated also that technical measures directed toward high elevation of the lateral lobes of the thyroid gland out of their beds could so stretch the recurrent laryngeal nerve that paralysis might well occur.

About 3 years ago we instituted the policy of dissecting the recurrent laryngeal nerve in practically every type of thyroid operation. In the year 1935, 998 thyroid operations were done; in the year 1936, 1,148, and during 1937 more than 1,300 thyroid operations have been done. It is obvious that in hundreds of cases the recurrent laryngeal nerve has been palpated while moderately on the stretch, dissected, and so visualized that in each case it could be clearly demonstrated to assistants and visitors. It has been demonstrated and visualized on one side, or on both sides, in patients with exophthalmic goiter, with a recurrent type of goiter, with toxic adenomas, with large and small discrete adenomas, with deep intrathoracic goiters, and in patients with all grades and types of malignancy. In none has there been either immediate or later paralysis or changes in position of, or motion in, the vocal cords as result of these dissections.

As the result of this large experience with the anatomical relationship between the recurrent laryngeal nerve, the inferior thyroid artery, the trachea and the thyroid itself, we are certain that there is a very definite constancy in the location of this nerve, and that this constancy of location

occurs no matter what type of goiter is present, regardless of how large it is or how deep it is situated in the chest. Formerly it was considered that when the intrathoracic goiter had extended deep into the mediastinum there was danger that the downward extension of the intrathoracic masses of thyroid tissue would result in downward pressure and stretching of the recurrent laryngeal nerve. We have now removed several hundred intrathoracic goiters, many of which have extended down to within a rib or two of the level of the diaphragm (Fig. 1). Following these removals we have done dissections and demonstrations of the recurrent laryngeal nerve on the side on which

Fig. 1 The depth of this intrathoracic goiter is outlined by arrows and the degree of tracheal deviation by dashes. If an intrathoracic goiter ever distorts the course of the recurrent laryngeal nerve, in this type of goiter the nerve should be displaced. In a large number of cases similar to this the recurrent laryngeal nerve has been dissected and found to be in the normal position.

Fig. 6 With the gland mobilized and inverted the typical and most common relationship is shown of the recurrent laryngeal nerve to the lower pole of the gland and the inferior thyroid artery. Note the direction of its course toward its point of entrance into the larynx also the quite common location of the inferior parathyroid gland.

the intra thoracic extension has been located. In all of the cases the recurrent laryngeal nerve has not been stretched, and has been in its usual position except that frequently it is pushed more closely against the trachea than usual.

In the course of performing several thousand thyroidectomies, the thyroid lobes routinely have been grasped with our own special grasping forceps and not only have both lateral lobes been dislocated from their beds after detaching them laterally from the internal jugular vein but they have been so dragged upon that they were displaced across the trachea so that the dislocated lobe rested bottom side up upon this structure. Temporary, or permanent paralysis of the recurrent laryngeal nerve has not occurred following this procedure. During the last 3 years we have repeatedly located the recurrent laryngeal nerve in the cellular tissue below the main trunk of the inferior thyroid artery by palpating it somewhat on the stretch and have taught every surgical fellow in the clinic who has served as an assistant to locate the recurrent laryngeal nerve at this point by palpation. As the result of this procedure no recurrent laryngeal nerve paralysis has occurred.

The course of the recurrent laryngeal nerve is constant but the shape and extension inferiorly and laterally of the thyroid tissue of the lower

Fig. 7 In this operative dissection the nerve has been exposed up to the point at which it enters the larynx. Note its division into two branches, one larger than the other. I surmise this is an extralaryngeal separation of the nerve into the segments to supply the abductors. We have repeatedly seen this extralaryngeal division in the course of our operative dissections of this nerve. Note again the quite constant location of the parathyroid gland in its position against the larynx.

pole of the thyroid gland are quite inconstant. Not infrequently there will be extensions of thyroid tissue from the posterior aspect of the lower thyroid pole. Often these extensions will so approach the course of the recurrent laryngeal nerve that this structure unless visualized and protected, can easily be injured.

The plan of leaving a strip of thyroid tissue over the region where the recurrent laryngeal nerve is presumed to be because of fear of injury to that nerve not infrequently results in leaving too large segments of thyroid tissue thus inadequate thyroid tissue is removed and the hyperthyroidism persists or recurs.

Every surgeon in the clinic operating upon thyroid glands has learned to dissect and demonstrate the recurrent laryngeal nerves. With the lateral lobe of the thyroid grasped in double hooks and pulled up out of its bed, the common carotid artery and internal jugular vein then are dissected and held outward by a special blunt retractor thus exposing the areolar tissue between these vessels and the trachea. In this region the trunk of the inferior thyroid artery is demonstrated. As is shown in Figures 2 to 7 the angle of approach of the recurrent laryngeal nerve is quite constant as it passes either behind or in front of the inferior thyroid artery, to reach the point at which the nerve enters the larynx by passing beneath the lowest fibers of the inferior constrictor muscle where this structure is attached to the horn of the

thyroid cartilage. At this point, just below the inferior thyroid artery, the recurrent laryngeal nerve can usually be palpated, and it is at this point that we routinely demonstrate the nerve trunk.

The trunk of the recurrent laryngeal nerve at this point is considerably larger than the lead in the average magazine pencil. It is of such definite thickness that it can be palpated easily as it is pushed and rolled against the cartilaginous rings of the trachea. The course of the recurrent laryngeal nerve beneath and above the inferior thyroid artery can usually be demonstrated by introducing a pair of right angle clamps over the nerve and beneath the artery, opening the clamps gently.

Although this method of demonstrating the trunk of the recurrent laryngeal nerve below the point where it passes behind the inferior thyroid artery, does not in many of the cases result in exposure of the nerve from the level of the inferior thyroid artery up to the point at which the nerve enters the larynx, its course here may very readily be visualized by placing a finger on the tip of the thyroid cartilage and laying a hemostat from that point down to the point where the trunk of the nerve is in plain view.

It is at this point, between the horn of the thyroid cartilage and the point where the nerve passes under or over the inferior thyroid artery, that the greatest number of injuries to the recurrent laryngeal nerve is produced. It is in this short course that the nerve is sometimes imbedded in thyroid tissue, or is frequently overlapped by thyroid tissue and pressed against the laryngotracheal junction. It is at this point that the upper branch of the inferior thyroid artery, as it rests against the trachea and enters the gland, is not infrequently torn in performing subtotal thyroidectomy. Attempts to control bleeding, at this laryngotracheal junction, from the upper branch of the inferior thyroid artery after the surface of the gland has been cut across anteriorly, sometimes result in passing the hemostat so deeply between the trachea and the stump of remaining thyroid tissue that the nerve is unknowingly caught at its most anterior point, just before it disappears behind the inferior constrictor muscle.

If the trunk of the recurrent laryngeal nerve has been demonstrated and its course visualized, it is obvious that attempts to control bleeding at this point from the upper branch of the inferior thyroid artery will endanger the nerve, a local ligation should not be applied, but the main inferior thyroid artery outside the point where the recur-

rent nerve passes over or beneath it should be ligated. By following this procedure, injury to many a recurrent laryngeal nerve will be avoided.

When the recurrent laryngeal nerve passes in front of the inferior thyroid artery, as it occasionally does, the course of the nerve up to the point at which it enters the larynx is usually much clearer than when it passes beneath the artery, and not infrequently in such cases the entire trunk of the nerve up to its point of disappearance into the larynx can be seen. At times the sharp angulation of the nerve as it passes into the larynx can be demonstrated. In an occasional case the nerve, as shown in Figure 7, may split into the relatively large group of fibers innervating the adductor muscles of the cords, the cricoarytænoideus lateralis, and the relatively small group of fibers innervating the abductors of the cords, the cricoarytænoideus posterior.

In the course of performing subtotal thyroidectomy and the dissection and demonstration of the recurrent laryngeal nerves, parathyroid bodies are frequently encountered and are always looked for. No attempt is made, however, to dissect these structures since the situation here is quite different from that of demonstration of the recurrent laryngeal nerve in that the parathyroids are dependent upon small end vessels for their blood supply and attempts to dissect and demonstrate these structures could well interfere with their blood supply and result in loss of their function.

CONCLUSIONS

A technical method of dissecting and demonstrating recurrent laryngeal nerves has been employed for over 3 years in performing subtotal thyroidectomy in more than 3000 cases. We have refrained from publishing this plan or advocating its use until it had been employed for a sufficient time and in a sufficient number of cases so that we could safely speak about it after a justifiable amount of experience.

We have all illogically accepted unproved statements of the past that manipulations around the region of the recurrent laryngeal nerve would produce interference with the function of that nerve.

This method, in competent hands (and no plan should be expected to fit incompetent ones), will not increase but rather definitely decrease the number of injuries to the recurrent laryngeal nerves. It will also encourage the removal of larger amounts of thyroid tissue, without added danger to the nerves.

BILATERAL NON-TUBERCULOUS ILIOPSOAS ABSCESS

MARIE ORTMAYER M D Chicago, Illinois

CHRONIC psoas abscess of other than tubercle bacillus origin is rare. No instance of bilateral non tuberculous iliopsoas abscess was found in the literature. The one to be reported occurred following pneumonia in a young girl who was ill with fever for 5 months and recovered after drainage of the abscesses.

Tuberculous psoas abscess is a well known condition of considerable frequency especially in children, originating from tuberculous caries of the lower dorsal or upper lumbar vertebrae, as a rule, and traversing downward along the planes of psoas muscles to point above, but most commonly below, Poupert's ligament.

Acute iliopsoas abscess due to the Staphylococcus aureus or albus or streptococcus, results according to textbooks on surgery (2), from trauma or strain of the muscle fibers with resulting hematoma and infection with pus formation. L. Long cites 6 cases of such abscess, 4 in boys under 17 years of age with a history of injury preceding the onset, 1 in a woman during the puerperium, and the sixth in a boy of 17 years ill for a year after. The first 5 had quick and permanent recovery following drainage of the abscesses from behind the iliac fascia or behind the iliopsoas muscles. In a discussion, Dr. Urban Maes cited 5 acute cases he had seen without a previous history of injury but following furuncle or carbuncle, Staphylococcus albus being the infecting agent. Reporting of so many instances by two men raises the question of the possible high frequency of acute iliopsoas abscess in spite of the meager number reported in the literature.

Curiously enough chronic iliopsoas abscess of other than tubercle bacillus infection has its origin as in the author's patient not from caries of the vertebrae but from perforated empyema and is found therefore under the subject of complications of empyema as empyema necessitatis or migrans. The literature before 1900 contains most of the references, because spontaneous perforation of empyema is much less common since x ray has been added to the diagnostic armamentarium of chest diseases. Unusual positions of encapsulated empyemas such as the basal and mediastinal collections of pus, are now more readily detected while a prolonged course of empyema without surgi-

cal drainage is the exception nowadays. Spontaneous perforations of empyema, however, still occur (6, 10, 16, 27). Rupture into the esophagus the pericardium into the stomach or abdominal cavity via the diaphragm into the urinary passages into the bowel and through the visceral pleura into the lung are cited. 'Pulsating pleurisy,' a dramatic variation of the escape of pleural pus through the chest wall usually in its thinnest places near the sternum or lateral to the pectoralis is mentioned in all the textbooks. Rarely mentioned but 'very remarkable are those which pass down the spine and along the psoas into the iliac fossa, and simulate a psoas or lumbar abscess' (21). Abscesses of this latter type are discussed in this paper.

Because of the difficulties in diagnosis and the extreme rarity of instances reported in the English language especially, the following patient's course is given in some detail.

C. D., a girl aged 15 years entered the hospital November 18, 1936. She had been well and in school until she caught cold 5 days previously. After remaining up and about for 7 days she developed severe general abdominal pain followed by a chill lasting 30 minutes a temperature of 101 degrees and inability to void. Her physician sent her to the hospital with a diagnosis of acute abdomen.

On entrance the temperature was 101 degrees the pulse 130 and the respirations 40. Well developed and fairly well nourished, this girl seemed acutely ill. Her expression was apathetic, she was moving markedly, the pharynx moderately injected, the cheeks flushed and respirations shallow and rapid. Postnasally there was a thick greenish discharge. The right lung was hyperresonant in its upper and middle lobes and dull over the lower. Fine rales were heard in the middle lobe, diminished breath sounds over the lower lobe without rales. By the following morning the left lung had developed flatness in the base with tubular breathing but no rales. The heart was rapid and regular not enlarged. A murmur almost presystolic in time was present loudest over the pulmonic area. The abdomen was rigid almost boardlike and extremely tender, most marked in the upper right quadrant. Marked tympanites was noted but no masses were palpable. The rectal and vaginal examinations were negative. The extremities were normal with normal reflexes.

Blood count showed hemoglobin 80 per cent, red blood cells 5,130,000, white blood cells 62,000, differential blood count polymorphonuclears 94 per cent, lymphocytes 2 per cent. The urine was normal except for a trace of albumin and occasional pus cell. The sputum was scant mucopurulent and contained many diplococci resembling pneumococci. At this time no x ray pictures were taken. Diagnosis: bilateral lobar pneumonia.

The patient appeared extremely toxic, cough was frequent though unproductive of much sputum, respiratory embarrassment and pains in both lungs were present for

From the Department of Medicine, University of Chicago and Women and Children's Hospital.

Fig 1 Anteroposterior view November 28, 1936, showing relatively clear right chest, shadows in lower left chest with obliteration of diaphragm and stomach air bubble, but with the heart shadow hiding the probable pathological condition in the left posterior pleural cavity

Fig 2 Left anterior oblique roentgenogram which was taken on December 8, 1936, showing shadow in the left posterior costomediastinal pleural cavity. From this infected area somewhere pus can have perforated downward

3 days, for which small amounts of codeine and morphine were given. Abdominal pain, generalized or shifting, continued for 10 days, catheterization was necessary for 2 days, diarrhea was quite persistent. Both lower lobes of the lung became dull to flat, with absent fremitus, with minimal rales, with distant tubular breathing only near the spine. Tympanites and "high standing diaphragm" interfered with evaluation of signs. The right chest gradually cleared and breath sounds came through by the end of 2 weeks. Though distention of the abdomen decreased at this time, tenderness was marked over the spleen and in both inguinal regions. The temperature had fluctuated daily from 100 to 104. The white blood count dropped in the first 4 days from 62,300 to 32,600 with the polymorphonuclears 97 per cent.

The x-ray diagnosis of this period was. Probably unresolved pneumonia of the left base. Fluoroscopic check for fluid was inconclusive, as the patient could be moved with difficulty (Fig 1).

Toward the end of the third week of her illness, the patient had a chill lasting 3 minutes. A consultant, finding a diagonal line of flatness posteriorly left, extending from the sixth vertebral spine downward almost to the posterior axillary line with egophony, bronchial breathing, and crepitant rales above it, made a diagnosis of left lower lobe atelectasis following bilateral lower lobe pneumonia. A second fluoroscopic examination verified the triangular shadow in the left chest near the spine and back of the heart (Fig 2). Left posterior pleural sinus pleuritis with effusion or suppurative was also considered, but as thoracentesis on three occasions by the internes failed to yield fluid or pus, the diagnosis was in doubt. The diagonal left posterior pleural flatness and its accompanying x-ray shadow gradually receded in the next few weeks and had completely disappeared by the end of the second month of illness.

Search continued for the cause of the temperature, which after the first month had dropped from 102 degrees to normal and remained so for 36 hours, only to rise again and remit once daily, in quite irregular fashion, from 99 degrees or thereabouts to over 100, 101, at times even to 103 degrees, for 2½ months more. The red blood count had

dropped to 2,900,000, the hemoglobin to 52 per cent, and the white cells to 13,800 with 58 per cent polymorphonuclears. The early diarrheal stools were repeatedly negative for occult blood, ameba, ova, pus and bacilli of the typhoid group. No tubercle bacilli were found in the sputum, only pus cells and lance-shaped diplococci. On the blood cultures yielded no growth, the Widal, typhoid, paratyphoid, and undulant tests were negative, the tuberculosis fixation was slightly positive. The area of infiltration of the Mantoux skin test was 1 centimeter at the end of 48 hours. In the urine mild traces of albumin were found, 15 to 20 pus cells and colon bacilli. Pyelograms, colon roentgenogram, and spinal x-ray films were normal.

Late in the second month of illness the patient began to complain of occasional vague abdominal cramping, indefinitely located, but later referred to both lower quadrants where some rigidity and tenderness were noted, especially left.

After a week, the rigidity of the abdomen became less marked and pain was practically absent. Firm masses could now be felt fixed in both iliac fossae. The left was the better outlined and the larger and lay just below the anterior superior spine of the ilium. For a month these masses definitely increased in size, though they were not tender. They were shown to be separate from the pelvic organs and colon. Free motion of the hip joints was possible, without pain!

Three and a half months after onset of illness in this girl, the final medical opinion was

In view of the stormy onset with "cold" and anuria, which was the beginning of a bilateral pneumonia, or possibly even of bilateral pleurisy with effusion; in view of the leucocyte count of 63,000 with persistence of polymorphonuclear neutrophils in high percentage, the finding of the triangular area of flatness occupying the posterior left pleural sinus position, with its gradual recession and clearing, the persistence of temperature in spite of this clearing, the indefinite abdominal pain appearing at the end of 2 months' illness, with localization of rigidity and tenderness in both lower quadrants and the detection of bilateral masses, gradually enlarging and fixed over the iliopsoas

Fig 3 Anterior attachments of diaphragm (viewed from below and inside). Illustrates (as at 1, 2, 3) points through which pus from anterior pleural sulcus could perforate downward. (From Spalteholz)

muscles. I am forced in spite of the failure to obtain pus on puncture from the pleura to make a diagnosis of low grade pus infection originating probably from a left posterior encapsulated and perforated pleural sinus empyema and traveling via the posterior mediastinum and retroperitoneum downward in front of both psoas sheaths to localize as bilateral abscesses in the iliac fossa.

These two abscesses were drained extraperitoneally above Poupart's ligaments near the anterior superior spines of the ilium in front of the psoas sheaths beneath the abdominal musculature and fascia. Direct smears from the pus on both sides yielded a gram positive diplococcus with capsule and a gram negative bacillus. Cultures failed on the diplococcus but the gram negative bacillus grew anaerobically. The guinea pig inoculated with pus from the abscess failed to develop tubercle bacillus infection in 8 weeks. Necrotic material obtained from the right abscess was composed of fibrin red cells polymorphonuclear neutrophils mononuclears and plasma cells and upon microscopic examination was found to be granulation tissue.

With evacuation of pus the temperature dropped promptly the blood count became normal and both incisions healed. Very small hard masses connected with the lower end of both scars could still be felt but the patient felt well had remained temperature free and had gained weight on June 15, 1937 when last seen 7 months after the onset of her illness.

Although there are some omissions in the recording of sequence of symptoms and chest findings in this patient and a failure to obtain pus from the left chest possibly due to aspiration too far lateralward or to inspissation of pus, which cast doubt on the origin of these bilateral psoas abscesses from perforated empyema there seems to be enough similarity to other reported cases which were subjected to autopsy or clinically better established than the author's to justify the

diagnosis. A hematogenous or lymphatic origin bilaterally into the prepsaos fascia seems even more fanciful and would be more rare. The recovery of the pneumococcus like organism (necrophorus) is apparently a secondary matter in many pus processes from both abscesses and the spurtum the occurrence of encapsulated empyema of the posterior pleural sinus in pneumonias giving a roentgen picture similar to the author's (3, 14, 26) the tendency of left encapsulated empyemas to perforate and travel downward into the lumbar and iliac fossa regions give credence to the conclusions.

Twenty five previously published cases all unilateral, 14 of them fully discussed by Bouveret (4, 5), have been found of 'migrating abscess' originating from empyema (11, 13, 17, 19, 20, 23, 24, 28). One of these pointed somewhere in the anterior abdominal muscle region 7 in the iliac fossa or below Poupart's ligament, 1 as low as the knee and 17 in the lumbar region between the lower rib margins and the iliac crests. All these abscesses developed on the same side as the empyema and in 19 in which the position of the empyema is definitely mentioned 5 only are right 13 are left and 1 is left and right. The latter however on autopsy showed the fistulous tract to be connected with the left empyema and an egg sized encapsulated collection of pus on the right diaphragmatic pleura to be totally unconnected with the pus in the upper two thirds of the left psoas. This instance of a 10 year old male published by Foot (11) is further interesting because of the very short illness of 3 weeks duration and the dispersal of pus beyond the left psoas into the spinal canal as well as into the right back muscles. Of the 17 patients in which sex is mentioned, 10 are male. Eighteen whose ages are given range from 9 to 35 years, 7 of them in the second decade of life. The existence of empyema was known or suspected anywhere from 2 to 3 weeks to 1½ years before the diagnosis of distant abscess was made. Either the abscesses pointed spontaneously or they were drained surgically after a tumor presented in one or more of the three areas. When the perforation of the pleura by pus occurred early in the disease and acutely severe pain in the thorax was not to be present, but not invariably so. In only 2 patients, Bouveret's own and that of the author, did the empyema disappear completely a considerable time before the discovery of the iliopectus abscess. Bouveret's patient a female of 31 had a proved left empyema which had been tapped 21 days after onset of left pneumonia with evacuation of 2100 cubic centimeters of pus. Repeated tapping and finally drainage, though it definitely improved

Fig 4 Posterior attachments of diaphragm (viewed from below and inside). Illustrates hiatuses of aorta and esophagus, origins of left psoas muscles and sheaths from internal arcuate ligament, and quadratus and its sheaths from external arcuate ligament. (From Spalteholz)

Fig. 5 Similar to Figure 4, but including lower projections of psoas and quadratus muscles on both sides. Illustrates how central descent of pus through the aortic hiatus could more easily spread bilaterally at third lumbar anterior to right and left psoas muscles, than if pus from the left pleura had pierced as far lateralward as the internal arcuate ligament

the chest did not reduce the temperature. Eventually, 13 months after her pneumonia onset the patient evacuated pus spontaneously from the left groin below Poupart's ligament, with cure! Several patients had final clearing of the chest when the abscesses drained. Three of the abscesses developing in the left lumbar region were pulsating—one of Courbon in a female of 24 who recovered, a second of Owen Rees, in a male of 9 years who came to autopsy (perhaps tuberculous pleurisy but with sinus tract from left pleura not from caries of vertebra) and a third of Dunin also subjected to autopsy. Bouveret gives a very able discussion of the mechanics of pulsating pleurisy (57) and the differentiation between these pulsating migrating abscesses and aneurism of the abdominal aorta.

When it is realized that of 19 patients in whom the outcome is definitely reported, 13 resulted in cure and 6 in autopsy, it is not surprising that it is still a matter of conjecture as to the exact manner in which the perforation of these pleuritis results in migrating abscess.

The appearance of pus anteriorly among the muscles of the abdomen and pointing somewhere below the diaphragm seems to be due to rupture through the anterior pleural sulcus (50). Whether the pus travels *via* the anterior mediastinum just back of the sternum through the known weak spot of the diaphragm between its sternal and costal origins or through the interdigitations of costal diaphragm and anterior abdominal muscles cannot be determined from reports (Fig 3). The autopsy on Loomis patient revealed the perforation in the extreme anterior border of the diaphragm, the fistula passing into the inferior peritoneum, leaving over the liver and downward in

front of the ascending colon to point above Poupart's ligament.

As to the psoas abscesses, J. J. Clark has contributed the most convincing proof in 1910.

He reports a male negro 35 years of age with a brawny swelling over the right thigh seen first complaining of pain over the right hip, developing 1 year after an attack of pneumonia. The swelling was treated as a localized abscess and drained. Later x-ray studies revealed a shadow in the right chest which was proved by thoracotomy to be empyema. Clark's serial x-ray studies after lipiodol injection into the right pleural cavity show two pools of dye above and behind the right diaphragm at the 4th and 5th interspace; later dye has passed "through the diaphragm close to the spine and under the right internal arcuate ligament" then a large cavity in the body of the psoas, which he believes proved by the striated appearance of the lipiodol among the muscle fibers; later a clot of oil over the right sacrum.

Whether one is entirely convinced or not of the interpretation of the reason for the striated appearance of the lipiodol in Clark's films, one must recognize this sole instance of x-ray visualization of the path taken by this pus as a valuable contribution.

It is assumed by most of the writers reporting instances of unilateral psoas or lumbar abscess that the pus has escaped from the empyema after perforating the pleura through the internal or external arcuate ligaments (Fig 4). Anatomically, however, it is difficult to visualize a bilateral spread such as resulted in the authors' patient from perforation through either. Any perforation through the internal arcuate would seem to confine pus to a spread downward in front of or within the psoas on the same side and through the external ligament to an equilateral path posterior to the psoas or within the quadratus lumborum (Fig 5). The most careful autopsies

Fig 7 Cross section at level of third lumbar vertebra Illustrates relationship of retroperitoneal space to great vessels and right and left psoas muscles and point at which pus could spread bilaterally anterior to these muscles (Modified from *Topography of the Thorax and Abdomen* by Peter Potter)

examination, that in a patient of Foot (11), corroborates this hypothesis, for the sinus was found to pass from the left pleural space behind the left crus of the diaphragm, posterior to the internal arched ligament, into an abscess in the upper two-thirds of the left psoas. The psoas sheath was intact, the pus was deep in the substance of the vertebral border of the muscle (Fig. 5). Tees believes that he traced a lumbar abscess "invading the quadratus lumborum" through the external arcuate ligament when he surgically explored his patient. Certainly the location of pus in the pleura and the primary site where lysis has produced perforation, as well as the routes of dispersion available at this point, must all influence the eventual paths of the pus, even though conceivably pus may spread anywhere. The variety of ways in which tuberculous pus traverses downward (1, 15) illustrates the rôle that is played by the exact position of exodus of pus from spinal caries. The pus may hollow out the sheath of the entire psoas, bulging it to the size of a man's arm, or less commonly may stay completely anterior or posterior to its fascial sheaths. Prevertebral cold abscess is usually to left or right of center, uncommonly directly median and this may explain the infrequency of bilateral tuberculous psoas abscess. The bilateral abscesses of the author's patient were located anterior to the sheath of the iliopsoas muscles. If these both originated from the left posterior pleural sinus empyema, it is easier to assume central evacuation of pus from the mediastinum into the retroperitoneum with bilateral spread than rupture through the left internal or external arcuate ligaments (Figs. 6 and 7). That perforation from the left posterior pleural cavity

into the posterior mediastinum occurs is proved by autopsy in the cases in which mediastinal abscess is found together with perforated empyema. Foot's (12) patient in whom the mediastinal pus lay anterior to the aorta and perforated the esophagus, as well as several of Knauer's perforating the esophagus prove this. It is not too great a flight of the imagination, especially when considered in the light of cross-sectional anatomy (25), to assume that pus so escaping could migrate downward along the great vessels between the crura of the diaphragm or through the esophageal hiatus.

As most of these reports were published in the early medical literature, it is not strange that bacteriology of the abscesses is so seldom mentioned. Usually the authors have merely stated that they were non-tuberculous. The direct smears herein reported demonstrating a diplococcus similar to that found in the sputum, resembling pneumococcus morphologically, and the additional gram negative bacillus found in the pus from the abscesses, with failure to develop tuberculosis in the guinea pig and apparent cure in the patient, establish the author's case, incomplete as it is, as bacteriologically the most fully studied in the literature. Knowledge of this report should stimulate more accurate study of the non-tuberculous psoas and lumbar abscesses occurring in the future.

SUMMARY

A case of bilateral iliopsoas abscesses originating from probable left posterior pleural sinus suppuration following pneumonia has been reported.

No other instance of bilateral abscesses of this type has been found in the literature.

The 25 other unilateral chronic abscesses, re-

ported in the literature as originating from perforated empyema and pointing at considerable distance below the diaphragm, are briefly reviewed and discussed.

The differences between these abscesses and the acute traumatic abscesses, usually of staphylococcus etiology, and tuberculous lumbar and psoas abscesses are mentioned, with special reference to anatomical variations in the paths of the migrating pus.

TENOSYNOVITIS OF THE LONG HEAD OF THE BICEPS HUMERI

V. L. SCHRAGER, M.D., F.A.C.S., Chicago, Illinois

TENOSYNOVITIS of the long head of the biceps is a non-specific inflammation of the tendon and its sheath. It is a shoulder complex characterized by pain, of various degrees, along the bicipital groove of the humerus, inability to raise the arm above the level of the shoulder, and diminution or loss of all other functions which put stress upon the tendon. It has a tendency to chronicity and, if untreated, may ultimately lead to muscular atrophy of the shoulder group of muscles and to a certain degree of loss of function.

The general literature, as far as I was able to ascertain, is silent on the subject, with the exception of some limited accounts in the French literature. Leclercq and Rouresco speak of tenosynovitis of the long head of the biceps humeri in connection with injuries of the shoulder in industries and the degree of disability thereof. They, evidently, took it for granted that the condition was well known and did not enter into further details. F. Pasteur,¹ medical colonel of the military hospital, Val-de-Grâce, recognized the condition in all its aspects, described it fully and clearly and raised it, unmistakably, to the rank of a distinct clinical entity.

Although I have been familiar with this condition for many years, interested my colleagues in the subject and presented clinical cases in clinics, my failure to record the facts in print gives Pasteur the priority of record.

Tenosynovitis of the long head of the biceps humeri is the most common cause of periarthralgias of the shoulder, a view which is fully shared by Pasteur.

In spite of the fact that the clinical picture is definite, constant, and easy of recognition, roentgenologists, orthopedists, and physiotherapists are mute on the subject.

ANATOMY

The biceps muscle has two heads. The short head arises from the coracoid process, close to the coracobrachialis. The long head arises from the

From the Department of Surgery, Northwestern University Medical School.

¹Some articles refer to E. Pasteur, others to F. Pasteur. I believe, however, that both are the same writer.

top of the glenoid cavity. It takes insertion into the supraglenoid tuberosity and the glenoid ligament by a long tendon (9 cm), which is either bifurcated or trifurcated at its origin. In the latter case, there is one intermediate portion attached to the scapula, and two smaller, collateral portions which diverge from each other and blend into the labrum glenoidale. The tendon glides over the head of the humerus, within the joint, invested by a synovial sheath (which is an evagination of the capsule), and then slides into the intertubercular, or bicipital groove, which is covered by an expansion from the pectoralis major and ends blindly opposite the insertion of the latter muscle.

PHYSIOLOGY, FUNCTION OF TENDON

The tendon of the long head of the biceps takes part in all the movements involved in either fixation or mobility of the upper extremity, which explains its vulnerability. It is an important factor in the dynamics of the upper limb. Together with the long head of the triceps, it helps to stabilize the humerus against the glenoid fossa (Steindler). According to Callander, the tendon of the long head of the biceps acts as a "standardizing brace" and "prevents any sudden impact between the head of the humerus and the underlying arch." Duchene of Boulogne, in his work on the physiology of movements, assigns important function to the short head of the biceps and looks upon the long head as a mere supinator, flexor muscle.

The function of the tendon of the long head of the biceps can be summarized as follows:

1. It helps to maintain and coaptate the head of the humerus against the glenoid cavity.
2. It reinforces the capsular ligaments.
3. It prevents the head of the bone from being pulled too close upward under the acromium (Treves).
4. It supplements the deficiency of the subspinous muscle.
5. Both biceps heads are flexors and medial rotators of the arm at the shoulder; both are abductors, the long head abducts the arm and rotates it inward.

Fig 1 Shows long head of the biceps entering capsule of shoulder joint (From Testut's *Traité d'anatomie humaine*)

ETIOLOGY

The etiological factors, although varied, are the following

- 1 Trauma
- 2 Metastatic infection from a systemic source
- 3 Exposure to sudden changes of temperature especially to cold and dampness
- 4 Generalized effusions in serous cavities and spaces
- 5 Rheumatic tendencies

Trauma Sudden muscular efforts in the course of infectious diseases are apt to initiate this syndrome, especially in the course of typhoid or influenza. Two of Pasteur's cases were the result of colon bacillus infection while another occurred during an infection of bacillary dysentery.

Hard upward pull upon a cork screw of a tightly corked bottle may bring about the condition.

Fall upon the extended hand may produce the lesion. In this connection it may be well to mention the occasional, coexisting pain in the corresponding shoulder in Colles fracture, which is usually noticed some days after the fracture. This is, very likely due to a coincidental injury of the tendon of the long head of the biceps which is overshadowed by the Colles fracture. Fall upon the extended hand was the etiological factor in 23 of the 32 cases of Pasteur. In 8 of 10 cases the patients were males past forty years of age.

Fall upon the shoulder is a frequent cause.

An attempt to prevent a fall may cause a sudden pain along the bicipital groove, which may be responsible for the syndrome.

Sudden jar of the shoulder among straphangers is apt to cause this condition.

Faulty position of the arm is another cause. False movements while the arm is in abduction and external rotation are also factors. Rheumatic

patients may develop this syndrome on the slightest exertion or false movement.

Muscle strain in systemic diseases may cause inflammatory changes in the tendon or its sheath.

The 4 remaining etiological factors are of lesser importance and frequency than trauma. Although they can initiate an attack, they are usually associated factors in the more severe attacks which are caused by trauma.

PATHOLOGY

The inflammatory process involves the tendon as well as its bursa which surrounds it. Although a tendon was never sectioned by analogy it may be inferred that all the inflammatory stages may be present, such as serous effusion, plastic exudate, fibrinous exudate, and adhesions. The tendon swells and loses its elasticity. Failure of the tendon to assist in the coaptation of the head against the glenoid cavity may lead to an outward dislocation. The tendon encased in a tight tunnel and pressed against arthritic deposits may gradually wear out, atrophy, and even disappear, in which case the remaining portion attaches itself into the bicipital groove. The muscles in and about the shoulder may atrophy.

SYMPTOMATOLOGY

There is pain along the bicipital groove, both subjectively and objectively. The subjective pains may be somewhat diffuse about the shoulder, but the objective pain is *always constant and always located in the bicipital groove*. It can be definitely elicited by pressure of the tip of the examiner's index finger upon the bicipital groove, especially when the arm is abducted and thus contrasts with the lack of response to pressure upon other points on the shoulder. If one is familiar with this situation it enables the examining physician to foretell the exact location of the pain before examination. A patient is frequently intrigued by the fact that the examining physician is able to locate and outline the location of pain without having previously examined the patient. The pain is superlative in quality in the acute cases. It is both diurnal and nocturnal exaggerated by movements of the arm or pressure upon the head of the humerus. The patient is unable to sleep and drugs have little or no influence upon the pain except perhaps morphine in half grain dose. In most cases the pain occurs suddenly occasionally it may be insidious.

Clinically there are three distinctive types:
1 The acute type characterized by violent pains in the shoulder both diurnal and nocturnal little or not at all influenced by drugs.

Fig. 2 Shows tendon of long head of biceps in relation to the joint, capsule, and humerus (After Callander, *Surgical Anatomy*)

Fig. 3 Shows tendon of long head of biceps with synovial sheath split and reflected outward (After Callander, *Surgical Anatomy*).

There is loss of shoulder function, because of pain. There is inability to raise, abduct, or place the arm against the back. Passively, the arm can be raised to the level of the shoulder, but not beyond that point. There is a *specific tenderness along the bicipital groove*. The pain lasts from a few days to a couple of weeks, when it gradually subsides, especially if diathermy has been used, or it may become subacute.

2. The subacute type, in which the pain is less severe, not so continuous, and may be paroxysmal, especially at night. There is some impairment of function and the patient learns to raise the affected arm with the opposite hand. The arm can be raised to the level of the shoulder and even beyond, although the movements are tolerably painful. The subacute type may be a continuation of the first type, or it may start as such in frank rheumatic cases. This second type may last from a few weeks to a few months, or it may merge into the chronic type.

3. The chronic type exhibits to a lesser degree all of the previous symptoms. The patients learn to fix the scapulohumeral structures and assist themselves in difficult movement with the opposite arm. There is more or less voluntary and involuntary fixation of the shoulder and there may be muscular atrophy present. This type may last indefinitely or be subject to either remissions or paroxysms.

Quite recently I have seen a patient who suffered from an acute attack of shoulder pain about 3 years ago. The condition had passed through all the three stages over a period of 9 months, and had left the patient with occasional pains in the shoulder, especially at night, and with inability to raise the arm much beyond the level of the

shoulder. He was unable to place the dorsum of his hand against his back. Although his occupation required the use of a hammer, he learned to fix his shoulder and do all the work with his forearm and hand, using a short range of excursion, with the elbow as a pivot, instead of his shoulder. He was rather surprised when he realized that he had discarded the shoulder movements in his daily work and admitted that occasionally he raised his arm with the assistance of the opposite hand. The shoulder muscles were considerably atrophied. During a recent exacerbation, he had acute pain along the bicipital groove.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Since most of the articular and periarticular affections express themselves in terms of pain and limitation of motion, it becomes a diagnostic problem to establish with accuracy the exact tissue, or structure, which is responsible for the clinical picture.

Most of the conditions which tenosynovitis of the long head of the biceps humeri resemble are due to some injury. In this affection the character of the trauma is in the nature of a jar, or sudden pull upon the tendon rather than a single, violent blow upon either shoulder, or tendon.

True enough, patients suffering from tenosynovitis of the long head of the biceps humeri may be arthritics or rheumatics, yet this factor alone is not sufficient to bring about the clinical complex, trauma being a requisite or an important contributory factor.

Topographical pain along the bicipital groove is a pathognomonic sign in this ailment.

Inability of the patient to raise his arm above the level of the shoulder, to abduct it, or place

FIG. 1 Shows long head of the biceps entering capsule of shoulder joint (from Testut's *Traité d'anatomie humaine*)

ETIOLOGY

The etiological factors, although varied, are the following

- 1 Trauma
- 2 Metastatic infection from a systemic source
- 3 Exposure to sudden changes of temperature, especially to cold and dampness
- 4 Generalized effusions in serous cavities and spaces
- 5 Rheumatic tendencies

Trauma Sudden muscular efforts in the course of infectious diseases are apt to initiate this syndrome, especially in the course of typhoid or influenza. Two of Pasteur's cases were the result of colon bacillus infection, while another occurred during an infection of bacillary dysentery.

Hard upward pull upon a cork screw of a tightly corked bottle may bring about the condition.

Fall upon the extended hand may produce the lesion. In this connection it may be well to mention the occasional, coexisting pain in the corresponding shoulder in Colles' fracture, which is usually noticed some days after the fracture. This is, very likely, due to a coincidental injury of the tendon of the long head of the biceps which is overshadowed by the Colles' fracture. Fall upon the extended hand was the etiological factor in 23 of the 32 cases of Pasteur. In 8 of 20 cases the patients were males past forty years of age.

Fall upon the shoulder is a frequent cause.

An attempt to prevent a fall may cause a sudden pain along the bicipital groove which may be responsible for the syndrome.

Sudden jar of the shoulder among straphangers is apt to cause this condition.

Faulty position of the arm is another cause. False movements while the arm is in abduction and external rotation are also factors. Rheumatic

patients may develop this syndrome on the slightest eversion, or false movement.

Muscle strain in systemic diseases may cause inflammatory changes in the tendon or its sheath.

The 4 remaining etiological factors are of lesser importance and frequency than trauma. Although they can initiate an attack, they are usually associated factors in the more severe attacks which are caused by trauma.

PATHOLOGY

The inflammatory process involves the tendon as well as its bursa which surrounds it. Although a tendon was never sectioned by analogy it may be inferred that all the inflammatory stages may be present, such as serous effusion, plastic exudate, fibrous exudate, and adhesions. The tendon swells and loses its elasticity. Failure of the tendon to assist in the coaptation of the head against the glenoid cavity may lead to an outward dislocation. The tendon encased in a tight tunnel and pressed against arthritic deposits may gradually wear out, atrophy, and even disappear in which case the remaining portion attaches itself into the bicipital groove. The muscles in and about the shoulder may atrophy.

SYMPTOMATOLOGY

There is pain along the bicipital groove both subjectively and objectively. The subjective pains may be somewhat diffuse about the shoulder but the objective pain is always constant and always located in the bicipital groove. It can be definitely elicited by pressure of the tip of the examiner's index finger upon the bicipital groove especially when the arm is abducted and thus contrasts with the lack of response to pressure upon other points on the shoulder. If one is familiar with this situation it enables the examining physician to foretell the exact location of the pain before examination. A patient is frequently intrigued by the fact that the examining physician is able to locate and outline the location of pain without having previously examined the patient. The pain is superlative in quality in the acute cases. It is both diurnal and nocturnal exaggerated by movements of the arm or pressure upon the head of the humerus. The patient is unable to sleep and drugs have little or no influence upon the pain except, perhaps, morphine in half grain dose. In most cases the pain occurs suddenly occasionally it may be insidious.

Clinically there are three distinctive types.

- 1 The acute type characterized by violent pains in the shoulder both diurnal and nocturnal little or not at all influenced by drugs.

general literature. He states, however, that the condition can be corrected by manipulation or operation

In the acute phase of tenosynovitis of the long head of the biceps, patient must rest in bed, placing the arm and forearm on 2 pillows in order to get some comfort.

Diathermy is the principal remedy, especially in the acute cases. This form of physical therapy induces hyperemia, which activates the blood supply, both superficial and deep. This, in turn, assists in the process of repair and promotes absorption of inflammatory exudates. It also maintains muscle tone and prevents atrophy. It should be administered daily from 30 to 60 minutes, preferably in the patient's home or in the hospital. I have found that patients who leave the office and come in contact with cold air do not fare well.

In the subacute stage, diathermy should also be used. However, if pain has definitely abated, gentle massage is recommended. Faradization of the tendon of the long head of the biceps is beneficial and should be administered either daily, or every other day, care being used to avoid muscle fatigue.

In the chronic cases, especially if there is muscular atrophy, massage, faradization, active and passive motion, in addition to diathermy, are definitely indicated. All forms of electrical treatment, such as high frequency, ultraviolet, infrared, carbon light and heat are beneficial and should be used in turn, the amount depending upon the relief the patient gets from their use.

Faradization diminishes pain and often allows patients to perform movements formerly impossible or painful. Galvanism is of value. Pasteur speaks of "rapid and remarkable success" in 5 cases by the use of high tension galvanism of weak intensity.

I advise my patients in the subacute and particularly in the chronic stage, to build a series of vertical shelves at a distance of 4 to 5 inches apart and instruct them to place the arm on these shelves. They start with the shelf which causes no pain, which is usually at the level of the deltoid. Then, they are asked gradually to reach higher shelves, daily, or several times a day, being guided by the absence of pain. The arm is kept on these shelves from 3 to 5 minutes. These exercises must not cause pain or tire the patient.

Potassium iodide is suggested in chronic cases.

SUMMARY

1. Tenosynovitis of the long head of the biceps is a new, yet definite, clinical entity.

TABLE I—PRESENTATION OF THE CONDITIONS
TENOSYNOVITIS OF LONG HEAD OF BICEPS
HUMERI RESEMBLES

Clinical entity	Etiology	Signs and symptoms	Function
Tenosynovitis long head biceps humeri	Trauma sudden jar, or pull Rheumatic tendency Metastatic infections Climatic changes	Diurnal and nocturnal pains, uninfluenced by drugs Topographical pain (bicipital groove) Afebrile	Inability to raise arm above level of shoulder, abduct, or place hand against back
Acute rheumatism	Definite etiology unknown (numerous contributory factors)	Polyarticular pains, often controlled by drugs Migratory pains Constitutional symptoms Febrile Diffuse local swellings, chiefly involving joints	Painful movements in any direction
Rupture of supraspinatus muscle	Blow upon the shoulder or strain with arm in abduction	Maximum pain over the tuberosity Pain, diffuse, shoulder weak Defect below and lateral to the acromion X-ray may reveal spicule of bone attached to tendon	Difficulty of raising and abducting arm
Rupture of biceps tendon	Trauma: old and arthritic Always in men Rare condition D. E. McKenna 85 cases, J. O. Rankin 4 cases from general literature	Laxness and spheroidal bulge of muscle near elbow Head of humerus drawn upward and forward, false dislocation	Flexion and supination painful Abduction of arm limited (rupture of long head tendon)
Sub-acromial bursitis	Fall or blow upon apex of shoulder Occupational (painters, for ex.) Pressure upon shoulder by heavy objects	Pain, especially nocturnal extending up to neck and down on arm Fullness beneath deltoid Tender spot below and close to tip of acromion, disappearing on abduction (latter hides bursa)	External rotation and abduction limited and painful, referred to insertion of deltoid X-ray wider space between acromion process and head of humerus (contrasts with well side)
Subdeltoid bursitis	Fall	Swelling and fluctuation over tip of shoulder Pain insertion of deltoid, bicipital groove Deltoid movements painful Muscular spasm (acute stage) Humerus approximated against scapula	Painful abduction and external rotation

2. F. Pasteur, medical colonel of the military hospital Val-de-Grâce, France, described the condition fully and clearly and should be given priority of record in medical literature.

3. The condition is the most common form of the periarthralgias of the shoulder (Pasteur).

Figs 4, 5, 6, 7 Fig 4 and 6 show movements which are limited and painful when attempted. Figure 5 shows in dotted line the extent of voluntary movement and

in full line the additional elevation with assistance (Suggested to the artist by Pasteur's photographs in *J de radiol et d'électrol*)

the dorsum of the hand against his back are like wise pathognomonic

Table I is a presentation of the conditions which tenosynovitis of the long head of the biceps humeri may resemble

PROGNOSIS

Mild and even severe inflammations occasionally subside within 5 to 6 days when properly treated and patient abstains from movements of the arm. The patient who is not in position to discontinue work as well as the patient who remains without treatment may suffer for several weeks and usually is a candidate for chronicity or recurrences

The three types already mentioned may merge into each other, the time period of each varying in various individuals. On the whole it may be said that when the cause is a mild trauma, or even a systemic, metastatic infection, the condition can be better controlled and temporized than when it is due to a severe trauma especially in older, arthritic patients. Recurrences are occasionally seen such recurrences in reality however, are exacerbations of conditions which have abated but which have not entirely subsided. I have seen violently acute inflammations subside within a few days, while mild lesions passed on into the other phases

TREATMENT

It is fair to state that the usual drugs which control or modify arthralgias, neuralgias, gout or rheumatism, have little or no effect upon tenosynovitis of the long head of the biceps and that there is no specific remedy for it. Morphine, in large doses controls the pain but is not capable

of abolishing it entirely, as the slightest movement or jar of the shoulder will bring on pain even with patient under the influence of morphine. Pasteur suggests ionization with salicylates, iodides and atropine

Much benefit and occasionally instant cure can be obtained by sudden traction upon the arm and shoulder while the arm is relaxed and in a position of abduction. The rationale of this treatment is based upon the supposition that the tendon does not fit properly in the groove and that the maneuver makes a satisfactory replacement in the groove. One may argue that since the biceps tendon fits snugly in the bicipital groove it is difficult to conceive its displacement out of the groove. Sumner L. Koch commenting on the sudden relief of pain by sudden traction upon the arm in abduction states "I am wondering if this may not be due to the tearing of adhesions rather than replacement of the tendon in its groove. As you well know, such manipulations constitute one of the helpful stunts of bone setters and they frequently secure relief in this way for patients who had persistent pain and discomfort from constant pulling and irritation of adhesions which have formed in spaces lined with synovial membrane. On the other hand E. L. Gilcreest in an article entitled 'Dislocation and Elongation of Long Head of the Biceps Brachii' speaks of many cases reported from dissecting and postmortem rooms and numerous others have been recorded as having been seen clinically but not operated upon." A. W. Meyer dissecting one thousand arms found 50 cases of marked dislocation of the tendon and many others of lesser degree. Gilcreest found no mention of any operative treatment for this condition in the

The result of accidental occlusion or injury of the ureters is governed by the location and extent of the damage.

The following summary by Robinson covers all eventualities:

- A Unilateral* 1. Section, followed by leakage and acute infection, either local or widespread
 2. Partial section with subsequent leakage and fistula formation, either uretero-abdominal or, and more likely, ureterovaginal
 3. Ligation, followed by atrophy of the kidney, with or without symptoms of renal inadequacy In some cases, acute or chronic uremia
 4. Ligation with reflex suppression and complete anuria (16 per cent—Barney)
B Bilateral 1. Double section, followed by leakage, general infection and death
 2. Double ligation with anuria and uremia, fatal if unrelied
C Partial occlusion or kinking from peri-ureteral adhesions following various abdominopelvic operations

In the 260 cases collected from the literature during the period 1925–1936, unilateral injury occurred in 236 cases, as follows:

1 Radical abdominal hysterectomy for cancer	54
2 Total abdominal hysterectomy (a) For uterine and cervical myomas or extensive pelvic inflammatory disease	48
(b) Ruptured uterus	1
3 Supracervical hysterectomy. (a) Indication not stated	26
(b) Complicated by chronic adnexal disease	18
4 Vaginal hysterectomy (a) Cancer of cervix and portio (radical Schauta method)	13
(b) Prolapse	6
(c) Myoma	3
(d) Indication not given	13
5 Salpingo-oophorectomy (a) Ruptured ectopic	5
(b) Ovarian cyst or adnexal disease	19
6 Operation for removal of intraligamentous tumors	19
7 Obstetrical procedures (a) Extrapentoneal cesarean	1
(b) Forceps	5
8 One each of the following inguinal herniotomy, incision and drainage of pelvic abscess, and operation for carcinoma of the rectum	3
9 Anterior colporrhaphy	2

CASE REPORTS

CASE 1 Unilateral injury—asymptomatic unilateral ligation Mrs N H, aged 31 years Previous operative procedure 4 years ago, left salpingo-oophorectomy for chronic tubo-ovarian disease Patient was admitted to the Israel Zion Hospital, March 23, 1932, with complaint of pain in left lower quadrant of abdomen

Pelvic examination revealed the uterus to be of normal size but displaced to the right by a tense cystic mass, which occupied the left lower quadrant The impression was that of an intraligamentous cyst.

Operative findings The left ureter had been ligated at the previous operative procedure, 1 inch from the bladder end, and the result was a huge hydro-ureter The pelvic portion of the ureter was dilated to the size of an orange; the middle third of the ureter was dilated 1 inch in diameter, narrowing to one-quarter of an inch at the upper end. The kidney was atrophic, the size of a plum.

Procedure The broad ligament was divided The pelvic portion of the ureter, which was markedly adherent to the

Fig 1 Giant hydro-ureter resulting from accidental ligation of distal end of ureter Case 1

adjacent tissue, was exposed and separated by blunt dissection The middle portion of the ureter was also exposed, by incising the posterior peritoneum, and freed from its adhesions The entire ureter and kidney were removed

Convalescence was complicated by a vesicovaginal fistula which healed spontaneously. The patient left the hospital in good condition, within 3 weeks of the time of operation.

This case illustrates the fact that in many gynecological operations the ureter is tied, yet convalescence is uneventful and any symptoms produced by the ligation are easily obscured by other postoperative symptoms; thus the unilateral ligation goes unrecognized, with the ultimate result that the corresponding kidney dies We are forced to the conclusion that many deaths, even when "suppression of urine" has been given as the cause of death following pelvic operations, are actually due to ureteral occlusion.

CASE 2 Ureterovaginal fistula treated by end-to-end anastomosis Y C, aged 43 years, was admitted to the Israel Zion Hospital, June 24, 1925 Primary operation, bilateral salpingo-oophorectomy, had been done 4 months previously Eight days later, the patient began to dribble urine per vaginam

The cystoscopic findings were as follows Bladder capacity was normal, the bladder urine clear Both ureteral orifices were normal except that the left one did not seem to function The catheter could be passed up easily on the right side On the left side the catheter met with an impassable obstruction $4\frac{1}{2}$ inches from the bladder

Operative procedure A catheter was passed up the left ureter as far as the site of obstruction An incision, 6 inches in length, parallel to, and about 0.5 inch above, Poupart's ligament, was made The muscle was divided by blunt dissection, and the posterior wall of the pelvis was exposed retroperitoneally After exploration, the lower end of the upper section of the severed ureter was isolated It was found to be greatly distended, its caliber being about the

4 Inability to recognize, appraise, and treat this condition adequately is responsible for invalidism, chronicity, and functional disability, which can be either improved, modified or cured, if properly diagnosed and managed

5 The treatment is largely mechanotherapy and physiotherapy

OPERATIVE INJURIES OF THE URETER

DAVID FEINER, M D, Brooklyn, New York

INJURY of the urethra bladder and ureter continues to plague the gynecologic surgeon because of its frequency as a complication of pelvic operations. Of these injury to the ureter is the most common and most serious. Various observers place the incidence of ureteral ligation as a complication in 1 to 3 per cent of all operations on the female genital organs. Although a fairly large number of case reports of operative injury of the ureter is revealed in a survey of the literature it is very likely that most of the cases have never been reported and that many of these have passed unrecognized. Caulk and Fischer speak of the accident occurring much more frequently than is generally believed. Sampson in one of the first comprehensive papers on ureteral trauma, claims that the injury either in the form of ligation or clamping 'is of common occurrence during gynecological work.

A notable presentation by Bland, in 1925, brought the literature up to that date. This paper included Herman's series of 24 bilateral cases, Barney's report on 63 cases including 32 cases presented by Sampson in 1902 and a group of 159 cases presented by Oeconomes. Thus Bland collected from the literature a total of 216 cases, and he himself gathered 125 additional cases from men active in abdominopelvic surgery. Nevertheless, he emphasizes the fact that even with this large array of cases collected it is probable that a large number of others have not been recorded or have escaped recognition.

In addition to the 8 cases recorded herein we

have collected from the literature, both here and abroad, another group of 260 cases which were reported from 1915 to 1916. This brings the total up to 710 cases, of which 109 were bilateral and 601 unilateral.

TYPES ETIOLOGY AND RESULTS EFFECTS OF URETERAL INJURY

Injury to the ureter may result from direct trauma, such as cutting (complete or incomplete), puncture crushing by clamps, or by ligation. Occasionally the wide dissection of the Wertheim technique leads to sloughing of the ureteral wall due to disturbance of its blood supply. In the majority of instances, ureteral injury is unilateral. Bilateral involvement of the ureters occurs in about one sixth of the cases.

In clinics in which the radical abdominal hysterectomy for carcinoma of the cervix is performed this operation is most frequently responsible for the occurrence of the accident. Vaginal hysterectomy is next in frequency. Abdominal hysterectomy was the primary operation in 4 of the 8 cases reported in this presentation. In 3 of them, the hysterectomy was performed for multinodular fibroid uteri, and in 2 the hysterectomy was complete. When chronic pelvic inflammatory disease distorts the anatomy during a hysterectomy for a fibroid uterus or when cervical or intraligamentous myomas change the normal relations of the pelvic course of the ureter, the risk of injury is increased. Operations for intraligamentous tumors are especially prone to this complication. In 1 case of this series the ureters were bilaterally involved during a Forthright operation.

From the Gynecological Services of the Israel Zion and Beth Moses Hospital, Brooklyn, New York.

made it necessary to take deep bites with mass ligatures in order to control the bleeding. A transfusion of 1000 cubic centimeters of whole blood was given. Eight hours after operation, 12 ounces of urine was obtained on catheterization. No urine was voided in the following 24 hours, at which time it was determined by catheterization that the bladder was empty.

Cystoscopy was now done under local anesthesia. "Both ureteral orifices were congested, flaccid, gaping, with no visible peristalsis. No urine was seen coming from either ureter. Catheters could not be passed beyond 4 centimeters from the bladder on either side."

An immediate laparotomy was done. The previous midline incision was opened. Cystoscopy was done at the same time, with ureteral catheters in place. On the left side, the ureteral catheter was palpated at the point of obstruction, and the sutures in that region near the cervical stump were cut. The catheter was then introduced beyond the obstruction and urine began to flow. The same procedure was followed on the right side, but the obstruction was found near the base of the ovarian ligament. Urine also began to flow freely from this side. The abdomen was closed. Both catheters were left *in situ*. Convalescence was stormy, in spite of the fact that urinary secretion was adequate. The patient died on the fifth day.

Opinion. Sepsis, pneumonia, paralytic ileus

CASE 6. A. S., aged 39 years, was admitted to the Beth Moses Hospital, January 12, 1933. A total hysterectomy for fibroid uterus and lacerated, eroded cervix was followed by complete anuria for 24 hours.

The general condition of the patient appeared good. The abdomen was soft. Her only complaint was nausea with occasional vomiting. No pain or tenderness was noted over either kidney region. She was taken to the operating room 24 hours after operation and cystoscoped. Cystoscopy showed the following: "Both ureteral orifices appear motionless, no urine is seen escaping from either orifice. Ureteral catheterization was attempted and both ureters were found obstructed 1 inch from the bladder end."

Operative procedure and findings. Immediate laparotomy was done through the previous incision. Although only 24 hours had elapsed since primary operation, the pelvic tissues were markedly thickened and edematous. The normal anatomy was completely distorted by a massive exudate which completely buried the cervical stump. The tissues on either side of the latter were separated by blunt dissection. The right ureter was isolated and found to be dilated to about the size of one's little finger. It was freed downward toward the bladder until the point of obstruction was reached. The offending ligature was found to be that which included the dense basal segment of the broad ligament on each side of the cervix, together with the vascular plexus adjacent to it. Both ligatures were cut with considerable difficulty because of the depth of the pelvis, the dense exudate, and the general oozing. The ureteral catheters, which had been previously passed through the cystoscope, were now advanced up on both sides to the pelvis of the kidney and urine was immediately excreted on both sides.

The postoperative reaction was poor, the patient was in moderate shock. She was transfused 4 hours later. She was catheterized and 14 ounces of urine was obtained. During the following 24 hours the patient excreted 60 ounces of urine. Her condition, nevertheless, gradually grew worse and she expired 36 hours after operation.

In explaining such mortalities, Barney has pointed out that the suppression of urine alone is not the determining factor. In neither of these

Fig 3. Huge tumor mass, originating from the left intraligamentous fossa, occupying the entire abdominal cavity, and displacing small uterus to the extreme right. Case 7.

cases was it long drawn out, as a matter of fact, the condition may exist for a much longer period of time before death ensues. Morris cites a case of anuria of 17 days' duration, while another surgeon with whom Barney corresponded, saw in consultation a patient who had passed no urine whatever for 23 days. Both these cases terminated fatally, but they serve as proof that the human system can sometimes offer good resistance to this particular onslaught. In the type of case under consideration, Barney ascribes the high mortality to other factors, such as severe and prolonged operation in a patient who is already below par and to whom the ureteral injury is merely the last straw. In our experience, deligation has proved a formidable operation which presents unusual technical difficulties. These are, chiefly, the extreme anatomical distortion, the extensive exudate, and the inevitable bleeding in the operative region.

CASE 7. Bilateral ligation treated by nephrostomy. Case No. 65218, Mrs. A. J., aged 43 years, was admitted to the Beth Moses Hospital, September 20, 1934. Her chief complaint was intermittent vaginal bleeding and marked enlargement of the abdomen. The previous history was essentially negative, except for a cesarean section 7 years ago. Pelvic examination revealed a normal size uterus which was displaced to the extreme right by a tumor mass filling the entire pelvis. Abdominally, the same tumefaction, reaching up to the costal margin on both sides, could be palpated.

Operative procedure and findings. At operation a huge tumor mass, which originated from the left intraligamentous space, displacing the uterus to the extreme right and

Fig. 2. Deep laceration through the left angle of the cervix extending up into the broad ligament and involving the distal end of the ureter. Case 3.

size of one's thumb. The lower segment of the ureter was found collapsed and hugging the ureteral catheter introduced from below. The two ends of the ureter were freed and an end-to-end anastomosis was performed. The ureteral catheter was passed up through the point of union and on into the upper segment as far as the kidney pelvis.

The convalescence was smooth and urinary drainage via the catheter was adequate. The patient was discharged August 15, 1925. At that time the incision was healed except for a small opening through which escaped a free watery urinous discharge (persistent urteroabdominal fistula). There was no evidence of vaginal leakage.

Bump and Crowe state that when ureteral anastomosis over a catheter is done the kidney pelvis should always be drained through a pyelostomy or ureterostomy above the line of repair. Had such prophylactic drainage been utilized in this case, the poor result obtained perhaps might have been avoided.

CASE 3. Uterocervical fistula treated by uterovesical anastomosis. R. P. aged 31 years was admitted to the Israel Zion Hospital August 25, 1924. Four months before admission the patient had had a difficult forceps delivery of a dead fetus with the result that there was a deep laceration through the left angle of the cervix extending up into the broad ligament. This laceration apparently missed the uterine vessel, but involved the left ureter as urinary dribbling followed immediately.

Examination on admission showed a thick scar in the cervix extending up into the base of the broad ligament and urine was observed escaping from the cervical canal.

Cystoscopic examination with ureteral catheterization revealed an impassable obstruction 1.5 inches from the left bladder orifice.

Operative procedure August 27, 1924. An incision was made just above and parallel to Poupert's ligament on the left side. The ureter was identified and separated down to the level of its crossing the uterine artery. The ureter showed no evidence of dilatation, and the point of injury was apparently at that level. The distal end of the ureter was ligated. The proximal end was then implanted into the bladder through a small incision which had been made in the latter viscus for this purpose.

In the week following operation the patient's condition was fairly satisfactory except for a profuse seropurulent discharge of urinous odor through the incision. For 3 weeks thereafter, the patient ran a septic temperature with drainage of pus and urine from the wound. On the twenty-first day after operation there was a profuse hemorrhage from the lower angle of the incision and the patient went into shock. She was taken to the operating room and the wound was explored. It was found that there was extensive retroperitoneal extravasation with free bleeding from a large vessel adjacent to the point of anastomosis. This vessel was ligated, and the wound was cleansed and packed with iodoform gauze. The usual shock treatment was instituted including blood transfusion but was unaiding and the patient expired 2 hours later.

CASE 4. Uterovaginal fistula treated by nephrectomy. G. G. aged 40 years. Hospital No. 2778. Patient was admitted to hospital with fibroid tumor of the uterus. Pelvic examination revealed an irregular hard tumor mass the size of a grape fruit in the fundal portion of the uterus.

On November 25, 1921, panhysterectomy was done.

Urinary leakage was observed from the vagina on the second day after operation. The patient had a stormy convalescence for the next 4 weeks during which time there was considerable discomfort in lower abdomen with intermittent temperature varying from 99 to 103 degrees. Marked frequency and urgency of urination were also present.

The patient was re-admitted to the hospital March 12, 1922. At that time there still was a free leakage of urine from the vagina. Cystoscopic examination revealed that the bladder now practically normal. Ureteral catheter passed without difficulty up the right ureter. On the left side an obstruction was encountered about 1 inch or 1.5 inches from the bladder. The right ureteral orifice was excreting normally with a good functional reaction in 34 minutes. No urine was excreted on the left side.

On vaginal examination urine was observed escaping from the left upper angle of the vaginal vault. The impression recorded on the chart was that there was present a uterovaginal fistula secondary to incomplete section of the ureter at the time of the original hysterectomy.

In view of the poor general condition of the patient, it was considered inadvisable to attempt ureteral anastomosis or implantation of the ureter into the bladder. Therefore a nephrectomy was done March 16. Convalescence following nephrectomy was uneventful. All urinary symptoms gradually disappeared and the patient was discharged April 15, 1922. The family physician reports that at present the patient is in fairly good health with no direct sequelae resulting from her operative complication.

CASE 5. Bilateral ligation treated by deligation. S. S. aged 33 years was admitted to the Israel Zion Hospital November 8, 1920. Following a curettage performed for incomplete abortion the patient went into extreme shock. Accidental perforation of the uterus was suspected. At laparotomy 2 hours later the abdomen was found full of blood-clots from a tear involving almost the entire breadth of the uterus and extending into the left broad ligament. Hysterectomy was performed with marked difficulty because of continuous bleeding from retracted vessels which

bladder was not sufficiently separated from its attachment to the cervix and pushed out of the way, or (2) that one of the sutures was inserted above the level of the reflection of the bladder. In cases in which the bladder seems to be very low I sometimes try to palpate the ureters, but I have never found any case in which they were inserted sufficiently low to be endangered by these deep sutures."

In the 253 cases assembled from the literature, unilateral injuries have been summarized in Table I.

The treatment of this group of cases is illustrated by Table II.

Bilateral injury of the ureters was present in 24 cases. These occurred as complications of the following operative procedures: radical abdominal hysterectomy for carcinoma, 13, radical vaginal hysterectomy for carcinoma, 1, complete hysterectomy for fibroid or pelvic inflammatory disease, 8, bilateral salpingo-oophorectomy for chronic adnexal disease, 2; Percy cautery operation for carcinoma of the cervix, 1.

Bilateral ligation of the ureters occurred in 11 cases, of these, 6 patients were treated by deligation, in 1 case, in which the interval was 48 hours, patient recovered but required a subsequent nephrectomy. Patients in the 5 cases remaining, deligated on the third or fourth day, died. Five patients in whom both ureters had been ligated were treated by nephrostomy. Of these, 2 required subsequent end-to-end anastomosis, 1 necessitated a secondary nephrectomy, and 1 a subsequent implantation of both ureters into the sigmoid. Four of these patients recovered and 1 died. In 1 case of bilateral ligation, no operative procedure was resorted to for relief of the obstruction, and death occurred on the fourth day.

There were 12 cases of bilateral ureterovaginal fistula, of these, 5 closed spontaneously, 3 were successfully treated by colpocelesis. In 3 cases, bilateral ureterovesical implantations were performed with a satisfactory result in all. One pa-

tient, on whom a Percy cautery operation had been done, developed gradual obstruction of both ureters, necessitating implantation of both ureters into the bladder. In this case the ultimate outcome was not stated.

TREATMENT

If at the time of operation it is discovered that one or both ureters have been ligated or included in a clamp, the proper treatment is to deligate or remove the clamp promptly. Ordinarily, the ligation around the ureter, or instrumental trauma of the latter, is not sufficient to cause permanent damage. If, however, there is evidence that the vitality of the ureter has been so impaired that a fistula is likely to develop, immediate repair

Fig. 4A left Fothergill operation with bladder and ureters mobilized and pushed above range of sutures. Case 8

Fig. 4B Fothergill operation. Bladder insufficiently mobilized. ureters within range of sutures. Case 8

occupying the entire abdominal cavity was found. The operative procedure consisted of supracervical hysterectomy and bilateral salpingo oophorectomy which was attended by great technical difficulties because of the unusual distortion of the anatomy. During the course of the operation the bladder which was densely adherent as a result of the previous low two flap cesarean was accidentally incised. At no time during the operation were the ureters visualized. The perforation in the bladder was repaired and a drain was inserted into the space of Retzius. At the end of the operation a Pezzer catheter was introduced into the bladder *per urethram*. The immediate postoperative course was uneventful except that no urine was expelled through the catheter. After 20 hours of anuria it was suspected that the ureters had been occluded by ligatures.

A cystoscopy was performed and attempts to pass ureteral catheters up to the pelvis of the kidney failed on both sides. Both met with impassable obstructions about 2 inches from the ureteral orifices. Indigo-carminum injected intravenously did not appear from either ureter after 20 minutes.

A right nephrostomy was done at once. The kidney appeared large hydronephrotic and congested. A curved Kelly clamp was thrust into the pelvis of the kidney and a considerable amount of bluish fluid (urine discolored by indigo-carminum) gushed from the wound. A Pezzer catheter was inserted.

The patient was given a direct blood transfusion of 350 cubic centimeters and rallied immediately. For the first 48 hours there was very little secretion through the nephrostomy tube but on the third day a flood of urine was excreted saturating the bed. This profuse drainage continued until the eighth day after operation when bloody fluid of urinous odor was removed from the bladder by catheter. Drainage through the nephrostomy wound decreased to almost nil and the tube was removed on the twelfth day after operation.

The blood chemistry figures in this case were extremely interesting showing enormous nitrogenous retention. On the second day after the nephrostomy and before any urine had appeared the urea nitrogen was 150 and the creatinine 10 milligrams. Two days later with urinary excretion the urea nitrogen was 76 milligrams and the creatinine 4.35 milligrams. Eight days later the urea nitrogen was 17 milligrams.

On the twenty fourth day after operation cystoscopy was done and again both catheters met with obstructions at the same level as before the nephrostomy but the indigo-

carminum was recovered from both sides within 5 minutes after intravenous injection of the dye.

The patient was discharged from the hospital on the thirty fifth day after admission.

In retrospect, the question that arises in this case is whether the ureters had been ligated with catgut and the lumen restored as soon as the catgut was absorbed. It has been shown experimentally that plain catgut is not absorbed before the end of the third week, whereas this patient developed spontaneous restoration of ureteral function 8 days after the nephrostomy. It would appear that the obstruction in this instance may not have been due to encircling ligatures but to kinking and inflammatory swelling on the subsidence of which the ureters opened spontaneously.

CASE 8. Bilateral ligation treated by vaginal dehiscence. F. B. aged 36 years was admitted to the Israel Zion Hospital March 10, 1936.

Operative procedure. Anterior colporrhaphy Fothergill method. The immediate postoperative reaction was good. However during the following 24 hours no urine was excreted through the retention catheter thereby arousing the suspicion of the operator that both ureters had been occluded by the ligatures. At this time a cystoscopic examination revealed the following: Right ureter identified and showed marked edema and pointing. All attempts to pass a ureteral catheter into the orifice were unsuccessful due to edema. The same condition was found on the left side. It is believed that the edema is secondary to ligation of the ureters higher up. Following intravenous indigo-carminum no dye appeared in the bladder after 30 minutes.

An immediate dehiscence from below was decided upon. The repaired anterior perineal wall was reopened and the superficial sutures were incised the three interrupted sutures approximating the lateral pubocervical tissues (bladder pillars) being laid bare. All three sutures were cut thus revealing the uppermost of the three to be the culprit. The area thus freed was packed with iodoform gauze and the mucous membrane approximated with continuous locked sutures of chromic catgut. A cystoscope was then introduced into the bladder and a No. 4 F catheter met with obstruction on both sides about 4 centimeters from the bladder (probable point of ligation) with great difficulty this obstruction was overcome and both catheters were passed up to the level of the kidney pelvis. Urine immediately returned from both sides and it was tugged with the blue dye the catheters were left *in situ* for drainage. In the next 24 hours 32 ounces of urine was excreted through the catheters. The ureteral catheters were then removed and the patient was catheterized at intervals of 6 hours for the next 5 days. On the seventh day after operation the patient voided spontaneously and from that time on the convalescence was uneventful.

Fortunately this type of injury as a complication of anterior colporrhaphy is extremely rare. This is confirmed by a personal communication from Dr. William Fletcher Shaw of Manchester who writes: "In this city we do some hundreds of this operation every year and have done so for the last 30 or 40 years and I have never known a case in which even one ureter was tied. I can only suggest that this accident occurred because (1) the

THE ALBEE SPINE FUSION OPERATION IN THE TREATMENT OF SCOLIOSIS

FRED H. ALBEE, M.D., Sc.D., LL.D., F.A.C.S., and ALEXANDER KUSHNER, B.Sc., M.D.,
Venice, Florida

IN SPITE of the many years it has challenged the ingenuity of orthopedic surgeons, the treatment of idiopathic scoliosis is still on an uncertain basis in many centers. The number of failures encountered in consultation practice and the variety of therapeutic procedures devised confirm this conviction. The problem of scoliosis has been characterized as one of the stumbling blocks of the orthopedic surgeon. In attempting to unearth the causative factors in this situation, the senior author feels that a critical survey of the therapy of scoliosis is warranted. The extensive experience gained in the operative treatment of diseases and deformities of the spine during a period of more than 25 years forces him to indict certain therapeutic regimens as having unsound bases. Many of these cases were especially instructive because of previous abortive attempts at treatment, particularly the injudicious employment of braces and plaster jackets. Their application seriously interferes later with a satisfactory realignment of the spine by surgical means. Unfortunately, the offending structures in early idiopathic scoliosis—the muscles, tendons, and ligaments—are weakened by suppression of the stimulus of function. It must be realized that in treating curvatures with a brace, one attempts to correct the spine indirectly through pressure on the thorax. The ribs are elastic structures and a great deal of the force exerted will be merely spent on increasing their angulation, or changing the relations at the costal vertebral joints. When the brace is removed, the spine collapses, as Whitman aptly put it, like an abandoned accordion. Obviously, to remove the brace is to court disaster and both patient and the physician will cling to it like the proverbial drowning man. Figure 3b is illustrative of such a catastrophe. Figure 1, patient A.N., reveals rapid progress of curvature after 1 year in a plaster jacket. Furthermore, the utilization of a brace in a mild case will often weaken the soft structures, increase the angle of deviation, and set up a vicious cycle converting a non-progressive spine to one requiring operative correction.

From the Florida Medical Center. Fred H. Albee, medical director.

Treatment by corrective medical gymnastics is rational therapy in early idiopathic cases. Curvature is overcome by strengthening, not undermining, the mainstays of the spine. Early non-progressive cases are easily eliminated. Our position in regard to operation is this: Corrective medical gymnastics without braces are carried on with periodical check up by trunk x-rays, which we find the most trustworthy method of recording the lesion. As soon as it is realized that the spine shows a tendency to increasing deformity, in spite of conservative treatment, operative stabilization of the spine is recommended. In the early days before the employment of the bone graft, such cases were almost a "nightmare" to the surgeon as he was compelled to see the most pronounced deformities develop right under his eyes and his hands were completely tied as to prevention. The operative treatment has proved a great satisfaction.

The Albee extra-articular arthrodesis as first conceived in 1908, was evolved from fundamentally sound biomechanical and physiological principles. That these were correct was attested to recently by the appearance of a patient whose spine had been fused a quarter of a century ago. He is pursuing an active and useful life today, as first officer on a transatlantic steamer. Although the profession was quick to adopt the operation in the treatment of Pott's disease and abandon conservative therapy, there has been a marked hesitancy to follow a similar course in the therapy of scoliosis. Steindler (7), after a large practice states "In the light of the experience made with all methods of scoliosis treatment, one is justified in saying that operative fusion, while at this time accepted as a temporary solution, does not entirely solve the problem. In the advanced deformities of non-compensated cases, it will be the only refuge, and we owe a debt of gratitude to those who have developed the method and perfected its technique." This apparently sums up the attitude of the profession in general.

At the Florida Medical Center where the Albee fusion is the treatment of choice, most encouraging results have been obtained in the maintenance of correction. Maximum correction is

should be done in the form of uretero-ureteral or ureterovesical anastomosis

Where both ureters have been ligated and it is not discovered until the following day or later, the condition is a serious one. The combination of complete anuria and threatening uremia makes immediate surgical intervention imperative. The three alternative procedures to be considered are deligation of the ligated ureter, nephrostomy, ureterovesical anastomosis

CONCLUSIONS

1 From the large number of cases of ureteral damage recorded in this paper, it is evident that the accident is a surgical complication far more common than is generally assumed

2 It is quite likely that a certain number of unilateral ligations occur during the course of pelvic operations which are not recognized and which do not provoke immediate symptoms, with ultimate autonephrectomy on the corresponding side

3 This accident may be sustained during any pelvic operation but it is more common following radical abdominal or vaginal hysterectomy and notably in operative procedures for the removal of intraligamentous tumors. In selected cases in this group, catheters may be inserted into the urethra before the operation is started as an additional safeguard

4 The majority of cases are those of unilateral injury, more rarely both sides are involved, the proportion being 6 to 1

5 As an index of the seriousness of ureteral injury, may be mentioned the mortality figures quoted by Bland of 33.3 per cent for the bilateral and 18.8 per cent for the unilateral cases

6 The most common sequelæ of ureteral injury are vaginal and abdominal fistulas

7 If the ureter is divided during the course of a hazardous or markedly prolonged operation the operator may be compelled to resort to ureteral ligation, but this is justifiable only when the risk of reparative procedure for the restitution of function of the injured ureter appears too great

8 If a ligature or clamp has been placed on either one or both ureters and the injury is detected at the time it is inflicted and there is evidence that the vitality of the ureter has been so impaired that fistula is likely to develop, immediate repair should be done in the form of uretero-ureteral or ureterovesical anastomosis

9 In the case of bilateral occlusion, discovered after operation with imminent danger of uremia immediate deligation is the operation of choice, provided the patient's condition is such that she can endure this hazardous and time consuming operation

10 Nephrostomy may be the most feasible procedure when intra abdominal work is contraindicated by gravity of patient's condition. This drainage should preferably be bilateral

11 In view of our results of 100 per cent mortality with two intra abdominal deligations the writer feels that nephrostomy with subsequent operation for ureteral anastomosis or bladder implantation, when found necessary is a much safer and, therefore, a preferable procedure

12 Finally, the operator, when confronted with a damaged ureter, should be prompted in his selection of the reparative procedure with the fundamental aim in mind of the preservation of both ureteral and kidney function

The author is indebted to the members of the staff who permitted him to utilize the records of their private patients as part of this study, and he gratefully acknowledges the co-operation of Dr Maxwell Dorr and Dr Harry Ehrlich for their assistance in assembling the preliminary data. He also desires to express his appreciation of the assistance given him in the completion of this survey by the Literary Research Department of the American College of Surgeons

THE ALBEE SPINE FUSION OPERATION IN THE TREATMENT OF SCOLIOSIS

FRED H. ALBEE, M.D., Sc.D., LL.D., F.A.C.S., and ALEXANDER KUSHNER, B.Sc., M.D.,
Venice, Florida

IN SPITE of the many years it has challenged the ingenuity of orthopedic surgeons, the treatment of idiopathic scoliosis is still on an uncertain basis in many centers. The number of failures encountered in consultation practice and the variety of therapeutic procedures devised confirm this conviction. The problem of scoliosis has been characterized as one of the stumbling blocks of the orthopedic surgeon. In attempting to unearth the causative factors in this situation, the senior author feels that a critical survey of the therapy of scoliosis is warranted. The extensive experience gained in the operative treatment of diseases and deformities of the spine during a period of more than 25 years forces him to indict certain therapeutic regimens as having unsound bases. Many of these cases were especially instructive because of previous abortive attempts at treatment, particularly the injudicious employment of braces and plaster jackets. Their application seriously interferes later with a satisfactory realignment of the spine by surgical means. Unfortunately, the offending structures in early idiopathic scoliosis,—the muscles, tendons, and ligaments—are weakened by suppression of the stimulus of function. It must be realized that in treating curvatures with a brace, one attempts to correct the spine indirectly through pressure on the thorax. The ribs are elastic structures and a great deal of the force exerted will be merely spent on increasing their angulation, or changing the relations at the costal vertebral joints. When the brace is removed, the spine collapses, as Whitman aptly put it, like an abandoned accordion. Obviously, to remove the brace is to court disaster and both patient and the physician will cling to it like the proverbial drowning man. Figure 3b is illustrative of such a catastrophe. Figure 1, patient A.N., reveals rapid progress of curvature after 1 year in a plaster jacket. Furthermore, the utilization of a brace in a mild case will often weaken the soft structures, increase the angle of deviation, and set up a vicious cycle converting a non-progressive spine to one requiring operative correction.

Treatment by corrective medical gymnastics is rational therapy in early idiopathic cases. Curvature is overcome by strengthening, not undermining, the mainstays of the spine. Early non-progressive cases are easily eliminated. Our position in regard to operation is this. Corrective medical gymnastics without braces are carried on with periodical check up by trunk x-rays, which we find the most trustworthy method of recording the lesion. As soon as it is realized that the spine shows a tendency to increasing deformity, in spite of conservative treatment, operative stabilization of the spine is recommended. In the early days before the employment of the bone graft, such cases were almost a "nightmare" to the surgeon as he was compelled to see the most pronounced deformities develop right under his eyes and his hands were completely tied as to prevention. The operative treatment has proved a great satisfaction.

The Albee extra-articular arthrodesis as first conceived in 1908, was evolved from fundamentally sound biomechanical and physiological principles. That these were correct was attested to recently by the appearance of a patient whose spine had been fused a quarter of a century ago. He is pursuing an active and useful life today, as first officer on a transatlantic steamer. Although the profession was quick to adopt the operation in the treatment of Pott's disease and abandon conservative therapy, there has been a marked hesitancy to follow a similar course in the therapy of scoliosis. Steindler (7), after a large practice states, "In the light of the experience made with all methods of scoliosis treatment, one is justified in saying that operative fusion, while at this time accepted as a temporary solution, does not entirely solve the problem. In the advanced deformities of non-compensated cases, it will be the only refuge, and we owe a debt of gratitude to those who have developed the method and perfected its technique." This apparently sums up the attitude of the profession in general.

At the Florida Medical Center where the Albee fusion is the treatment of choice, most encouraging results have been obtained in the maintenance of correction. Maximum correction is

From the Florida Medical Center. Fred H. Albee, medical director.

Fig 1 a left Patient A N Idiopathic scoliosis Spine at onset of treatment. b After wearing plaster of Paris jacket constantly for 1 year

obtained by the Risser cast. Operation is performed through a window cut through the plaster cast over the area of primary curvature to be fused. The cast is retained for 3 months and physiotherapy is then instituted. If the area of spine involved be extensive, then a second cast is applied, correction is accomplished with a turnbuckle, and a second bone graft is inlaid into the secondary curvature. Thus in early cases arrest may be reached in 4 months and in decompensated spines in 8 months. Except in the most advanced ones, if the primary curve is fused then, the secondary responds to the correction. Control of the primary is usually sufficient. Second operation is necessary in only about 10 per cent of cases.

Figure 2 illustrates the various procedures. The lower pole of graft B was interlocked with the upper end of A at C, welding the unstable chain of articulations into a solid bar of bone. An increase in height of several inches is often noted as a result of opening up the curve with turnbuckle and hinged cast before operation. This method of realignment by an eccentric hinge and turnbuckle brings a powerful force to bear upon the curvature. Jackets designed to apply corrective compression to apex of curve are constructed contrary to the engineering principle of the key stone constituting the strongest part of the arch.

THE PROP GRAFT

Patient E P presented an interesting problem in treatment. Her curvature was of such a

degree that her ribs had telescoped into the pelvis producing painful symptoms with locomotion (see Fig 3 a and b). The soft structures on the concave side had so contracted after prolonged conservative therapy that it was found impossible even by applying excessive force with the turnbuckle to secure a satisfactory correction. Accordingly it was decided to extract the ribs from the pelvis at operation and prevent their prolapse by interposing a stout prop bone graft between the ilium and tenth rib to augment the spinal inlay graft with cross grafts at central portion of curvature (see Figs 4 and 5). The prop graft must be carefully mortised into the tenth rib, as shown in Figure 5, to prevent it from slipping past into the pleural cavity. The graft is tunneled through muscle planes as it is always desirable to provide for an adequate blood supply. Grafts should never be placed in an avascular environment such as fat or scar tissue. During convalescence the patient displayed excessive zeal in developing her musculature and fractured the strut graft. Happily, a pseudarthrosis developed at the fracture site (1, Fig 4), and thus there resulted a new articulation in the evolution of man. This structure permits articulation between the ilium and thoracic cage and removes any restriction of motion that absolute fixation may have occasioned. It is in this type of spine that the bone graft meets its supreme test and to judge its worth one has only to listen to the enthusiastic comment of patients and parents.

Fig 2 a, Same as Figure 1 Correction of lumbodorsal curve with turnbuckle and hinged cast Turnbuckle not visualized Compare with Figure 1b b, Roentgenograms showing permanent fusion of lumbodorsal spine by means of bone graft, A, to prevent recurrence Correction of dorsal curve by turnbuckle Patient ready for second

Albee fusion. c, Roentgenogram taken 5 months after second fusion operation The lower pole of graft B was interlocked with upper pole of graft A at C so as to abolish articulation, construct an unyielding bony ridge, and as well to insure permanent correction Note hypertrophy of graft A

That the graft retains its vitality is proved by its permanency in cases of over 18 years' duration. To those clinicians who regard the graft as an osteogenetic scaffold for osteoblasts to make their way from ilium and pelvis and meet in the center, we would point out there is no confirmation—clinically or experimentally—for such a stand The graft retains its vitality and advertises this fact by its ability to produce callus when fractured, or enter into the formation of pseudarthrosis as noted in Figure 4

The routine employment of spine fusion without a tibial graft in early cases has been opposed chiefly because of the magnitude of the operation and the uncertainty of fusion We admit that these criticisms are justified after noting that Brogden reports failure of fusion in 47 per cent of patients operated on at the Hospital for Ruptured and Crippled when done according to the Hibbs method Steindler (7) reports "the so called break or false motion in a fused spine is very frequent" after the Hibbs fusion Gaenslen remarks "to those who have done the Hibbs operation, it will be quite apparent that it is a difficult matter to get anything like a continuous periosteal tunnel by denudation of the lamina . It is extremely

difficult to carry out fusion on one side, especially when one considers that just one break in the operative procedure, such as missing a single set of articular facets, may jeopardize the entire operation'

With such poor results from the hands of competent orthopedic surgeons, there can be no doubt that the Hibbs operation is unsuited for scoliotic spines The chain of arthrodesed articulations is no stronger than its weakest link When marked rotation of the vertebræ has occurred, many of the articulations are inaccessible. The mechanical basis of the operation is incorrect. Fracture of the spinous processes tends to encourage further flexion and rotation The center of gravity passes anterior to the bodies of the vertebræ in the dorsal region and the tendency of the spine to forward flexion is counteracted by ligamentous structures attached to the spinous processes—the ligamenta interspinale and supraspinale Furthermore, there are important muscle attachments to this structure—the multifidus, semispinalis, and sacrospinalis groups Denuding and fracturing the processes, by releasing the favorable action of these ligaments and muscles tends to encourage rather than correct further

Fig. 3 a left Patient E.P. Idiopathic scoliosis. Spine at onset of conservative therapy b Corkscrew spine after prolonged treatment by corrective exercises, braces, plaster jackets and traction

deformity. Complete immobilization is disturbed by the slight motion transmitted to the vertebrae by the costovertebral ligaments during the respiratory excursion of the ribs. The extended period of postoperative traction on a Bradford frame followed by plaster cast and brace for 1½ years does not invite recourse to surgery. A minor point but of clinical importance is the fact that the x ray picture may not be of any assistance in determining whether or not fusion has been obtained. The superimposition of the shadows of potential areas of arthrodesis make this unlikely. Figure 6 is a case in point. The patient had been subjected to a Hibbs fusion and complained of pain with inspiration and motion—where none had previously existed. The x ray film did not furnish any clues as to the localization of the pseudarthrosis, which was subsequently disclosed at operation. A tibial graft was inlaid at the break and complete relief was obtained. The authors wish to tarry upon this as an undisputed fact—that presence of pain is indicative of interruption of fusion. Pain is associated with muscle spasm when fusion has been attempted and failed. This superadded spasm tends to increase deformity. In other words the *modus operandi* of the rapid increase of the distortion is due to induced pain and its resultant muscle spasm upon an unbalanced musculature. Finally the operating time of 1 to 1½ hours is a major drawback when one considers the

paucity of reserve that some of these patients possess.

The Albee operation offers a technique calculated to encourage corrective biomechanics and mobilizes the maximum osteogenicity of vertebral bone. The tibial graft is an active osteogenetic brace which re-enforces itself by proliferation of bone at points of greatest stress according to Wolff's law. In regard to this an interesting phenomenon has been observed. We have noted that when the graft was implanted nearer the tip of the spinous process fusion occurred earlier and proliferation of bone was greatest. This is entirely in keeping with the mechanics of the operation. The spinous process is the arm of a lever the fulcrum of which is the intervertebral articulation. Therefore the tip of the process is subject to the maximum stress or vice versa the greatest corrective effort should be applied at the greatest distance from the fulcrum, i.e. at the tip. Practically this is not always possible. However the potential leverage of the spinous process is almost always available and is utilized to its maximum extent in the Albee operation.

A study of the trabecular system of a vertebra will elucidate this conception (Fig. 7). Translated into mechanical terms the significance of these systems is as follows. The vertebrae manifest a more passive function in the body and a more active function in their processes.

Fig 4 Same as Figure 3 Four years after operation showing bone graft holding securely the corrected position of ribs after they were extracted from the pelvis at operation Union with tenth rib at A Note increased density of tenth rib—also hypertrophy of spinal graft Full correction not attained because of extreme contracture of soft tissues on concave side following extended conservative therapy This patient indulges in the most strenuous of exercises, including skating and tennis

Fig 5 Schematic representation of prop graft (Fig. 4) Note interlocking of graft and tenth rib, also auxiliary grafts at right angle to spinal graft, necessary in extreme degrees of curvature

The body principally sustains pressure while the apophyses or processes are levers for the application of muscle force Thus, when the process is fractured at its base, important ligamentous and muscular tension stresses are disturbed, so that the fusion obtained is unable to cope with the severe strain of the superincumbent weight and pseudarthrosis will result in almost 50 per cent of fusions attempted in the lumbodorsal region, in spite of the supporting brace (Steindler)

The graft should cover 7 to 8, or sufficient vertebrae so that the upper and lower poles will contact processes the vertebrae of which have not rotated to the degree present at the apex of the curve In this way, a forceful derotating as well as straightening influence will be exerted on the intermediate vertebrae, and a corrective force brought to bear directly on the vertebrae In contrast to the insertion of the graft for purely anteroposterior curvatures such as Pott's disease in which the graft is put in edgewise, it is important in this instance to put it into the split spinous processes and their embedding ligaments flatwise, so that its maximum strength can be used as an internal lever and splint still further to force the spine into alinement beyond that secured by the turnbuckle plaster jackets We regard this as an outstanding feature of the operation In extreme degrees of curvature, it may be necessary to shortcut several vertebrae because

of the impossibility of obtaining a graft of sufficiently acute curve. They may be controlled by placing several auxiliary grafts at right angles from the main graft to the spinous processes of the central vertebrae into which the main graft cannot be inlaid because of inadequate curvature. In this instance, the spinous processes are split longitudinally but crosswise to receive one end of the auxiliary graft while the other ends are contacted with the main graft. This was necessary in our patient. E P. (Figs 4 and 5). The graft functions as a prop in this type of case and tends to be compressed between the bases of the arch This is a favorable stress for the graft and maximum proliferation occurs

An analysis of the divers stresses and strains that the graft is subjected to in different areas of the spine and its response to these offers an interesting study. Our investigation along these lines will be published at a later date.

The inferior osteogenicity of vertebral bone was demonstrated by Albee (1) in 1908, by animal experiments This is readily confirmed by the surgeon who relies entirely on such bone for fusion. Furthermore, it will become quite evident when the statistics concerning the failure of repair of vertebral fractures are studied, and particularly those of the transverse processes Although lying wholly within muscle, when broken and not displaced, they unite in less than 5 per cent of cases Spies states, in his studies of

Fig 6

Fig 8

Fig 9

Fig 6 Non fusion in spine after Hibbs operation demonstrating difficulty of localizing break. Onset of pain which did not exist before operation indicated failure of fusion—confirmed at operation. In three locations fusion had failed to take place but roentgenograms failed to disclose interruptions of fusion for the reason that the shadows of the bony elements were superimposed upon each other.

Fig 8 Patient R H Excellent visualization of graft in lateral roentgenogram. This is of considerable aid to the surgeon in evaluating the progress and permanency of bony fusion.

Fig 9 Patient L A This roentgenogram taken 24 years after the spinal graft was inserted has not yielded to the early tendency to progression—convincing evidence of the permanent corrective influence of the tibial graft.

an extensive number of cases of fractured articular processes, that they practically never unite. Likewise the progress of union in fractures of the spinous processes is very poor. Willis has offered an embryological explanation. He states that vertebral bone together with the cerebrospinal

system is derived principally from the ectoderm and that ectodermal tissue such as spinal nerves, have a low degree of reparative potentiality. This is a distinct contrast to mesodermic tissues such as skeletal bones including the tibia, which exhibit a high degree of osteogenesis.

Because of this inadequate callus forming capability of vertebral bone it is clear that in order to secure a strong fusion, a single graft from a long bone of high osteogenicity should be used to supplement that of the local vertebrae. The tibia fortunately for the purpose of the reconstruction surgeon inherently has not only great osteogenetic potentiality and excellent reparative power but great strength. When inlaid into the spinous processes it not only serves as an excellent corrective internal immobilization splint but immediately fuses by its own osteogenetic influence and that of the spinous processes themselves with the spinal column. When one considers the wide limits of variations inherent in different individuals in regard to vertebral osteogenicity it becomes incumbent upon the surgeon

Fig 7 Architecture of vertebra illustrating different and distinct systems of trabeculae. The graft is inlaid and exerts its stress through system 4 thereby obtaining maximum leverage and corrective influence. (After Gallis and Japet)

to play the game as safely as possible and select not only an ample amount of bone in the form of a complete splint, but bone of the greatest known osteogenetic potentiality. To rely on the low osteogenetic potentialities of vertebræ, particularly in the form of chips, is to gamble on getting a favorable outcome instead of being practically certain of it (2).

In analyzing the vertebral bone chip operation, we mentioned the difficulty in following the progress of fusion by means of the x-ray picture. After the tibial bone graft operation, the x-ray is invaluable in this respect. Figure 8 demonstrates the excellent visualization of the bony bridge.

An important consideration when deciding treatment is the length of time required for an operation and the shock occasioned by it. An operation that consumes little time and induces comparatively little shock may obviously be undertaken when the surgical resistance of the patient is not of the best. The bone graft operation has been completed in as little as 9 minutes, in a favorable case of Pott's disease, if one's operating team is thoroughly familiar with the routine and the special instruments used. The technique does not require excessive retraction and there is no necessity to operate more or less blindly in regions difficult of access (3).

Postoperative care consists of 3 months in the turnbuckle cast, followed by physiotherapy. In severe cases, a modified Knight spinal brace is fitted and utilized until the x-ray discloses a firm bony bridge of large diameter.

Modifications in the method not in accord with these principles diminish its efficiency and unjustly bring it into disrepute. It cannot be satisfactorily combined with the Hibbs technique because the spinous processes should not be cut off. Osteoperiosteal grafts are too frail to obtain any immediate immobilization. Heterogenous grafts are biologically unsound and are to be condemned. In the series quoted above, Brogden reported non-fusion in 66 per cent of patients operated upon according to the Hibbs method, re-enforced by beef bone grafts. Rib grafts do not have the osteogenicity of the tibial grafts and do not lend themselves to being shaped as the strength depending on the thin cortical tubular form is lost. Their structure is too elastic to be able to exert the proper stress required.

Preston, after a careful study of the literature, comments "It is evident that some form of operative treatment is thought necessary for all cases which cannot be easily controlled by exercise. Widespread dissatisfaction with the results of fusion operations which do not utilize some

form of internal splint is shown by the large number of new procedures reported, most of which are modifications of the Albee technique. Many of them are mechanically unsound because either the firm anchorage of the graft is destroyed or the internal splint itself is composed of a substance which soon disintegrates."

This communication is based upon 518 cases over a period of 26 years. In 7 cases, the spinal supportive graft or grafts have been supplemented by a costal pelvis prop. The anterior end of the tenth rib has been selected as the point at which to affix the tibial graft. These ribs, rather than one of the lower ones, have been selected because they are more firmly anchored to the thoracic cage and will therefore transmit the corrective influence directly to the spine. X-ray films of cases taken over 20 years after operation disclose that grafts maintain their conformation and do not yield to the extensive pressure which they have often withstood for so long a time. Even after many years their stabilizing and corrective influence continues.

SUMMARY

The bone graft is of the greatest aid to the surgeon in the following manner:

1. The leverage and splintage action of the graft is exerted directly upon the vertebræ themselves at the curvature.
2. The graft is subject to a favorable stress in scoliosis and exhibits remarkable hypertrophy.
3. The graft lends itself to x-ray study in establishing progress and permanency of fusion.
4. The graft adds more bone when it is urgently needed; the bone in the spinous processes of thoracic region of spine is insufficient.
5. The graft brings a rapid callus producing bone into a low osteogenetic area.
6. Fusion after the curve is opened up or partially straightened often increases the height of the patient by several inches.

PRIMARY FIBROBLASTIC TUMORS OF THE CHOROID PLEXUS OF THE LATERAL VENTRICLES

A Clinicopathological Study of Three Cases

W. JAMES GARDNER, M.D., and OSCAR A. TURNER, M.D. Cleveland, Ohio

P RIMARY benign intraventricular tumors are uncommon and, with few exceptions, the literature consists of scattered reports of single cases. Dandy (4) states that they constitute about 0.75 per cent of all brain tumors. While this number is exceedingly small, certain clinical and pathological findings related to these tumors make them of interest.

The recognition of primary benign intraventricular tumors by clinical means is practically impossible. Usually associated with marked increase of intracranial pressure, these tumors produce signs which, as a group, point to no specific area of the brain but may occasionally cause neurological changes which direct attention to several widely separated cerebral areas. Thus the symptoms and signs are apt to be quite confusing. However, with the advent of pneumographic studies as an aid to the localization of intracranial growths, the absence of localizing phenomena has come to be of less serious consequence than formerly.

From the standpoint of the biohistory and histological character of the tumors, the prognosis for the patient is excellent, but the large size which these tumors attain and the trauma which is concomitant with their removal makes this a hazardous procedure. The study of the pathology of this group of tumors has been neglected to a great degree. As Davis and Cushing have stated, there is a tendency in the literature to describe in one category a great variety of lesions which protrude into the ventricle and to assume, without accurate histological evidence, that they actually have originated from the adjacent plexus.

The 3 following cases are of interest both from the clinical and pathological standpoints. The diagnostic difficulties have already been referred to and the fact that all three tumors are primary fibroblastomas which arose, without reasonable doubt, from the choroid plexus or tela choroidea makes them worthy of consideration.

REPORT OF CASES

Case 1. The patient, a 36 year old white man, entered the hospital in September, 1927, complaining of severe headaches, nervousness, loss of memory and staggering gait. About 6 weeks before admission he had experienced a severe headache which had lasted for about 6 hours. Two weeks later he had an attack of faintness which had lasted but a few minutes. Following these episodes he became very nervous, somewhat unsteady in walking, developed and he had lost confidence in himself. Drowsiness had been present since the beginning of the year, but there had been no nausea or vomiting. For 3 weeks previous to admission the patient had himself noticed a failing memory and for the past 10 days the headache which had been most marked over the vertex had become almost constant. No history of failing vision, sensory or motor defect was elicited nor had there been diplopia or tinnitus.

Neurological examination revealed little at that time. There was a slight bilateral exophthalmos, some decreased auditory acuity on the right side and a slight amount of ataxia. Motor and sensory defects were absent. The optic discs appeared normal. Subjectively there was a loss of memory and some dizziness. Arrangements for the administration of lumbar fluid was instituted and the patient was told to report at regular intervals for further observation.

Repeated spinal punctures during the subsequent interval revealed normal fluid dynamics but some xanthochromia. However, after 2 months the patient began to show definite signs of an expanding intracranial lesion. He was found to be mentally dull and he had almost total motor aphasia. There was slight edema of both optic discs, but definite choking was absent. Bilateral exophthalmos was present. Marked hypertonicity was present over the entire right side and the Babinski sign was present bilaterally. There had been a transient paralysis of the right lower part of the face and the headaches had become more severe.

In November, 1927, in the hope of finding a removable growth, an osteoplastic flap was reflected in the left temporoparietal region. The exploring brain cannula localized a deep seated tumor. The wound was closed leaving a decompression without an attempt at removal of growth. After a somewhat stormy course, patient was discharged with little improvement over his former condition. Subsequent therapy with filtered x-rays was followed by considerable improvement and he was practically symptom free up to the time of the second admission in July, 1930—32 months after operation.

Two days previous to the second admission the patient had experienced a generalized convulsion in his sleep but aside from a rather sluggish mentality and a slightly drawing speech there was nothing to suggest a cerebral lesion. Lencephalography was advised in the hope of localizing a cyst which could be drained. Roentgen examination (Fig. 1) gave evidence of a large tumor obstructing the posterior portion of the body of the ventricle in the left occipitoparietal region.

Fig 1 Encephalogram The outlines of the previous bone flap and decompression are evident There is dilatation of the right ventricle The left ventricle is obstructed so that only the anterior half of the body is visualized Case 1

Under avertin ether anesthesia, a left occipital craniotomy was performed. Cannula exploration yielded 3 to 4 cubic centimeters of yellow coagulable fluid at a depth of about 3 centimeters. An incision into the cortex exposed an encapsulated tumor which apparently was confined to the posterior portion of the left ventricle. An immediate biopsy was reported as possibly a fibroblastoma. Since piece-meal removal with the electric loop caused marked bleeding, the growth was removed by finger-enucleation after a preliminary transfusion. The tumor came away in two pieces and this was followed by sharp bleeding from its anterior attachment which was well forward on the mesial wall of the lateral ventricle. The anterior limit of the growth was almost as far forward as the foramen of Monro. This anterior portion was much more firm and much more nodular than the posterior portion and was thought to be the older part of the neoplasm.

Although the immediate response after operation was surprisingly good, the subsequent course was consistently downhill. An encephalogram made 10 days after operation showed that the symmetry of the ventricles was restored and there was no evidence of a clot. The patient died 5 weeks after operation. No autopsy was granted.

Pathological description The total weight of the tumor was 135 grams. The largest piece measured approximately 6 by 5 by 5 centimeters and was grayish-white, soft, and rather friable. A scanty capsule covered the surface. The cut surface appeared slightly granular and without whorl formation. A smaller piece was somewhat firmer and rather nodular, but differed in no significant way from the above.

Sections of the tumor were stained with hematoxylin and eosin, Mallory's phosphotungstic acid hematoxylin, Weigert's resorcin-fuchsin for elastic tissue, Wilder's silver impregnation for reticulum, Mallory's anilin blue orange G, acid fuchsin, and Perdrau's silver impregnation for connective tissue. Poor staining quality interfered to some

Fig 2 Section of tumor Note the indefinite cell boundaries and the abundance of intercellular collagenous material Case 1 (Hematoxylin and eosin $\times 120$)

extent with the histological examination of the specimen.

Microscopically, there is present a rather thin capsule composed of moderately dense collagenous connective tissue containing numerous small, thin walled vessels. The tumor tissue is quite cellular and with some disposition toward whorl formation, although this is not marked in all parts of the tumor. The individual cells have moderately small, round or oval, vacuolated nuclei which contain a relatively small amount of chromatin material in the form of coarse granules. Several nucleoli are usually present and the nuclear membrane is fairly distinct. There is a fair amount of finely granular cytoplasm which tends to be bipolar in distribution, although cytoplasmic boundaries are quite indistinct and often invisible. Intercellular material is quite abundant and, although the tumor appears densely fibrous, a definite reticulum is not present (Fig 2). However, about the vessels in the immediate surrounding tumor tissue, there are small collections of fine fibrils which appear to have their origin from the vessel walls. There are numerous thin walled vessels and occasional large vessels both of which are filled with moderately well preserved blood.

Where whorl formation is marked, hyalinization is often present and a few well formed calcospheres are evident. Fibroglia fibers were not demonstrated by the special stains although it is possible that the poor state of preservation of the tissue interfered with the staining of these. Pleomorphism is not marked, although occasional cells contain several nuclei and cells with large, round, swollen atypical nuclei can be found. Scattered throughout the tissue are numerous round cells and in a few places these appear as focal collections. Areas of degeneration, although present, are not particularly common and not very extensive.

The tumor is regarded as a fibroblastoma.

CASE 2 A patient a 26 year old white man, was admitted to the hospital in May, 1932, complaining of ataxia, headaches, spontaneous vomiting and drowsiness. The patient at the time of admission was stuporous and it was necessary to obtain most of the history from his wife.

Headache of mild severity had been present for 5 years. About 9 months prior to admission, the headaches had increased in severity and spontaneous vomiting had begun. For about 3 months the patient had complained of attacks of pain which were localized to the upper cervical region. These lasted from 15 minutes to 1 hour and necessitated sitting with the neck bowed and the chin resting on the

Fig. 3. Photomicrograph of tumor. Note evident fibroblastic character of the cells. Case 2. (Hematoxylin and eosin $\times 187$)

sternum. About 6 weeks before admission the patient had been hospitalized elsewhere for observation and at that time ataxia with staggering to the right had been noted. For 5 days prior to the first hospitalization there had been marked drowsiness and regurgitation of food through the nose had prevented him from obtaining much nourishment.

Neurological examination gave definite evidence of an expanding intracranial growth although localization was uncertain. There were bilateral choked discs with edema of one disc on the right and two discopons on the left. The left pupil was fixed to light and although a definite nystagmus was absent, short nystagmoid jerks were present when the patient fixed the eyes to the left. A partial lower facial paralysis was present on the right and there was generalized muscular weakness most marked in the right arm and leg. Sensation was normal throughout. Ataxia was present and the Romberg test was positive, the tendency being to fall to the right. Moderate bilateral adiadochocinesia was present also. The abdominal reflexes were absent and the gag reflex was impaired. The posture causing the patient the least discomfort was with the head bent forward and the chin resting on the chest. Perimetry could not be carried out. Roentgenograms of the skull gave evidence of long standing increased pressure. There was atrophy of the dorsum sellae and clinoid processes with erosion of the floor of the sella turcica.

Ventriculograms taken on the third hospital day showed the air present only in the posterior portion of the right ventricle and this was dislocated to the right. The ventriculographic diagnosis was tumor of the left frontal lobe.

Left frontal craniotomy was performed following ventriculography. The exposed brain was tense but otherwise normal in appearance. Incision into the brain exposed the outer surface of a firm, encapsulated tumor confined within the anterior horn of the left lateral ventricle. After considerable difficulty the tumor was removed in two large pieces. Free bleeding occurred from the tumor bed, the blood coming from the vessels of the choroid plexus about the foramen of Monro.

Following a stormy postoperative course in which infection complicated recovery, the patient was discharged on the forty-fifth hospital day. He was readmitted 2 months later complaining of drowsiness, weakness and projectile vomiting. Neurologic examination was essentially negative but in view of a previous infection and the presence of a high spinal fluid cell count, exploration for a cerebral

Fig. 4. Pre-operative ventriculogram. There is marked dilatation of the right ventricle. In the left ventricle there is an obstruction at about the midpoint of the body so that only the anterior portion and the occipital horn is visualized. Case 3.

abscess was carried out. No lesion was discovered and subsequent ventriculographic studies revealed nothing abnormal aside from the presence of a moderate dilatation of the ventricles. The patient was discharged on the seventh hospital day with considerable improvement in his condition. He died, however, 1 month later. No autopsy was granted.

Pathological description. The weight of the two large tumor masses was 100 grams. The larger measured 7 by 5.5 by 5.5 centimeters and with the exception of one surface which was cut across in removal, the tumor was covered by a smooth, thin, glistening capsule in which numerous veins were visible. The surface was irregular with numerous large bosses. Sections through the tumor mass revealed a uniformly white, somewhat granular surface with numerous areas of recent hemorrhage. No cysts were present and gross calcification was not observed. The smaller mass weighed 45 grams and measured 4.5 by 4 by 1.5 centimeters. The tissue was similar to that of the larger mass but due to the presence of more diffuse hemorrhage its color was grayish red.

Tissue taken from various portions of the tumor was stained by the methods listed previously. Here again the staining quality of the tissue interfered with the microscopic study of the growth.

Microscopically there is a thin capsule composed of loosely woven connective tissue in which numerous large and small vessels are present. The cells are arranged in sheets and although the first impression is one of marked streaming and parallelism, close examination reveals the fact that this picture is due to the peculiar type of chromatin present. The individual tumor cells are small, round or elongated and for the most part quite uniform. They contain one but rarely two small round rather dense nuclei in which the chromatin material appears as coarse granules. The nucleus is usually centrally placed and in most instances occupies a large portion of the cell. The cytoplasm is moderate in amount and often appears as a small rim about the nucleus. It is finely granular and quite

Fig 5 Photograph of tumor at operation Case 3

Fig 6 Photomicrograph of tumor. Note the fibroblastic character of the tissue and the intimate relationship between tumor cells and blood vessels. Case 3. (Hematoxylin and eosin, $\times 105$).

eosinophilic. Mitotic figures are present but not numerous. The tumor has an abundance of fine, collagenous stroma which supports numerous, fair size blood vessels. Specific stains fail to reveal fibroglia.

Degeneration is quite extensive and gives the tissue a loosely woven appearance. Definite whorl formation in the tumor is not present and streaming, although present, appears most marked where degeneration is present. In some areas the cells are in close contact to form sheets while in other places, streaming and parallelism predominates (Fig. 3). Extensive degeneration causes the tissue to appear under low magnification as focal cell collections separated by bands of fine collagenous connective tissue. The tumor is regarded as a fibroblastoma.

CASE 3. The patient, a $3\frac{1}{2}$ year old white girl, entered the hospital in February, 1935 because of difficulty in the use of the right arm and leg. About 7 months prior to admission she had been knocked over by a dog and had fallen forcibly, but there was no history that she had struck her head. About that time the parents noticed a tremor in the right hand while the child was eating. Upon medical advice, she was put to bed for 1 week but upon getting up uncertain gait and marked difficulty in walking up and down stairs had been noticed. The child had become quite irritable and it was observed that the left hand was used much more than the right. There had been an increase of about 1 centimeter in the circumference of the head in the preceding 7 months. At no time had there been headaches or vomiting and speech had been normal.

Examination at the time of admission showed a bright child with a large head and an uncertain gait. The pupils were somewhat dilated but were equal and regular and responded normally to both light and distance. There was no nystagmus and the extra-ocular muscles were normal. Macewen's sign was positive. There was questionable slight weakness of the right lower portion of the face and the right hand, and definite ataxia of the right hand and leg. Deep and superficial reflexes were all active and equal but the Babinski response was present on the right. Both optic discs showed definite choking, and pressure over the left temple caused some pain. Perimetry was not carried out. The clinical diagnosis made was left frontal lobe tumor.

On the day following admission during the process of ventriculography a cyst was encountered through a drill opening in the left parietal region and about 30 cubic

centimeters of thick yellow fluid was removed at a depth of about 4 to 5 centimeters. Following this procedure, air was introduced but from the subsequent films it was impossible to state whether the injected air outlined a cyst or an obstructed posterior horn of the left lateral ventricle. Consequently, 90 cubic centimeters of fluid from the right lateral ventricle was replaced with air and roentgenograms were made. These revealed a dilated right ventricle which was dislocated to the right and an obstruction at about the midpoint of the body of the left ventricle (Fig. 4). The diagnosis of left parieto-occipital cystic glioma was made and immediate operation performed.

Through a left parietal craniotomy opening, the brain was explored. The cerebral surface appeared normal with the exception of two gyri in the inferior portion of the parietal lobe. These were pale yellow, and soft, and, upon exploration with a biopsy cannula, increased resistance was encountered at a depth of about 5 centimeters. Several small fragments of tissue were removed with the cannula but because of the location and depth of the growth it was considered unwise to attempt its removal. The tissue removed proved to be normal brain tissue without evidence of inflammation or neoplasm.

The postoperative course was uneventful and the patient was discharged on the sixteenth day after operation. There was no measurable choking of the optic discs and the degree of ataxia was decidedly less than at the time of admission. Roentgentherapy was instituted and the child continued to make good progress until about 2 months after discharge, at which time she suffered from an illness in which vomiting was a prominent feature. Following this episode the use of the right side was definitely impaired. Symptoms of pressure developed gradually until, in November, 1935, 10 months after the first admission, the patient was re-admitted for aspiration of the cyst. About 100 cubic centimeters of syrupy, yellow fluid was removed with subsequent improvement in the child's condition. In January, 1936, it was necessary again to aspirate fluid. At this time the child had complained twice of headache, and spontaneous vomiting had been present. One hundred cubic centimeters of fluid was removed but with much less improvement than was formerly obtained. The subsequent course was down-hill and in March, 1936, it became apparent that radical operation was the only measure which could

FIG. 3. Photomicrograph of tumor. Note evident fibroblastic character of the cells. Case 2 (Hematoxylin and eosin $\times 187$)

FIG. 4. Pre-operative ventriculogram. There is marked dilatation of the right ventricle. In the left ventricle there is an obstruction at about the midpoint of the body so that only the anterior portion and the occipital horn is visualized. Case 3

sternum. About 6 weeks before admission the patient had been hospitalized elsewhere for observation and at that time ataxia with staggering to the right had been noted. For 5 days prior to the first hospitalization there had been marked drowsiness and regurgitation of food through the nose had prevented him from obtaining much nourishment.

Neurological examination gave definite evidence of an expanding intracranial growth, although localization was uncertain. There were bilateral choked discs with edema of one diopter on the right and two diopters on the left. The left pupil was fixed to light and although a definite nystagmus was absent, horizontal nystagmoid jerks were present when the patient fixed the eyes to the left. A partial lower facial paralysis was present on the right and there was generalized muscular weakness most marked in the right arm and leg. Sensation was normal throughout. Ataxia was present and the Romberg test was positive, the tendency being to fall to the right. Moderate bilateral adiadochocinesia was present also. The abdominal reflexes were absent and the gag reflex was impaired. The posture causing the patient the least discomfort was with the head bent forward and the chin resting on the chest. Perimetry could not be carried out. Roentgenograms of the skull gave evidence of long standing increased pressure. There was atrophy of the dorsum sellae and clinoid processes with erosion of the floor of the sella turcica.

Ventriculograms taken on the third hospital day showed the anterior part only in the posterior portion of the right ventricle and this was displaced to the right. The ventriculographic diagnosis was tumor of the left frontal lobe.

Left frontal craniotomy was performed following ventriculography. The exposed brain was tense but otherwise normal in appearance. Incision into the brain exposed the outer surface of a firm, encapsulated tumor confined within the anterior horn of the left lateral ventricle. After considerable difficulty the tumor was removed in two large pieces. Free bleeding occurred from the tumor bed, the blood coming from the vessels of the choroid plexus about the foramen of Monro.

Following a stormy postoperative course in which infection complicated recovery, the patient was discharged on the forty-fifth hospital day. He was re-admitted a month later complaining of drowsiness, weakness and projectile vomiting. Neurologic examination was essentially negative but in view of a previous infection and the presence of a high spinal fluid cell count, exploration for a cerebral

abscess was carried out. No lesion was discovered and subsequent ventriculographic studies revealed nothing abnormal aside from the presence of a moderate dilatation of the ventricles. The patient was discharged on the seventh hospital day with considerable improvement in his condition. He died, however, 1 month later. No autopsy was granted.

Pathological description. The weight of the two large tumor masses was 100 grams. The larger measured 7 by 5.5 by 5.5 centimeters and with the exception of one surface which was cut across in removal, the tumor was covered by a smooth, thin, glistening capsule in which numerous veins were visible. The surface was irregular with numerous large bosses. Sections through the tumor mass revealed a uniformly white, somewhat granular surface with numerous areas of recent hemorrhage. No cysts were present and gross calcification was not observed. The smaller mass weighed 45 grams and measured 4.5 by 4 by 3.5 centimeters. The texture was similar to that of the larger mass but due to the presence of more diffuse hemorrhage its color was grayish red.

Tissue taken from various portions of the tumor was stained by the methods listed previously. Here again the staining quality of the tissue interfered with the microscopic study of the growth.

Microscopically there is a thin capsule composed of loosely woven connective tissue in which numerous large and small vessels are present. The cells are arranged in sheets and although the overall impression is one of marked streaming and parallelism, close examination reveals the fact that this picture is due to the peculiar type of stroma present. The individual tumor cells are small, round or elongated and for the most part quite uniform. They contain one but rarely two small round rather dense nuclei in which the chromatin material appears as coarse granules. The nucleus is usually centrally placed and in most instances occupies a large portion of the cell. The cytoplasm is moderate in amount and often appears as a small rim about the nucleus. It is finely granular and quite

While in many instances the symptoms are less than 1 year in duration there are wide variations. The successful removal of an intraventricular tumor from a patient in whom symptoms had been present for 22 years has been reported (10). It must be remembered that, in tumors in this location, the duration of symptoms is no index of the malignancy of the growth since, by reason of their location, they may block circulation of the cerebrospinal fluid and produce fulminating signs of increased intracranial pressure, despite the fact that they may be encapsulated and perfectly benign.

PATHOLOGICAL CONSIDERATION

Tumors arising from the choroid villi have been described and usually referred to as psammomas (3, 11) or meningiomas (8). Although the microscopic structure of these tumors is variable many of them cannot be distinguished from the common variety of meningioma. The tumors described here differ from the common variety of meningioma and, for reasons to be discussed, have been called fibroblastomas.

As has been pointed out elsewhere (2) cerebral neoplasms composed almost exclusively of fibroblastic elements are extremely uncommon. Their origin has not yet been definitely established, although Alpers has stated that these tumors may arise from the pia, the vascular adventitia, or the perithelium of the blood vessels. Inasmuch as the embryological derivation of the leptomeninges is still the subject of considerable debate, the term fibroblastoma eventually may prove to be incorrect.

There are several reasons for believing that the tumors described here arose from the mesodermal elements of the choroid plexus. Collagen fibrils, fibroglia fibrils, and elastic fibers are known to be the products of cells potentially fibroblastic. The first tumor described is densely fibrous and quite cellular and contains considerable intercellular collagenous material. In the third tumor, in addition to an abundant collagenous stroma and numerous fibroblasts, there are scattered areas in which fibroglia fibrils are present. While the fibroblastic character of the second tumor cannot be established definitely it appears that all three tumors are fibroblastomas. None of the tumors

contained a definite reticulum. The three tumors described here probably arose from the fibrous elements of the choroid plexus, either from the numerous fibroblasts found normally in the choroidal villi or from cells potentially fibroblastic.

SUMMARY

1. Three cases of primary fibroblastoma of the choroid plexus of the lateral ventricle have been described. All 3 tumors were removed at operation.
2. In none of the 3 cases was the intraventricular location of the tumor suspected from the clinical findings and in all 3 cases the exact localization was made at operation.
3. The tumors are of mesodermal origin and probably arose from the fibrous elements of the choroid plexus or tela choroidea.

possibly save the child. At this time there was a high degree of papilledema, marked ataxia and separation of the cranial sutures.

Through a craniotomy opening, corresponding to that of the previous operation, the left parietal region of the brain was again exposed. An incision through the cortex disclosed a collection of 6 or 8 cysts, all of which were located in a greatly dilated posterior horn of the ventricle. Evacuation of these brought to view a large firm smooth encapsulated tumor lying anteriorly (fig. 5). With the electrocautery, a loop the tumor was removed piecemeal until there remained only a small portion of its anterior wall which was found to be attached to the choroid plexus at a point opposite a greatly dilated foramen of Monro. The vessels of the choroid plexus were greatly dilated and represented the only point of attachment of the growth. After coagulation of these it was possible to remove the last fragment of tumor tissue. An enormous cavity resulted; the walls of which consisted of the ependymal lining of a greatly dilated lateral ventricle. The cavity was filled with saline and the wound was closed in the usual manner.

The subsequent course was uneventful and the patient left the hospital on the eleventh day after operation. At the time of discharge there was some residual paresis and ataxia of the right side but not demonstrable aphasia. Nine months after operation the patient was able to run and walk alone. She was able to use the right arm and leg and her condition had continued to improve steadily. However there was still a definite right hemiparesis.

Pathological description. The total amount of tumor tissue removed weighed 217 grams. The largest piece measured 4.5 by 4.5 by 3 centimeters and was covered on its outer surface by a thick, yellowish gray to grayish white capsule. At one point a fragment of choroid plexus was attached to the surface. The tissue was quite firm and upon section presented a homogeneous yellowish gray somewhat granular surface.

Sections taken from various parts of the tumor were stained by the methods already enumerated. The tumor is covered with a moderately thick capsule consisting of fairly cellular collagenous connective tissue in which numerous large and medium sized blood vessels are present. The tissue is composed of sheets of cells of the connective tissue type with fairly marked streaming and somewhat less marked whorl formation. Degeneration is extensive throughout the tissue.

The parenchymal cells are fibroblasts with elongated compact and highly chromophilic nuclei and a fair amount of pink staining cytoplasm which is bipolar in distribution (fig. 6). Intercellular material is abundant and forms a heavy collagenous carpet. Mitotic figures are not commonly found. Vessel spaces are quite numerous and about these there is some tendency for whorl formation with an intimate relationship existing between the walls of the vessel and the surrounding tumor tissue.

Although not very abundant there are isolated areas in which fibroblast fibers can be seen. Scattered here and there throughout the tissue are small focal collections of hyperplastic epithelium derived from the choroid plexus. These have round vacuolated centrally placed nuclei and a small amount of very lightly staining cytoplasm with almost no definition of cell boundaries. No reticulum could be demonstrated in the tumor tissue either with the Wilder or Weidman method although the latter demonstrated beautifully the abundant intercellular collagenous stroma. Sections taken at a point corresponding to the choroid plexus seen on the gross specimen reveal the presence of numerous villi containing large and small vessels with thin poorly formed walls.

The tumor is regarded as a typical fibroblastoma.

CLINICAL CONSIDERATIONS

Although the incidence of tumors of the lateral ventricle is relatively low they arise often enough in neurosurgical practice to make their clinical consideration of value. There is no clinical picture which will localize an intraventricular growth although there are certain neurological features which may at times direct attention to the possibility of a lesion in this location. This is particularly true when localizing signs are absent in the presence of an obviously expanding intracranial lesion.

Periodic headaches or intermittent attacks of increased intracranial pressure have both been cited as the most suggestive evidence of a growth within the lateral ventricle (5). This periodicity is due to the ball valve action of the tumor and can occur in other parts of the ventricular system, namely in the third ventricle (6). When the large size of the tumor prevents it from moving freely or when local adhesions fix the tumor in one position this phenomenon may be absent as it was in the 3 cases presented here. Obvious signs of increased intracranial pressure may be late in developing in patients of the younger age group since here cranial suture separation may serve to decompress the brain until the bulk of the tumor plus the concomitant cerebral edema overcomes this compensation. Of the host of signs and symptoms described hemianesthesia and hemiplegia have been pointed out as the most important localizing evidence. This is interesting in view of the fact that in none of the 3 cases described here was there any evidence of sensory impairment. Many of the signs are misleading and in one instance at least the presence of staggering gait, ataxia and positive Romberg's sign has led to cerebellar exploration (7).

Intraventricular tumors appear to occur most frequently during the first three decades of life. Dandy (5) found that in about 67 per cent of the cases of tumor of the lateral ventricle, the patients were less than 31 years of age at the time of operation or necropsy and that nearly 50 per cent of these tumors occurred before the age of 21 years. Van Wagenen has reported the successful removal of a papilloma of the choroid plexus from the lateral ventricle of an infant 3 months old and Graves and Fliess report the occurrence of a similar tumor, found at autopsy, in the left lateral ventricle of an infant 9 months old. Tchernyschew and his associates have reported a psammoma which was located in the right lateral ventricle of a boy 10 years old and Christophe has reported a similar tumor which was found in a boy 13½ years old.

by (1) inspection and palpation of the tumor; (2) palpation of the lymph nodes in the neck; (3) biopsy of the tumor. The findings of each of these examinations should be known before treatment is decided upon. Biopsy tissue can be taken from the ulcerated surface of the tumor with a punch; this step should be a simple one and should not cause pain or danger to the patient. The report of the pathological examination must go further than merely state the presence or non-presence of cancer. It should, if an epidermoid carcinoma, give information as to the index of malignancy according to Broders or some similar classification.

An attempt at cure should be made in cases in which the largest lymph node is 1 centimeter or less, and in which the tumor is not over 2 centimeters in diameter, if of pathological grades 2 or 3 and also if the tumor is wider than 2 centimeters, but not over 4 centimeters provided the lesion is of papillary type, does not infiltrate, and is of pathological grade 1.

THE PREPARATION OF THE PATIENT FOR CURATIVE TREATMENT

Good hygiene of the mouth must be achieved before starting any course of curative treatment. In more cases this will entail extensive extractions than it will entail mere cleaning and temporary filling of teeth. This takes time, but it is believed to be so important that up to a week or 10 days for the extractions and partial healing of the sockets may well be spent in this effort before operation or radiation. Many serious post-treatment infections are thereby avoided and no appreciable increase in the size of the tumors have been noted during this time.

THE CURATIVE TREATMENT OF THE LOCAL LESION

The results of treatment by modern methods are very close to each other. A clean surgical excision by endothermy probably gives the least painful convalescence. We tend to favor this method especially if there is associated leucoplacia, as the latter does not respond well to radiation. A proper surgical endothermy or surgical excision operation should excise or devitalize the normal tissue to a distance of at least $\frac{1}{2}$ centimeter in all directions beyond the edge of the gross cancer, and if possible, 1 centimeter distance is better. Endothermy combined with surgical excision is absolutely the method of choice if there is invasion of the jaw. A wide resection of the jaw will be followed by cure in many such cases. In an increasing number of the curable

TABLE I.—CLINICAL VERSUS PATHOLOGICAL EXAMINATION OF NODES OF NECK

cases, however, the treatment starts with a series of 2000 to 3000 r units of short wave x-ray, given through the skin or 1500 units intra-orally if the tumor is so located that this is feasible. When this treatment is started, no change is ever made to surgery later. Three weeks after the first treatment the situation is reconsidered and further treatment given by either more x-ray or by the implantation of radium needles. A third series of treatments is given by x-ray at the end of a second 3 weeks when the dose is pushed to the limit of tolerance of the skin, the underlying tissues, and the patient. This is not necessarily the only way to give x-ray. Berven, of Stockholm, favors daily doses for 1 month, totalling 5000–6000 r units. If, after this treatment, the tumor has not regressed or, if after regression it recurs, no further effort is made to cure. After several months a few hundred, but only a few hundred, r units may be tolerated for palliative purposes.

THE CURATIVE TREATMENT OF INVOLVED GLANDS IN THE NECK

It is often impossible to tell by clinical examination whether glands palpated in the neck are actually involved by cancer or not. There are two reasons for this. First, very small, impalpable glands may have a small cluster of cancer cells in them. Second, due to the infection of the teeth or the secondary infection of the ulcerated primary cancer the glands may be considerably enlarged due to their reaction to the infection, and yet contain no cancer cells. It goes without saying that really large glands practically always do contain metastases. Table I will show the difficulty of telling by any criteria on physical examination whether nodes are involved or not.

The data on comparison of the examiner's opinion as to the presence of cancer in the neck are from the paper by Simmons published in 1930, and the data on the described size, from reference Lund (4).

It is generally recognized that any feasible dosage of x-ray or external radium will very rarely cure metastatic epidermoid carcinoma in glands, and that the cure of such glands by implanted radium is extremely unlikely due to the

EPIDERMOID CARCINOMA OF THE BUCCAL MUCOSA

CHARLES C LUND, M.D., F.A.C.S., Boston, Massachusetts

BUCCAL cancer is typically an epidermoid cancer and typically very malignant. The results of treatment by any means, surgery, radium, or x ray, cannot by any criteria be considered to be at all satisfactory except in a very few, very small cancers and a few others that are of a relatively low grade of malignancy. (4) Most of the few cases that are amenable to cure are curable by any of the afore mentioned forms of treatment properly given. This situation does not prevail with respect to any other form of cancer except that arising in the skin or on the lips. Of course, in the latter two locations the cancers are much more frequently curable. This paper will discuss epidermoid cancer only, of the following locations: tongue, floor of mouth, upper and lower gingival mucosa, both palates and inside of cheeks. Notice that cancers of the tonsil and lips are not included and that the very rare adenocarcinomas and the so called lympho-epithelioma are not included. The characteristics of these other types and locations of cancer are so different that a wholly separate paper would be needed to discuss them in any worth while manner.

CAUSE AND PREVENTION OF BUCCAL CANCER

Normally the mucous membrane of the mouth is comparatively resistant to the development of cancer as shown by the fact that women who very largely do not chew tobacco or smoke pipes and whose mouths average much cleaner in other ways than men do, have buccal cancer but one eighth as frequently as men. (2) This statement holds approximately true for Europe, America, and many other parts of the world but not for countries where betel nut chewing is commonly practiced by both sexes. The etiological factors well recognized to be causative of mouth cancer are first, overuse of the stronger forms of tobacco such as, in order, chewing either plain tobacco or snuff, pipe smoking and cigar smoking; second, dirty broken infected teeth; third important for some unknown reason in tongue cases only tertiary syphilis. In most cases of buccal cancer at least two of these factors are present and have been operating over a long period of time. It is

unfortunate that the irritative factor that leads to mouth cancer does irreversible damage to the tissues long before any visible effect takes place. This of course is similar to the effect of x ray or the various tar chemicals, whose effects may be demonstrated only following a long latent period but if sufficient dosage has been given will be shown eventually even if further administration of the agent be stopped.

This is mentioned because in this disease even more than in most diseases the prevention of it is better than the cure and it can be largely prevented. How far should one go in recommending preventive measures? Should we advise the confirmed pipe smoker to give up his pipe? I am afraid such advice would go unheeded. Notice that two or more of the causative factors are nearly always needed to cause this kind of cancer. Therefore, it would be fairly safe for the young man about to begin to enjoy adult pleasures to follow these rules: (1) avoid syphilis, or if an accident has happened be treated efficiently, (2) either do not use tobacco or keep the teeth with the help of a dentist, in perfect order at all times.

THE SELECTION OF PATIENTS FOR CURATIVE TREATMENT

As with other kinds of cancer the patients must be sharply divided into two classes: (1) those in whom an attempt will be made to cure; (2) those in whom palliation only will be attempted. Ill advised attempts to cure will often result in excessive suffering and will even prevent effective palliation. The converse use of palliative measures when curative methods are indicated leads to an even more tragic result. Except for the occasional patient who has serious complicating disease or is very feeble from old age no wide search has to be made before deciding on the curability of the cancer. No x ray pictures are indicated to hunt for metastases as the disease practically never shows metastases below the clavicle except in such a late stage that local cure is impossible. When, however, a cancer is adherent to the upper or lower jaw x ray examination of this one bone is indicated to demonstrate the amount of direct extension.

Except as indicated herein the decision as to curability of the individual case is determined

From the Cancer Commission of Harvard University.
Read before the section meeting of the American College of Surgeons, Halifax, Nova Scotia, May 21, 1937.

by (1) inspection and palpation of the tumor; (2) palpation of the lymph nodes in the neck; (3) biopsy of the tumor. The findings of each of these examinations should be known before treatment is decided upon. Biopsy tissue can be taken from the ulcerated surface of the tumor with a punch, this step should be a simple one and should not cause pain or danger to the patient. The report of the pathological examination must go further than merely state the presence or non-presence of cancer. difficulty of securing curative dosage in all the glands that may be involved. For these reasons one must state positively that if a patient has cancer in the glands his only important chance of cure is by surgery. What is this chance? In a previous paper (4), the results of radical operations on 33 such patients were reported. Radical operation is defined as an adequate local excision by knife, cautery, or endothermy, plus a neck dissection which includes the removal on one side of the submaxillary gland, submental gland, the greater portion of the sternomastoid muscle and of the internal jugular vein, together with all the gland bearing tissue from the clavicle to the jaw. The results following this operation are given in Table II. This table includes only cases in which the pre operative description of the glands was given as small or not over 1 centimeter in diameter. In 7 other cases with larger glands none resulted in a 5 year cure.

Table II shows that it is possible to cure by surgery patients with buccal cancer who have small cervical metastases. Therefore if the patient is otherwise curable and the glands are thought to be involved a radical neck dissection should be done, whether the primary lesion is irradiated or excised. This dissection should be done before, rather than after, radiation treatment as in most instances of radiation to buccal cancer the tissues of the upper neck will be so seriously damaged by the radiation that fatal infection is not unlikely to occur after operative procedure.

TABLE IV—EPIDERMOID CARCINOMA OF THE BUCCAL MUCOSA

Location	Cases	No glands—per cent
Palate	3	100
Upper jaw	8	50
Floor	11	45

Size—cm	Cases	Cures	Per cent
0-1.0	30	13	43
1.1-2.0	103	19	18
2.1+	386	22	6
Total	510	54	11

If I should be asked whether we always do such neck dissections in favorable cases (as described herein) the answer would have to be no. What defense is there for not doing them in view of the data presented as the impossibility of telling from the examination of the neck as to the presence or absence of glands? Still other criteria have been used. These criteria concern the location, character, size, and pathological appearance of the primary tumor itself.

THE DETERMINATION OF CASES THAT WILL PROBABLY NOT HAVE INVOLVED NODES

Table III is constructed on the basis as to whether positive involvement of the nodes was found either at operation or developed so that it was obvious at any subsequent time. The operations were by no means always radical ones. The pathological grades were determined by Dr. C. C. Simmons. It is seen that the chance of gland metastasis is comparatively small in low grade tumors and also is small in very small tumors. Therefore, we believe that it is safe not to do a primary neck dissection if this combination is found.

As a matter of fact, unless there is evidence from the glands themselves we do not do such dissections if the tumor is either small or low grade. The 'large' low grade tumors that are cured are nearly always those papillary ones that cannot be distinguished clinically from cases of papillary leucoplakia except on microscopic examination.

In other types of cancer the duration of the history of cancer has often been used as a criterion for doing non-radical surgery. In the mouth our histories are particularly unreliable as there is difficulty in knowing when actual cancer began in the presence of a patch of leucoplacia. It may be stated that duration as found expressed on our histories does not help us make this decision.

However, the location in the mouth is important. From the same paper quoted in Table III is found the data in Table IV.

It may be seen from Table IV that the danger of gland metastasis is distinctly less when the cancer arises elsewhere than on the tongue and lower jaw. Therefore, the location of the tumor must also be considered when a decision is made for or against active treatment of the lymph nodes.

RESULTS OF TREATMENT

In my previous paper (4), tables of results are given. They show as stated before that the form of treatment given (surgery or radium) is not so important as the choice of cases for treatment or the correctness of application of the particular treatment. In the great bulk of cases the results are discouraging. In cases with small or no enlargement of the lymph nodes the "cures" amount to only 11 per cent as seen in Table V. However, this table is not a fair statement of the results of curative treatment as at least half of the cases were incurable because of local exten-

sion of the disease and were given x-ray treatment for palliative purposes only.

Table V shows 3 things: first, the very small number of cases coming in when the lesion is small; second, the really good results obtained in these cases, and third, the nearly hopeless situation that is found in the more advanced cases.

SUMMARY AND CONCLUSIONS

1. Epidermoid carcinoma of the buccal mucosa in most cases is difficult to cure.
2. Very small, and pathologically low grade tumors are very susceptible to cure by proper application of any recognized method.
3. Therefore, there is a tremendously important field in relation to this kind of cancer: the education of the public and of the doctor in order to bring about better results.
4. The choice of treatment has been discussed.

THE CHOICE OF SUTURES IN THE SURGERY OF THE LARGE INTESTINE

IN the current discussion as to whether resection of the large intestine should be done in one stage, or in several by some adaptation of the principle of Mikulicz the significance of the method of suture employed seems not to be fully appreciated. This is of great importance because of certain conditions associated with the large intestine which do not obtain to the same degree in the small intestine.

Such are the infectiousness of its contents, the vulnerability of its blood supply, and the thinness of its walls. Minor soiling of the peritoneum by the contents of the stomach, duodenum, jejunum, or ileum, while to be avoided if possible, does not carry the grave danger of a spreading peritonitis as does a contamination from within the large bowel. Similarly, relatively gross interruption of the blood supply in the former where the anastomotic circulation is so profuse, has not the

danger of causing necrosis that it has in the latter where the interruption of a single terminal vessel may at times lead to a localized ischemia at the suture line. Then too, the walls of the colon, particularly in the sacculi are of a thinness which allows a smaller margin of safety as regards both the placing of the suture and its holding power.

It is apparent then that, although the large bowel seems to be a grosser structure than the small, the surgical manipulation of it requires a more rigorous technique. This may be on the one hand the abandonment of a suture method within the abdomen and the carrying out of a resection and anastomosis extra peritoneally as is the case with the Mikulicz principle, or, on the other hand, the refinement of the method of suture. Should the latter produce as good results as the former, then there would be no question in any one's mind as to its desirability.

That it can do so in the hands of those accustomed to the employment of the fine silk technique seems probable, while the attempt to do so with the relatively gross manipulations accompanying the use of catgut sutures seems improbable. The latter even in the larger sizes and with attached needles tends to tear as the running suture customarily employed is drawn taut, and the fault is intensified in the large sizes and with the threaded needle. In addition any type of aseptic or relatively aseptic form of anastomosis is dependent upon the accurate placement of multiple interrupted sutures and is well nigh impossible to carry out in the large intestine with catgut. On the other hand fine twisted silk mounted on an equally fine needle and used in interrupted stitches can be employed with great accuracy and with a minimum of damage to the wall of

the large intestine and its circulation. When perforations into the lumen occur, there is to a far lesser degree danger of serious leakage, while soiling of the peritoneal cavity during resection and anastomosis can be avoided by the use of an aseptic or relatively aseptic method of anastomosis which this refined technique permits.

From this consideration of the relative value of the resection and anastomosis according to the Mikulicz principle and that of resection and primary suture of the large intestine, it would seem that to those familiar with and experienced in the fine silk technique, the latter will be preferable, but that to those who for any reason persist in using catgut in the surgery of the large intestine, the Mikulicz procedure is the safer one.

SAMUEL C. HARVEY.

TREATMENT OF COMPOUND FRACTURES

THIS is not an extended treatise on the treatment of compound fractures but an attempt to emphasize three important points

1. *Early attack.* Following the accident, the period in which it is possible, by débridement and thorough irrigation, to prevent infection is a limited one. Probably after 2 hours and surely after 4, the best we can hope for by such treatment is to limit the severity and the extent of the infection. Therefore, the operative attack should not be delayed, except for extreme shock.

2. *Early reduction.* After infection has developed it may be unwise to attempt a reduc-

tion of displacement of the fragments lest the infection be carried into areas as yet uninvaded. After the infection has subsided, new bone formation and the condition of the adjacent soft parts will usually prevent proper adjustment. The time to obtain satisfactory alignment is when the débridement is carried out. It is apt to be then or never. Surgeons are apt to wait for a better time to reduce the displacement. There is no better time than right away.

3. *Immobilization.* During the process of repair, it is of the greatest importance that the zone of infection be limited as much as possible. Any motion of the bone ends tends to tear the young granulation tissue and to break down the barriers of resistance. Traction and suspension alone do not provide sufficient immobilization. Circular plaster, even if carried well beyond the adjacent joints, is not always sufficient. This is especially true when a large window has to be cut in the plaster to allow treatment of the wound. Molded plaster gutters in connection with traction and suspension should be used more often than they are.

The use of internal fixation by screws and perhaps plates is often definitely indicated. In many comminuted cases it is the only way by which the proper length can be maintained. Their use in compound fractures frequently will limit the area of infection and hasten repair. They should be regarded as a temporary means of maintaining immobilization and should be applied in such a manner as to permit their removal with as little additional trauma as possible.

THE CHOICE OF SUTURES IN THE SURGERY OF THE LARGE INTESTINE

IN the current discussion as to whether resection of the large intestine should be done in one stage, or in several by some adaptation of the principle of Mikulicz, the significance of the method of suture employed seems not to be fully appreciated. This is of great importance because of certain conditions associated with the large intestine which do not obtain to the same degree in the small intestine.

Such are the infectiousness of its contents, the vulnerability of its blood supply and the thinness of its walls. Minor soiling of the peritoneum by the contents of the stomach, duodenum, jejunum, or ileum, while to be avoided if possible, does not carry the grave danger of a spreading peritonitis as does a contamination from within the large bowel. Similarly, relatively gross interruption of the blood supply in the former where the anastomotic circulation is so profuse has not the

danger of causing necrosis that it has in the latter where the interruption of a single terminal vessel may at times lead to a localized ischemia at the suture line. Then too the walls of the colon, particularly in the sacculi, are of a thinness which allows a smaller margin of safety as regards both the placing of the suture and its holding power.

It is apparent then that, although the large bowel seems to be a grosser structure than the small, the surgical manipulation of it requires a more rigorous technique. This may be on the one hand the abandonment of a suture method within the abdomen and the carrying out of a resection and anastomosis extra peritoneally as is the case with the Mikulicz principle, or, on the other hand, the refinement of the method of suture. Should the latter produce as good results as the former, then there would be no question in any one's mind as to its desirability.

That it can do so in the hands of those accustomed to the employment of the fine silk technique seems probable while the attempt to do so with the relatively gross manipulations accompanying the use of catgut sutures seems improbable. The latter even in the finer sizes and with attached needles tends to tear as the running suture customarily employed is drawn taut, and the fault is intensified in the large sizes and with the threaded needle. In addition any type of aseptic or relatively aseptic form of anastomosis is dependent upon the accurate placement of multiple interrupted sutures and is well nigh impossible to carry out in the large intestine with catgut. On the other hand fine twisted silk mounted on an equally fine needle and used in interrupted stitches can be employed with great accuracy and with a minimum of damage to the wall of

The parts dealing with malignant tumors of the pharynx and larynx by Lionel Colledge, tongue, mouth, and lips by Stanford Cade, and the esophagus and diaphragm by Laurence O'Shaughnessy are deserving of special mention. It was a delight to read them.

Parts are devoted to the medical aspect of surgery, hernia, plastic surgery, obstetric surgery, orthopedics, eye, ear, nose, endoscopic methods, tonsils and adenoids and retropharyngeal abscess, mandible, teeth, venereal disease, physical medicine, deep X-ray therapy, some aspects of general surgery including shock, blood transfusion by the continuous drip method, gangrene, burns and the like, and some neurological and psychiatric aspects of surgery.

Because of lack of space it is impossible to give an adequate impression of the entire work. It is replete with vital information and a ready assistant to the student of surgery.

After having carefully surveyed the three volumes of *Post-graduate Surgery* an impression as to the merits of the system as a whole is volunteered. It consists of 5500 pages of material prepared by 59 authors, each a recognized master of his specialty. Much of the fundamental material depicting basic principles of surgery has been purposely omitted because the editor assumes that the post-graduate student should be in possession of this information and if not it can be procured in practically any textbook of surgery. Therefore the 5500 pages are devoted to what may be termed live clinical surgery. The presentation is excellent and the illustrations are numerous and beautifully done. Many subjects are treated exhaustively. The final opinion is that this work is probably the most complete and modern of any of its kind to be found today. The reviewer will cherish this system and use it frequently. In trying to offer a criticism, one fault may be found: a volume of 2000 pages is too large and heavy for convenient reading. JOHN A. WOLFER

THE first part of the book *The Physiology of the Kidney*¹ by Homer W. Smith contains a good discussion of the physiological anatomy of the kidney and a review of the theories of renal function with some added recent concepts of the author. Smith has presented supportive experimental evidence for the theory of tubular excretion as seen in the aglomerular fish and embryonic preparations of lower animals.

The rôle of the kidney in mineral metabolism, acid-base balance, and water excretion is well handled from a practical standpoint, and helps to elucidate some of the problems and findings of advanced renal disease. The action of diuretics on the kidney is summarized.

Much of the book is devoted to the "concept of renal clearance." The clearance of inulin, phenol red creatine, urea and glucose is discussed thoroughly, involving technical detail and a thorough knowl-

edge of biochemistry. The author believes that "independent absolute values of renal clearance are of little value" and, it is essential to observe the simultaneous clearance of two or more substances which we wish to compare.

It is unfortunate that the publishing of the book antedates the recent epoch making and generally accepted reports of the effect of renal ischemia. No mention of this work is made in the chapter devoted to renal blood flow.

The relationship of the kidney to the hypothalamus and adrenals is briefly discussed but the relationship of kidney and other organs such as heart, blood vessels, and liver are not elaborated upon.

As a whole the book is a scholarly presentation of the author's own experimental work on the physiology of the normal kidney of many laboratory animals. To this he has added an exhaustive review of the work of similar nature as initiated by Cushing and Richards.

It is a presentation written for those particularly interested in the subject of renal physiology, and not for the general practitioner. M. HERBERT BARBER

ONE need only scan the contents of this the fifth edition of Ormsby's *Practical Treatise on Diseases of the Skin*² to discover why it has been so extremely popular. In order to incorporate new material and yet keep the book reasonable in size a great deal of reconstruction has been done. Twenty new diseases are described, descriptions of 12 have been rewritten, and the entire work has been brought up to date. The bibliography, always an excellent one in all of the editions, has been improved by selecting articles on the various subjects which contain bibliography to the date of publication, thus reducing the literature references.

The revision of the histopathology and mycology by Dr. Finnerud is an excellent piece of work and under each disease, a complete description of the histopathological findings is given in a short, concise, yet comprehensive manner.

The volume always has been well illustrated with excellent black and white engravings and to this volume are added 44 new plates. The subject matter is sound and presented in a direct, concise manner, reflecting the extensive knowledge and long teaching experience of the author. This book is the most readable, the most understandable, and the most authentic of all the textbooks on dermatology printed in the English language. It would be impossible to find a better book on the subject of dermatology in which every disease of the skin is so accurately described and in which everything known to date about any given disease is so ably presented.

The book is printed on good paper in clear, readable type, interspersed with bold type for key words and headings.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE mortality of acute bowel obstruction has always been high when contrasted with statistics of other types of acute abdomen. The death rate following operations to remedy the conditions is still inexcusable. Ignorance of the mechanism and effects of distention of the mechanism of death faulty diagnosis late operation and peritonitis resulting from the unskilled handling of distended bowel are factors which contribute to this high mortality. Therefore no treatise on the operative technique of bowel surgery is presented by Wangensteen in his recent book *The Therapeutic Problem in Bowel Obstructions*¹ but rather an experimental and clinical study of the effects of obstruction, methods of diagnosis and a description of conservative aids to recognized operative procedures.

This volume has three sections: (1) the therapeutic problem of acute bowel obstruction; an essay awarded the Gross prize in 1935; (2) general considerations of diagnosis and treatment in bowel obstructions; (3) the special obstructions. The following brief résumé contains facts which the reviewer believes worthy of special emphasis.

Obstruction produces distention and loss of fluid, the chief sources of distention are digestive fluids and swallowed air. Contrary to prevalent opinion high obstruction is less vicious than blocks in the lower bowel because vomiting prevents distention and attendant mechanical damage in the former type. Salt solution is a specific for the loss of electrolytes in high obstruction; it has no specific action in low obstruction. In obstructions of the colon the latter becomes a closed loop, because of the action of the ileocecal valve. Vomiting is infrequent and normal absorption occurs. The danger lies in possibilities of damage to the colonic wall from a sustained enteric pressure which may reach 24 centimeters of water. The cause of death in simple or non strangulated obstructions of the small bowel is not toxic absorption but loss of viability and subsequent permeability of the bowel wall leading to peritonitis.

Criteria for the diagnosis of obstruction are thoroughly discussed. Roentgenographic findings are of value in determining the approximate level and degree of obstruction as well as the efficacy of conservative decompression. The presence of peritoneal reaction is the important sign in differentiating simple from strangulating obstructions.

The therapy of bowel obstruction is summed up

as follows: (1) saline solution; (2) blood transfusions; (3) decompression with intubating duodenal tube; (4) operation. Transfusion of blood is particularly indicated in strangulating obstructions because of blood loss in the mesentery and bowel of the obstructed segment.

Conservative decompression, concerning which the author has made numerous experimental and clinical contributions to the literature is discussed at great length. A simple siphon device for maintaining suction is described. Criteria for determining the efficacy and limitations of suction are presented as well as are the indications for surgery. Some cases particularly those of partial obstruction will be relieved by suction. Aseptic enterostomy close to the obstruction level is the safest procedure in late cases with great distention. Surgical attack is still our most important therapeutic agent and should be resorted to promptly when conservative decompression fails.

In the opinion of the reviewer Wangensteen's work will long remain as the outstanding contribution to the treatment of acute obstruction. He has done a fascinating and intelligent piece of research. Could every doctor called upon to treat acute bowel obstruction be made to master the relatively few and simple concepts of the mechanism, diagnosis, and treatment of this catastrophe as herein presented the mortality would be reduced to a negligible percentage. J. R. BUCHSNER.

VOLUME 3 of *Post graduate Surgery*² the final volume has been released and is comparable in every way to the two previously issued. This large volume consisting of about 2000 pages has many points of interest. One part consisting of 164 pages is devoted to the surgery of the vascular system. Of this 56 pages are given over to a discussion of the surgery of the heart. This section is complete and contains all new material and is an excellent compilation of the data of the day pertaining to the subject. Probably the outstanding part of the volume is that devoted to the lymphatic system. As one surveys practically every text of surgery definite information pertaining to the lymphatic system is either very brief or vague. Here is to be found a very comprehensive yet concise dissertation upon the subject. The material is prepared by several authors: three chapters by Rodney Maling and an interesting chapter on Hodgkin's lymphogranuloma by Sir Humphrey Rolleston and an impression of status thymoplymphaticus by R. Sleigh Johnson.

THE INFLUENCE OF THE SERUM PROTEIN ON THE MOTILITY OF THE SMALL INTESTINE

ROBERT P. BARDEN, M.D., WESLEY D. THOMPSON, M.D., I. S. RAVDIN, M.D., F.A.C.S.,
and IRVING L. FRANK, M.D., Philadelphia, Pennsylvania

IN two previous papers (1, 3) we have shown that the emptying time of the stomach of man and dog is markedly prolonged in the presence of a definite hypoproteinemias. In the dog the retardation of gastric emptying time occurred in the intact stomach and after various gastric short-circuiting operations, while in man we have studied this mechanism only in the presence of a gastric or duodenal lesion, and after gastric operations. In our studies the gastric emptying time varied inversely with the level of plasma protein. The implications of this relationship in surgical patients have been pointed out (5). The picture of obstruction in a patient who has recently undergone a gastric operation of the Billroth I or II type may be so striking as to suggest a mechanical defect, at the site of the new stoma, requiring a secondary operation, when in reality efforts directed toward a restoration of a normal serum protein level are more efficacious and not attended by so high a risk.

In the present study, we have studied the effect of hypoproteinemia on the small intestine. The methods employed were similar to

those reported in our previous papers. The plasma recovered by plasmapheresis was lyophilized by the method of Flosdorf and Mudd and retained under sterile conditions for intravenous infusion when it was desired to restore a normal serum protein concentration. The dogs were kept, for varying lengths of time, on a diet containing less than 1 per cent protein, but entirely adequate in every other respect including the known vitamins. In addition the animals were subjected to a variable number of plasmaphereses. Serum protein determinations were made upon each animal at frequent intervals. Gastro-intestinal studies were made at weekly intervals after the administration of a water-barium meal. The passage of barium through the small intestine was studied fluoroscopically and radiographically. Since the emptying of the small intestine was, in part at least, dependent on the emptying of the stomach, it was necessary to adopt some more independent index of motility. It was decided to take as an index of small intestinal motility the length of time required for barium to reach the cecum once a bolus had passed through the pylorus.

RESULTS

The first group of dogs was studied over a long period of time during which the blood proteins were reduced chiefly by diet. In each

From the Harrison Department of Surgical Research, Schools of Medicine, University of Pennsylvania, and the Department of Radiology, Hospital of the University of Pennsylvania, Philadelphia.
Submitted by Dr. Barden in partial fulfillment of the requirements for the degree of Doctor of the Medical Sciences, Graduate School of Medicine, University of Pennsylvania.
Dr. Thompson, Eli Lilly Fellow in Surgical Research.

Needless to say, it is a pleasure to recommend this volume to all medical students and to all practitioners who are interested in the subject of dermatology and syphilis as an excellent work from which the medical

student may grasp the fundamentals of dermatology and to which the practitioner may turn as a most valuable reference hand book.

CORRESPONDENCE

THE FRANCIS AMORY SEPTENNIAL PRIZE OF THE AMERICAN ACADEMY OF ARTS AND SCIENCES

IN compliance with the requirements of a gift under the will of the late Francis Amory of Beverly, Massachusetts, the American Academy of Arts and Sciences announces the offer of a septennial prize for outstanding work with reference to the alleviation or cure of diseases affecting the human genital organs to be known as the Francis Amory Septennial Prize. The gift provides a fund the income of which may be awarded for conspicuously meritorious contributions to the field of knowledge during the said septennial period next preceding any award thereof through experiment, study or otherwise in the diseases of the human sexual generative organs in general. The prize may

be awarded to any individual or individuals for work of extraordinary or exceptional merit in his field.

In case there is work of a quality to warrant it the first award will be made in 1940. The total amount of the award will exceed ten thousand dollars and may be given in one or more awards. It rests solely with the discretion of the Academy whether an award shall be made at the end of any given seven year period and also whether on any occasion the prize shall be awarded to more than a single individual.

While there will be no formal nominations and no formal essays or treatises will be required the Committee invites suggestions which should be made to the Amory Fund Committee care of the American Academy of Arts and Sciences, 28 Newbury Street, Boston, Massachusetts U S A.

Fig 7 Small intestinal pattern—water-barium meal in a normal dog.

Fig 8 Small intestinal pattern—after water-barium meal in animal which has become hypoproteinemic.

Fig 9 Small intestinal pattern—water-barium meal in an animal showing nutritional edema

In the first group, when the hypoproteinemic animals were placed upon a high protein diet, the gastric emptying and small intestinal motility quickly returned to normal. In the second group of animals, the same effect was produced by transfusions of the plasma which had been removed during the plasmapheresis.

The tissue edema which was shown to be chiefly responsible for the delay in gastric emptying time in our earlier experiments is, we believe, the chief factor in producing the retardation in motility of the small intestine.

During the present study it was found that the pattern of the barium-filled small intestine became quite bizarre and abnormal as the concentration of the serum proteins fell, and that this pattern was a reflection of the altered physiology in the small intestine, associated with the hypoproteinemic state. This observation merely emphasizes the importance of the small intestinal pattern as a reflection of systemic disease, a relationship which has been discussed in several recent papers (4, 6). Figures 7, 8, and 9 show this change as it occurred in one of our animals.

CONCLUSION

The present paper extends our former study of the relation of serum protein concentrations

to gastro-intestinal activity. It has been demonstrated that a reduction in the concentration of the serum proteins is associated with a marked retardation of the passage of a water-barium meal through the small intestine of the dog. Concomitant with this physiological change there is an anatomical change, as evidenced by the change in the intestinal pattern. Both these alterations from the normal can be corrected by restoring the serum protein to a normal level either by diet or transfusions of lyophilized plasma.

instance, the gastric emptying time behaved as we had been led to expect from our previous studies. The charts, Figures 1, 2, and 3 compare the serum protein concentration with the gastric emptying time and time necessary for a barium meal to reach the cecum. It was found that on a protracted low protein diet the animals lost weight at times developed ulcers, and were prone to lose their hair. This occurred even though adequate amounts of vitamin A and the B complex were present in the diet.

In order to eliminate the effect of an unrecognized dietary factor at work over a long period of protein restriction, a second group of dogs was rapidly rendered hypoproteinemc. This was accomplished largely by repeated plasmaphereses although the animals were placed on the low protein diet. Figures 4, 5, and 6 demonstrate the same constant relationship between the serum proteins and the small intestinal motility. Unlike the previous group these dogs were in excellent condition throughout the period of the experiment.

NON-INVASIVE POTENTIAL "CARCINOMA" OF THE CERVIX

CHARLES SUMMERS STEVENSON M D Baltimore Maryland

ELEMER SCIPIADES, Jr, M D, Budapest, Hungary

A STUDY of the most recent and best results of radiative and operative treatment of cervical cancer shows that, by and large, not more than one quarter of the cases are cured. Statistics reveal that cancer is the second most frequent cause of death in the Western World and that carcinoma of the uterus is responsible for about one third of the deaths from cancer in women.

In approximately 90 per cent of these cases it arises in the portio of the cervix, an organ which, like the tongue, skin and penis can be not only readily seen but also carefully scrutinized in a few minutes during the course of a routine physical examination. As has been reiterated, the operative and radiative types of therapy for this kind of carcinoma have about reached their peak of development and give no promise of any great further advancement in the near future. The most favorable statistics show that in those cases in which the cancer is still definitely limited to the cervix at the time radiative therapy is instituted about 52 per cent (Ward and Sackett) may gain a 5 year cure. This is accomplished only with frequent and careful check on their progress and with further radiation when required.

The average for several similar groups of cases given surgical treatment or combinations of both forms gives about a 50 per cent cure. In advanced cases one fifth or less are alive after 5 years (30-25). The inference from this is as Celsus is credited with having pointed out about 30 A.D. that the earlier in the course of the disease the diagnosis can be made the better the chance for cure. With the view of trying to assemble and study as large a group of early carcinomas as possible this work was undertaken.

From the Department of Gynecology of the Johns Hopkins Hospital and University.

Dr. Scipules, interne at the Seco d Women's Clinic of the Peter Pázmány University Hospital Budapest Hungary.

HISTORICAL

Cancer research was first centered upon the question of etiology, but none could be found comparable to the specific causal relationship of the gonococcus to gonorrhea. Research then turned, especially with those working on cervical carcinoma, to a study of the symptoms, and soon the asymptomatic phase was realized. The study of this, like that of prevention, brought investigators to consider the earliest forms of cancer.

The first mention of the general type of early cervical carcinoma with which this paper is concerned is found in the large work on carcinoma of the uterus by Schottlaender and Kermauner which was published in 1912. They noted the presence of a thin layer of surface carcinoma extending over the portio from the edge of a larger invasive growth. It completely replaced the normal epithelium, and was compared morphologically to the icing on a cake. These two workers considered it to be definite carcinoma and described its cells as being exactly similar to those of the main deep growth. They also mentioned its usual abrupt ending and junction with the normal stratified squamous epithelium of the portio. About 15 years ago Schiller who had worked under Kermauner began concentrated work on the genesis of tumors, and chose the cervix as his medium because of its accessibility and the frequency with which carcinoma develops there.

In his first paper on this subject published in 1927 (18), he points out the evidence against cervical carcinoma being caused by irritation. He describes what he calls beginning carcinoma of the cervix and states that it consists of a non invasive anaplastic epithelial growth usually located at the external os. Since the morphological characteristics of the cells are like those of the cells comprising an advanced carcinoma he designates these early non invasive lesions uncon-

ditionally as carcinoma. He also describes in detail the sharp and usually oblique border between the carcinoma and normal squamous epithelium, and mentions the frequent presence of vacuoles in those normal cells which are closely adjacent to the carcinomatous ones. He could find no evidence of precancerous cellular alteration, or of carcinoma in definite connection with erosion or repair. In the development of cancer he considers two changes, that of the surface epithelium into carcinoma, and, after a period, its invasion of the stroma. He describes the light superficial lymphocytic infiltration of the stroma beneath the surface carcinoma and believes it to be evidence of the conflict between the two types of tissue, the cancer cells, and those of the connective tissue. He believes that the normal cells lying immediately adjacent to the carcinomatous ones change very suddenly to cancer cells due to a "complete assimilatory metabolic change" resulting from the influence of the adjoining malignant cells. He feels that this change is irreversible and so rapid that no intermediary morphological stages are to be seen. General pathological opinion both here and in Europe does not completely support these hypotheses.

Schiller believes that metastasis may take place as soon as invasion has begun, and that all carcinomas, whether invasive or not, should receive radical treatment.

Contrary to Lahm's work, Schiller was unable to find *any* glycogen in carcinoma cells and so tried various stains with which to bring out this difference grossly. He finally was able to obtain good results using a weak aqueous iodine and potassium iodide solution (19). He points out (23) that although grossly these areas often differ little or none from the normal epithelium of the portio they are sometimes dull, white, opaque, and slightly wrinkled. In serial sections of cervixes from 425 panhysterectomies, Schiller found 6 incipient "carcinomas," an occurrence of 1.41 per cent.

The American literature covering the pathology of this type of early carcinoma of the cervix is rather meager. One of the first reported cases of early carcinoma was that of Cullen in 1921 (2). A few of the recent notable papers in this group are those of Novak (13,

14), Martzloff (9, 10), Norris, Broders, Pemberton and Smith (16, 17), TeLinde, Freedman, and Henriksen (5). Novak, Martzloff, and some others have held the view that as long as the intra-epithelial changes are not invasive, the lesion is not malignant, and since it is not malignant it cannot be called "cancer." On the other hand Graves, Smith and Pemberton, Broders, and some others have agreed with Schiller, believing that these growths are cancer as soon as the cells have assumed the morphological characteristics common to all cancer cells. Thus we find that pathologists are divided upon the questions as to whether these non-invasive lesions inevitably become invasive and as to whether they can legitimately be called cancer.

GENERAL DISCUSSION

The studies, begun by Schottlaender and Kermauner and carried on by Schiller, on early carcinoma of the cervix have been a great contribution and have called the attention of the medical world to this important pathological condition. There are many, as was previously stated, who do not agree with Schiller in his calling non-invasive growths definite cancer. Lubarsch, Frank, Menne, MacCallum, Novak (13), Martzloff (9), and others disagree with him on this point. However they do believe that these lesions are in some way related to carcinoma and may develop into the invasive destroying growth commonly recognized as cancer. It is their view that without heterotopia these lesions cannot be looked upon as cancer, as the inherent connotation and original meaning of this word is "an invasive destroying growth." In favor of their side of the question is the fact that the word "cancer" was used long before the individual characteristics of malignant cells were known. In addition, although "carcinoma" is a more recent term it has always been used synonymously with "cancer" when the growth was composed of malignant epithelial cells.

One of us (C S S) also agrees with the viewpoint that these non-invasive lesions definitely may become typical, destructive and invasive cancers, and suggests that they be called "non-invasive potential carcinomas"

NON-INVASIVE POTENTIAL "CARCINOMA" OF THE CERVIX

CHARLES SUMMERS STEVENSON M D, Baltimore, Maryland

ELEMER SCIPIADES, Jr, M D, Budapest Hungary

A STUDY of the most recent and best results of radiative and operative treatment of cervical cancer shows that, by and large, not more than one quarter of the cases are cured. Statistics reveal that cancer is the second most frequent cause of death in the Western World and that carcinoma of the uterus is responsible for about one third of the deaths from cancer in women.

In approximately 90 per cent of these cases it arises in the portio of the cervix, an organ which, like the tongue, skin and penis can be not only readily seen but also carefully scrutinized in a few minutes during the course of a routine physical examination. As has been reiterated, the operative and radiative types of therapy for this kind of carcinoma have about reached their peak of development and give no promise of any great further advancement in the near future. The most favorable statistics show that in those cases in which the cancer is still definitely limited to the cervix at the time radiative therapy is instituted about 52 per cent (Ward and Sackett) may gain a 5 year cure. This is accomplished only with frequent and careful check on their progress and with further radiation when required.

The average for several similar groups of cases given surgical treatment or combinations of both forms gives about a 50 per cent cure. In advanced cases one fifth or less are alive after 5 years (30-25). The inference from this is, as Celsus is credited with having pointed out about 30 A D., that the earlier in the course of the disease the diagnosis can be made the better the chance for cure. With the view of trying to assemble and study as large a group of early carcinomas as possible this work was undertaken.

From the Department of Gynecology of the Johns Hopkins Hospital and University
Dr Scipades, interne at the Second Women's Clinic of the Peter Pázmány University Hospital Budapest Hungary

HISTORICAL

Cancer research was first centered upon the question of etiology, but none could be found comparable to the specific causal relationship of the gonococcus to gonorrhea. Research then turned, especially with those working on cervical carcinoma, to a study of the symptoms, and soon the asymptomatic phase was realized. The study of this, like that of prevention brought investigators to consider the earliest forms of cancer.

The first mention of the general type of early cervical carcinoma with which this paper is concerned is found in the large work on carcinoma of the uterus by Schottlaender and Kermauner which was published in 1912. They noted the presence of a thin layer of surface carcinoma extending over the portio from the edge of a larger invasive growth. It completely replaced the normal epithelium, and was compared morphologically to the icing on a cake. These two workers considered it to be definite carcinoma and described its cells as being exactly similar to those of the main deep growth. They also mentioned its usual abrupt ending and junction with the normal stratified squamous epithelium of the portio. About 15 years ago, Schiller, who had worked under Kermauner began concentrated work on the genesis of tumors, and chose the cervix as his medium because of its accessibility and the frequency with which carcinoma develops there.

In his first paper on this subject, published in 1927 (18) he points out the evidence against cervical carcinoma being caused by irritation. He describes what he calls 'beginning carcinoma' of the cervix and states that it consists of a non invasive anaplastic epithelial growth usually located at the external os. Since the morphological characteristics of the cells are like those of the cells comprising an advanced carcinoma he designates these early non invasive lesions uncon-

Fig 7, left Case 4 (Gyn Path. 27258). The "carcinoma" here has grown down into and lined a gland. The portion which covers the surface (upper right) is thinned out apparently due to the fact that the superficial spinal cells have been eroded away. In the gland they are intact and compose the major portion of the growth. A few of the spinal cells are multinucleated; the one at *A* is seen to contain 5 nuclei under the microscope. The basement membrane of the gland and the layer of basal cells of the "carcinoma" are intact. $\times 55$

Fig 8 Case 7 (Gyn Path. 30818). The "carcinoma" has grown into and lined a superficial gland. As in Figure 7 the superficial spinal cells remain intact and make up a large portion of the growth. Some fairly large hyperchromatic nuclei can be found in the superficial cells. $\times 50$

tissue from about four thousand cases, picking from them all those which had any suggestion of epithelial hyperactivity or anaplasia exclusive of the cases which showed invasive carcinoma. We then separated these into two groups, those in which the cells showed definite carcinomatous change and those in which we believed the epithelium to be merely hyperactive. As a result we had a few sections which appeared to show non-invasive "early carcinoma." Realizing, as Schottlaender, Ker-

mauner, and Schiller have pointed out, that any of these might be merely the surface edge of a large advanced carcinoma, we looked through our files for any further pathological material on these patients. As a result of this we found that several of the biopsies had come from the external os and had contained part of an outer extension from a larger carcinoma situated up in the cervical canal, or that they were taken from the edge of a small ulceration on the portio, which on shortly repeated

Fig 9

Fig 10

Fig 11

Fig 9 Case 12 (Gyn Path. 40282). This is a relatively high power photomicrograph showing the detail of a typical oblique border between the "carcinoma" (on the right) and the normal stratified squamous epithelium (on the left). The hyperchromatism of the lesion is marked and causes it to stand out sharply from the adjacent normal cells. The border is much more oblique than usual, the superficial part begins at *A* and the basal part extends far laterally under the normal epithelium to *B*. A large mitotic figure is seen at *C*. $\times 95$

Fig 10. Case 13 (Gyn. Path. 40900). The lesion is characterized chiefly by the large variously shaped dark staining nuclei scattered among many similar sized or smaller light staining ones. A few of the superficial nuclei are large and darkly stained. $\times 55$

Fig 11 Case 13 (Gyn Path. 41429). This is another biopsy section, taken 5 months after that shown in Figure 10. The general appearance is similar to that of the biopsy specimen taken from the same patient 5 months previously, the same "level" of activity being present. $\times 55$

Fig 1

Fig 2

Fig 3

Fig 1 Case 2 (Gyn Path 25171) The lesion is essentially limited to the squamous epithelium to the left of the gland mouth A The sharply cut edge of the carcinoma at the extreme left has curled inwardly probably in the fixing solution $\times 25$

Fig 2 Case 2 (Gyn Path 25171) The nearly complete absence of stratification the intact basal layer of cells and

the closely packed large anaplastic epithelial cells denote the lesion $\times 75$

Fig 3 Case 2 (Gyn Path 25171) Despite the thickness of the section some large 'black' nuclei can be seen with much smaller light staining ones nearby At the upper left corner the most superficial cells are seen to contain large very darkly stained nuclei $\times 300$

of the cervix The large invasive carcinomas which developed, as will be described, in two of our cases following the biopsy which showed them in their non invasive but potential state, coupled with the few other similar known cases, are evidences in favor of this view

The other writer of this article (E S Jr) believes, with Schiller and his adherents, that the presence of the malignant morphological characteristics in the individual cells comprising these lesions is sufficient for the unqualified pathological diagnosis of carcinoma of the cervix, the presence or absence of invasion being of no practical diagnostic importance The fact that many cervixes from

which the original biopsy contained a non invasive "carcinoma," on serial sectioning show a few small tongues of invasion, points, he believes to the danger of not calling them carcinoma These two viewpoints are illustrative of the differences of opinion among various workers on cancer problems

METHOD

On the basis of the present knowledge of this subject, we recently undertook to examine all the cervical tissue in the files of the Gynecological Pathology Laboratory of the Johns Hopkins Hospital We carefully studied some ten thousand microscopic sections of cervical

Fig 4

Fig 5

Fig 6

Fig 4 Case 2 (Kelly Hospital Path 13414) This is a typical section of the large invasive carcinoma which developed after 8 years apparently from remains of non invasive potential carcinoma pictured in Figures 1 2 and 3 $\times 65$

Fig 5 Case 2 (Kelly Hosp Path 13414) High power detail of the carcinoma in Figure 4 Note the large round and oval darkly stained nuclei similar to those in Figure 3 $\times 265$

Fig 6 Case 3 (Gyn Path 26010) The carcinoma extends through A to B and is separated from the normal squamous epithelium by a fairly sharp border Of chief interest in this section is the dense localized infiltration of lymphocytes in the stroma which are present just beneath the lesion and which extend a short distance laterally beyond it $\times 18$

Fig 7, left Case 4 (Gyn Path 27258) The "carcinoma" here has grown down into and lined a gland. The portion which covers the surface (upper right) is thinned out apparently due to the fact that the superficial spinal cells have been eroded away. In the gland they are intact and compose the major portion of the growth. A few of the spinal cells are multinucleated; the one at A is seen to contain 5 nuclei under the microscope. The basement membrane of the gland and the layer of basal cells of the "carcinoma" are intact. $\times 55$

Fig 8 Case 7 (Gyn Path 30818) The "carcinoma" has grown into and lined a superficial gland. As in Figure 7 the superficial spinal cells remain intact and make up a large portion of the growth. Some fairly large hyperchromatic nuclei can be found in the superficial cells. $\times 50$

tissue from about four thousand cases, picking from them all those which had any suggestion of epithelial hyperactivity or anaplasia exclusive of the cases which showed invasive carcinoma. We then separated these into two groups, those in which the cells showed definite carcinomatous change and those in which we believed the epithelium to be merely hyperactive. As a result we had a few sections which appeared to show non-invasive "early carcinoma." Realizing, as Schottlaender, Ker-

mauner, and Schiller have pointed out, that any of these might be merely the surface edge of a large advanced carcinoma, we looked through our files for any further pathological material on these patients. As a result of this we found that several of the biopsies had come from the external os and had contained part of an outer extension from a larger carcinoma situated up in the cervical canal, or that they were taken from the edge of a small ulceration on the portio, which on shortly repeated

Fig 9

Fig 11 Case 13 (Gyn Path 41429). This is another biopsy section, taken 5 months after that shown in Figure 10. The general appearance is similar to that of the biopsy specimen taken from the same patient 5 months previously, the same "level" of activity being present. $\times 55$

Fig 12

Fig 13

Fig 14

Fig 12 Case 13 (Gyn Path 45520) This section is through the anterior lip of the cervix. The carcinoma covers the entire portio extending from the general region of the external os (lower right corner) out over the surface almost to the vaginal wall (upper left corner). No points of invasion are seen $\times 20$.

Fig 13 Case 13 (Gyn Path 45520) This is a typical part of the superficial carcinoma which covers the portio of both the anterior and posterior lips of the cervix. This field was taken from a point 2 millimeters from the area shown in Figure 14. This carcinoma when compared to those in Figures 10 and 11 is seen to bear a striking re-

semblance to the lesions found in these biopsy specimens taken 2½ and 3 years previously from the same cervix $\times 70$.

Fig 14 Case 13 (Gyn Path 45520) This field is from the posterior lip of the cervix and is in the same section as the field shown in Figure 13. The surface (upper left) is covered with somewhat inactive and eroded superficial carcinoma. There is a fairly large tongue of quite active carcinoma growing into the stroma from the surface. Its component cells show not only the anaplastic characteristics of those in the original surface lesion but in addition there are many mitoses and the hyperchromatism is more marked $\times 70$.

biopsy had been proved a moderately advanced carcinoma. Several cases were apparently bona fide non invasive "carcinomas," but had to be discarded when careful serial sectioning of the rest of the cervical tissue disclosed a few small tongues of early invasion. Thus, after submitting each case to an impartial study, only 18 remained which we could definitely classify as "non invasive"

carcinoma of the cervix. All of our diagnoses were very kindly checked and confirmed by Dr. Walter Schiller and Dr. Emil Novak.

Brief histories of the 18 cases follow with pathological description when important.

CASE 1 (Path 23772) F. L. aged 57 years. Patient had one child at 45 preceded by three spontaneous abortions. She was seen on February 21, 1918 and complained of complete uterine prolapse.

Fig 15

Fig 16

Fig 17

Fig 15 Case 13 (Gyn Path 45520) This is another section through the posterior lip. It shows the carcinoma covering the surface like icing on a cake, and at one point there is an invading tongue of actual carcinoma. The stroma contains several circumscribed masses of the growth which are identical in appearance with the tongue seen in Figure 14. In them the transitional cell predominates although the borders are composed of several layers of spindle cells $\times 16$.

Fig 16 Case 16 (Gyn Path 44092) This photograph includes the entire thickness of a non invasive carcinoma with the intact basal layer on the extreme right and the roughened surface on the extreme left. Five mitoses are

denoted by 1. The variations in the size, shape, and staining density of the nuclei is rather marked. There is practically no erosion of the surface as the atrophic spinal cells are still present and even their black pyknotic nuclei show more than the usual variation in size and shape $\times 190$.

Fig 17 Case 18 (Gyn Path 45133) The carcinoma here has been stripped away from its stroma and by some artifact of fixing or sectioning rotated so as to face an adjacent portion of the cervix (lower right). The large variably shaped extremely dark staining nuclei are very prominent and some of them are present in the most superficial cells. This finding is one nearly infallible characteristic of non invasive potential carcinoma $\times 95$.

for the last 6 months. She had worn a pessary for 2 years previous to this. Examination showed lacerations of the perineum and complete uterine prolapse. A trachelorrhaphy (Emmett), anterior and posterior colporrhaphy, and Wertheim suspension of the uterus were done. Pre-operative examination of the cervix had shown that it was slightly enlarged and edematous and that the portio was smooth and pink despite moderately deep transverse lacerations. The microscopic section from one trachelorrhaphy specimen (this V-shaped wedge is usually taken so as to include all of the laceration) shows a rather large block of tissue which has obviously been trimmed down. At one end of it a superficial gland opens to the surface, and around its mouth there is a very small localized non-invasive "carcinoma." Its cells are generally large and they show a marked variation in size and shape. Many, both large and small, are very deeply stained. Similarly, many are lightly stained regardless of size. The surface is slightly eroded, and the usual superficial, flat, atrophic spinal cells, in which the nuclear remains are normally marked by a small dark dot, are replaced by large cells which contain large round or oval nuclei and have rather indefinite cytoplasmic borders. In many instances a cell can be found which has a diameter four times that of its neighbor and their staining densities may be similar or at opposite extremes. The finding of about 12 mitoses per high power field indicates a relatively hyperactive growth. This patient died of hypertension with coronary thrombosis in November, 1935, at the age of 74 years. Either all of the growth was removed or that which remained did not become a cancer over a period of 17 years.

CASE 2 (Path 25171, K-13414) C. P., aged 28 years when first seen June 30, 1919. She had had 4 children and was "badly torn" with the last one 3 years before. She came in because of "bearing down pains" since the birth of her last baby, leucorrhea for the past year, and occasional slight spotty intermenstrual vaginal bleeding for this same period. Examination showed a relaxed vaginal outlet, rectocele, and lacerations of the cervix. She then had a trachelorrhaphy, posterior colporrhaphy, and appendectomy. Pre-operative examination showed the cervix to be enlarged, firmer than usual, and slightly elongated. It pointed in the vaginal axis due to retroposition of the uterus. There were deep transverse lacerations, more so on the left, and there was moderate eversion on both lips around the external os. The portio was smooth and clean. The microscopic section from one trachelorrhaphy specimen shows a junction of the cylindrical cervical epithelium and the squamous type on one surface. As Figure 1 shows, the carcinomatous cells are limited to a point on one side of the mouth of a large cervical gland, and there is the afore mentioned junction on the other side. The "carcinoma" is 0.5 millimeter long and its left edge is sharply cut off. This is either the result of trimming the block, or, since it looks as though it has curled in, may well be the edge of the specimen as re-

moved at operation. One thus might conclude that the non-invasive potential carcinoma extended out over the portio and all of it was not removed. The higher power microscopic detail is about the same as that in Case 1, and a rough idea of it can be obtained from Figures 2 and 3. Unhappily the section is a thick one and the photographs are not what they might be. The variations in nuclear sizes, shapes and staining densities are of average degree except that hyperchromatosis is rather marked in a few cells. There is no definite spindle-shaped basal cell, the round or oval nucleated transitional type comprising nearly the entire thickness of the epithelium. Consequently, despite a few flattened superficial cells, there is a rather marked absence of stratification. The presence of about 8 mitoses per high power field indicates that it is a fairly hyperactive growth.

This patient next came to the hospital May 4, 1921, complaining of leucorrhea, backache, and profuse menstruation. At this time the cervix was smooth, firm, nearly flush with the vaginal vault, and there was a profuse leucorrhea exuding from the external os. A large ovarian retention cyst was found and removed. The cervix was not treated.

On February 28, 1928, she came to the hospital again complaining of continuous vaginal bleeding since the onset of her last recognizable menstrual period 4 months before. Examination disclosed a large cauliflower-like tumor replacing the cervix and filling the vaginal vault. It was friable, firm, and bled upon manipulation. There was thickening and induration of the vaginal vault and both broad ligaments half way laterally to the pelvic wall. In spite of radium treatment she died in a little over a year. A biopsy of this tumor (slide K-13414) shows several pieces of tissue made up of irregular large solid masses and thick columns of anaplastic epithelial cells (Fig. 4). These cells have predominantly large, round to oval nuclei which show all the variations seen in the original non-invasive growth. A high power field gives a picture (Fig. 5) generally similar with that of the earlier carcinoma, as a comparison of the two photomicrographs will disclose. The diagnosis here was "epidermoid carcinoma of the cervix, transitional cell type." Since the transitional type of cell predominated in both growths it may indicate that the relative degree of cell differentiation in the original anaplastic cells has not changed with invasion.

CASE 3 (Path 26010) M. M., aged 38. She had had one child and came to the hospital June 3, 1920, complaining of leucorrhea, backache, complete prolapse of the uterus for 3 years, and metrorrhagia for 5 weeks. Examination showed obesity and third degree uterine descensus. She had a conservative panhysterectomy and left oophorectomy. Pre-operative examination of the cervix showed it to be twice normal size, edematous, and tender. It was moderately deeply lacerated transversely and was eroded around the external os. A microscopic slide shows a cross section through one lip of the entire cervix. There is a non-invasive potential "carcinoma" which begins at

the external os and extends out over the lip for 8 millimeters. As Figure 6 poorly demonstrates the anaplastic cellular changes are marked the basal layer is intact and there is the usual oblique border. In addition there is a strikingly dense superficial infiltration of lymphocytes in the stroma as has been described by Schiller. In typical fashion it extends a short distance beyond the edge of the lesion, and the significance of this may be that the adjacent as yet non anaplastic cells are in some manner under the influence of the carcinomatous ones. The fact that they are morphologically normal and do not even show any structural evidences of hyperactivity does not exclude the possible presence of a profound physiological change and some believe that such might be the case. Unfortunately all efforts to trace this patient proved fruitless.

CASE 4 (Path 27258) G V aged 46 years who had had 12 children and two abortions came to the hospital complaining of severe lower abdominal pain, leucorrhea and dysuria for 1 month. Examination showed a relaxed vaginal outlet. She had a trachelorrhaphy and an anterior and posterior colporrhaphy. Before operation the cervix was slightly enlarged and irregular but the portio was relatively smooth. There were very deep transverse lacerations extending out to the vaginal vault which bled on examination. A microscopic section of one trachelorrhaphy specimen shows a non invasive potential carcinoma beginning in the laceration exactly at the junction of the columnar and stratified squamous epithelium and it extends out over the portio for 6 millimeters. The nuclear variations in size shape and staining density are very marked (Fig. 7). The basal layer consists of about one layer of spindle cells and is intact. Superficial to this there are about two layers of the characteristically round nucleated transitional cells. The main epithelial thickness lies superficial to this and is made up of typical pinial cell which have a prominent and relatively large amount of grayish pink cytoplasm with rather definite cell borders. Their nuclei show marked anaplasia, as already mentioned and a few very large cells contain 5 and 6 nuclei clumped together in the center. Many mitoses can be found. As Figure 7 shows these anaplastic cells have grown down into a gland for a short distance. This phenomenon has been described by Nowak (13) Schiller and others and is no indication of invasion. This woman is alive and well and many biopsies of the now atrophic cervix have shown no suggestion of malignancy.

CASE 5 (Path 28559) M B aged 50 years upon being examined in the dispensary on May 2 1923 was found to have a cervical polyp. It was removed with the biopsy forceps. The microscopic slide shows a section through its entire length. There is a non invasive potential carcinoma 1 centimeter long on one surface well up and away from the base. It appears to arise about 6 millimeters from the cylindrical squamous cell junction and is chiefly apparent due to its marked hyperchromaticous. The section is too thick for photography but under the

microscope the malignant characteristics of the cells are obvious. The presence of about 16 mitoses per high power field denotes unusual hyperactivity. Some of the mitotic figures are tripolar and many show markedly uneven division of the chromosomes which, as Mendelsohn and others have pointed out is characteristic of malignant cells. This woman unfortunately could not be traced.

CASE 6 (Path 30583) J S aged 49 years a mother of 3 children came to the hospital on August 21, 1925. She complained of leucorrhea for 1 year and came to the hospital for verification of the diagnosis of cervical polyp made by her family physician. Examination revealed a polyp. It was resected and its base and the cervical canal were thoroughly cauterized with 30 per cent silver nitrate. Before operation the cervix had been very firm and normal in size and shape. A full length cross section of the polyp is found in the microscopic slide and it reveals a non invasive potential carcinoma 1 millimeter long which lies practically at the cylindrical squamous cell junction and extends down to the cut border at the base of the polyp. The woman is asymptomatic and recent biopsies of the cervix and scrapings from its canal show no evidence of malignancy.

CASE 7 (Path 30818) M C aged 38 years had had 4 children and 1 abortion and came to the hospital November 24 1925 complaining of moderate leucorrhea for 3 years and lower abdominal pain for 6 months. Examination revealed obesity and a relaxed vaginal outlet. A left sided trachelorrhaphy and an anterior vaginal repair were done. Before operation the cervix was described as being about normal in size and consistency and it was transversely lacerated more deeply on the left. The microscopic section of the tissue removed from the cervix shows the carcinoma to be practically limited to a shallow gland ingrowth (Fig. 8). It can be seen the growth is made up of relatively highly differentiated cell and roughly consists of equal amounts of transitional and spinal cells. While the lack of cell uniformity is not as striking as in some of the sections the wide differences in nuclear sizes and shapes are readily apparent. She is alive and well and has no symptoms suggestive of cervical carcinoma. In this case a biopsy cannot be obtained and we may thus assume that if all of the lesion was not removed the remaining portion has not become invasive after twelve years or has in some manner been destroyed.

CASE 8 (Path 31795) A B aged 56 years a mother of 6 children had had a hysterectomy 3 years before for uterine fibroids. She came to the hospital November 23 1926 complaining of leucorrhea for 3 years and slight post coital bleeding for 3 months. Examination showed the cervix (stump) to be slightly smaller than normal about 2 centimeters long and of average consistency. There was some erosion around the external os and a few lightly roughened dark red areas of erosion 7 millimeters in diameter were situated on both the anterior and posterior lips.

These bled slightly upon examination. Several biopsies of the portio were taken, the canal of the stump was curetted, and the cervix was thoroughly cauterized with the actual electrocautery. The section of the biopsied tissue contains a great many strips of stratified squamous epithelium and one wonders if any was left on the portio. The non-invasive potential "carcinoma" is limited to two of these strips, which, due to the hyperchromatosis, stand out sharply from the neighboring normal epithelium. This woman died of apoplexy at the age of 64, by which time she had not developed a gross clinical cervical carcinoma. If the growth was not either all removed or destroyed at the time of operation that which remained was non-invasive for 8 years at least.

CASE 9 (Path 33968) C. B., aged 34 years, a mother of two children, came to the hospital November 16, 1928, complaining of menorrhagia for 5 months and metrorrhagia for 2. Examination showed retroposition of the uterus and relaxation of the vaginal outlet. A trachelorrhaphy, anterior and posterior colporrhaphy, and suspension of the uterus were done. Pre-operative examination showed the cervix to be normal in size and consistency and slightly lacerated transversely. The microscopic slide of the trachelorrhaphy specimen contains several fragments of cervical tissue, 2 of which are partly covered by non-invasive "carcinoma." This patient is alive and well and has no symptoms of carcinoma of the cervix. A biopsy of the cervix cannot be obtained.

CASE 10 (Path 35546 and 35573). H. C., aged 34 years, a negress who claimed she had never been pregnant, and who had had gonorrhea recurring off and on since the age of 18, came to the dispensary February 11, 1930, complaining of menorrhagia for 1 year. She was found to have a large myomatous uterus and chronic salpingitis and had a hysterectomy and bilateral salpingectomy. Shortly after discharge the cervix was found to be slightly enlarged, soft, and roughened. There was some erosion of the portio around the os which bled following examination, there were superficial transverse lacerations. Several biopsy specimens were taken from the lacerations and the eroded areas. The microscopic section shows some semicircular fragments of cervical tissue, one of which is covered with a non-invasive potential "carcinoma." The nuclear variations are marked and there is some fairly obvious hyperchromatosis. The patient was given radium and is alive and well, and a small scarred nodule in the now contracted vaginal vault is all that marks the former location of the cervix. A biopsy shows only scar tissue covered with a very thin layer of markedly atrophic squamous epithelium.

CASE 11 (Path 35996) E. W., a 27 year old mother of 5 children, came to the hospital July 7, 1930, complaining of post-coital bleeding for 1 month. The cervix was of about normal size and shape, but was softer than usual. There was "a reddened area on the anterior lip" from which several biopsy specimens were taken. Under the microscope

one of the several fragments was found to be covered with a non-invasive "carcinoma." This patient was alive and well and without any symptoms of cervical carcinoma in July, 1936. She has never received any treatment for the lesion and at present cannot be located.

CASE 12. (Path. 40282) D. B., a 61 year old mother of 5 children, came to the hospital November 2, 1933, complaining of complete uterine descensus for 5 months. She had a Watkins interposition operation and a low cervical amputation. Before operation the cervix was found to be small, softer than normal, and bilaterally lacerated. The portio was smooth and there was slight eversion around the os. The microscopic slide includes a full sized section from each lip of the cervix. On one lip, for a distance of 1 millimeter, there is a non-invasive potential "carcinoma" which, due to its marked anaplasia, stands out sharply from the adjacent benign epithelium. At one edge (Fig 9) there is a typical sharp oblique border. The "carcinoma" shows an extreme degree of hyperactivity, there being about 27 mitoses per high power field over one area. This woman is alive and well, and the cervical stump looks normal. Biopsies from it and scrapings from the canal show no evidence of malignancy.

CASE 13 (Path 40900, 41429, and 45520). M. S., a 34 year old mentally retarded woman who had had 2 abortions, came to the hospital July 31, 1934, complaining of dyspareunia of 2 years' duration. She had contracted gonorrhea at the age of 21 years, following which she had had a bilateral salpingo-oophorectomy with its subsequent surgical menopause. The cervix was found to be small and of normal consistency. There were deep transverse lacerations, and the portio was otherwise smooth and normal except for a slight perioral reddening. Several biopsies were taken around the os. The microscopic slide of these shows two fragments of cervical tissue, the surface of one being partially covered by a non-invasive potential "carcinoma" (Fig 10) which totals 3 millimeters in length. The cells show an average amount of malignant anaplasia manifested chiefly by the wide variations in nuclear sizes and shapes. The variations of staining density are of average diversity and there is a moderate amount of hyperchromatosis. The growth looks very inactive and only one mitotic figure can be found. There is a moderate infiltration of lymphocytes in the stroma beneath the lesion. At that time the slide was considered suspicious but the patient refused to allow further biopsy and left the hospital. She returned January 8, 1935, complaining of lower abdominal pain. The cervix was found to be as it was 5 months previously except that now the portio was smooth and normally pink. Biopsy specimens were again obtained from the cervix and the canal was curetted, but the scraping produced no tissue. Under the microscope the fragments of cervical tissue were found to be normal except that the surface of one of them was covered with a 4 millimeter length of non-invasive potential "carcinoma." A small piece of

the external os and extends out over the lip for 8 millimeters. As Figure 6 poorly demonstrates, the anaplastic cellular changes are marked the basal layer is intact and there is the usual oblique border. In addition there is a strikingly dense superficial infiltration of lymphocytes in the stroma as has been described by Schiller. In typical fashion it extends a short distance beyond the edge of the lesion, and the significance of this may be that the adjacent as yet non anaplastic cell are in some manner under the influence of the 'carcinomatous' ones. The fact that they are morphologically normal and do not even show any structural evidences of hyperactivity does not exclude the possible presence of a profound physiological change and some believe that such might be the case. Unfortunately all efforts to trace this patient proved fruitless.

CASE 4 (Path 27258) G V aged 46 years, who had had 12 children and two abortions, came to the hospital complaining of severe lower abdominal pain, leucorrhea and dysuria for 1 month. Examination showed a relaxed vaginal outlet. She had a trachelorrhaphy and an anterior and posterior colporrhaphy. Before operation the cervix was slightly enlarged and irregular, but the portio was relatively smooth. There were very deep transverse lacerations extending out to the vaginal vault, which bled on examination. A microscopic section of one trachelorrhaphy specimen shows a non invasive potential carcinoma beginning in the laceration exactly at the junction of the columnar and stratified squamous epithelium and it extends out over the portio for 6 millimeters. The nuclear variations in size, shape and staining density are very marked (Fig 7). The basal layer consists of about one layer of spindle cells and is intact. Superficial to this there are about two layers of the characteristically round nucleated transitional cells. The main epithelial thickness lies superficial to this and is made up of typical spinal cells which have a prominent and relatively large amount of grayish pink cytoplasm with rather definite cell borders. Their nuclei show marked anaplasia as already mentioned and a few very large cells contain 5 and 6 nuclei clumped together in the center. Many mitoses can be found. As Figure 7 shows these anaplastic cells have grown down into a gland for a short distance. This phenomenon has been described by Novak (13). Schiller and others and is no indication of invasion. This woman is alive and well and many biopsies of the now atrophic cervix have shown no suggestion of malignancy.

CASE 5 (Path 28559) M B aged 50 years upon being examined in the dispensary on May 2, 1923, was found to have a cervical polyp. It was removed with the biopsy forceps. The microscopic slide shows a section through its entire length. There is a non invasive potential carcinoma 1 centimeter long on one surface well up and away from the base. It appears to arise about 6 millimeters from the cylindrical squamous cell junction and is chiefly apparent due to its marked hyperchromatism. The section is too thick for photography but under the

microscope the malignant characteristics of the cells are obvious. The presence of about 16 mitoses per high power field denotes unusual hyperactivity. Some of the mitotic figures are tripolar and many show markedly uneven division of the chromosomes which as Mendelsohn and others have pointed out is characteristic of malignant cell. This woman unfortunately could not be traced.

CASE 6 (Path 30583) J S aged 49 years a mother of 3 children came to the hospital on August 21, 1925. She complained of leucorrhea for 1 year and came to the hospital for verification of the diagnosis of cervical polyp made by her family physician. Examination revealed a polyp. It was resected and its base and the cervical canal were thoroughly cauterized with 30 per cent silver nitrate. Before operation the cervix had been very firm and normal in size and shape. A full length cross section of the polyp is found in the microscopic slide and it reveals a non invasive potential carcinoma 1 millimeter long which lies practically at the cylindrical squamous cell junction and extends down to the cut border at the base of the polyp. The woman is asymptomatic and recent biopsies of the cervix and scrapings from its canal show no evidence of malignancy.

CASE 7 (Path 30818) M C aged 38 years had had 4 children and 1 abortion and came to the hospital November 24, 1925 complaining of moderate leucorrhea for 3 years and lower abdominal pain for 6 months. Examination revealed obesity and a relaxed vaginal outlet. A left sided trachelorrhaphy and an anterior vaginal repair were done. Before operation the cervix was described as being about normal in size and consistency and it was transversely lacerated more deeply on the left. The microscopic section of the tissue removed from the cervix shows the carcinoma to be practically limited to a shallow gland (ingrowth) (Fig 8). As can be seen the growth is made up of relatively highly differentiated cells and roughly consists of equal amounts of transitional and spinal cells. While the lack of cell uniformity is not as striking as in some of the sections the wide differences in nuclear sizes and shapes are readily apparent. She is alive and well and has no symptoms suggestive of cervical carcinoma. In this case a biopsy cannot be obtained and we may thus assume that if all of the lesion was not removed the remaining portion has not become invasive after twelve years or has in some manner been destroyed.

CASE 8 (Path 31295) A B aged 56 years a mother of 6 children had had a hysterectomy 3 years before for uterine fibroids. She came to the hospital November 23, 1926 complaining of leucorrhea for 3 years and slight post coital bleeding for 3 months. Examination showed the cervix (stump) to be slightly smaller than normal about 2 centimeters long and of average consistency. There was some erythema around the external os and a few slightly roughened dark red areas of erosion 7 millimeters in diameter were situated on both the anterior and posterior lip.

had an amputation of the cervix, an anterior and posterior colporrhaphy, and a dilatation and curettage. Before operation the cervix was found to be small, firm, and bilaterally lacerated. The portio was clean, smooth, and pink, except for very slight injection around the os. Careful gross examination of the cervix with a magnifying glass after operation disclosed no peculiar conditions of the portio epithelium, even though we knew from the section the position of the "carcinoma" around the os. The microscopic slide contained a section from each lip of the cervix. A non-invasive potential "carcinoma" was found at the external os on the anterior lip, and, in a thin layer, it extended out over the portio for nearly 1 centimeter. This woman was given radium, and a recent biopsy examination of the cervical stump showed no evidence of malignancy.

CASE 18 (Path 45133). N. S., aged 56 years, who had had two children and three miscarriages, came to the hospital June 11, 1937, complaining of a "sore growth at the outlet of the bladder," dysuria, a persistent slight vaginal discharge, and "a feeling as though the womb was falling out" of the pelvis. Examination disclosed chronic inflammation and some prolapse of the urethral mucosa, a relaxed vaginal outlet with cystocele and rectocele, and slight descensus of the uterus. The cervix was small, roughened, and irregular, and transversely lacerated. The portio was generally injected and there was a zone around the os which was sunken, granular, irregular, red, and which bled easily on examination. Several biopsy examinations were taken from this perioral zone of erosion. The microscopic slide showed three small fragments of cervical tissue, near one of which there was a detached, thin strip of non-invasive potential "carcinoma" 2 millimeters long (Fig. 17). The hyperchromatic nuclei cause it to stand out sharply from the normal squamous epithelium of the neighboring fragments. There was only about one mitosis per high power field. This patient was given radium and thus far has shown no evidence of the persistence of the lesion.

An analysis of these 18 cases shows that all the women were or had been married; 41 per cent were under the age of 40, and their average age was 46 years when the carcinoma was first discovered. The two extremes in age were 27 and 62 years. The menstrual onsets included the ages of 12 through 16, the average age being 14 years. Seven of the patients were beyond normal menopause, the average time being 7 years. One had had a surgical menopause as the result of a bilateral salpingo-oophorectomy, 2 had had hysterectomies. Five had had some dysmenorrhea. In all cases the menstrual durations and intervals were within normal limits. All but one woman had been pregnant, and the series had had a total

of 53 babies and 14 abortions, an average of 3.0 babies and 0.8 abortions per woman or 3.8 pregnancies. One woman had had 12 babies and 3 had had only 1. Four women had had prolapse of the uterus, 2 with procidentia and 2 with second degree; 3 of these had worn pessaries. Three had had gonorrhea; 1 had also had buboes. The mother of 1 woman had died of cancer. Nine, or 50 per cent, complained of leucorrhea. Seven had had metrorrhagia, and in 2 of these it had been post-coital. Three women were found to have retroposition of the uterus.

Seven came to the hospital because of slight metrorrhagia (9 cervixes showed eversion or erosion and 7 bled upon examination), 4 came because of prolapse of the uterus, and 2 came because of lower abdominal pain and leucorrhea. One woman came for each of the following causes: infectious arthritis, dysuria, dyspareunia, menorrhagia apparently due to uterine myomas, and for verification of the diagnosis of cervical polyp made by her family physician.

Thirteen of the cervixes, or 72 per cent, were transversely lacerated, and in 3 of these the lacerations were very deep and extended down to the vaginal wall. Thirteen cervixes showed eversion, erosion, or some injection around the os, while 4 were hypertrophied. In 3 cases the "carcinoma" was found in a cervical stump. The original pathological diagnosis in 9 cases was "epidermoid carcinoma of cervix," while in 7 it was "chronic cervicitis"; both polyps were called benign. As far as we were able to determine, from making serial sections of all available tissue on these cases, all of the growth was apparently removed with the specimen in 4 of the 5 trachelorrhaphies, the 2 amputations, and the 1 panhysterectomy. In 9 of the 11 other patients subjected merely to biopsy, sectioning of the remaining available tissue did not allow us to make up our minds definitely on this point, although in one instance it might well have all been removed (Case 8). Five of the "carcinomas" were found in the V-shaped wedge of cervical tissue removed when the trachelorrhaphy was done.

In most of Schiller's cases the growth has been found centered at the external os at the

stroma remained attached to it and was infiltrated with lymphocytes (Fig 11). The anaplasia of the cells was marked and the general picture was identical with that seen 5 months previously. The same activity level prevailed as no mitoses could be found.

This woman again refused any treatment and returned to her home in one of the Southern states. When we finally located her she was extremely ill with pernicious anemia but was without any symptoms of cervical cancer. She died of the anemia July 15, 1937, and we were very fortunate to obtain the cervix for pathological study. Grossly it was normal in size, shape and consistency and the portio appeared to be smooth and shiny to the unaided eye. On section it showed nothing unusual. It was cut serially into blocks from each of which microscopic sections were made. One of these (Fig 12) showed the anterior lip of the cervix to be nearly entirely covered even out to the vaginal vault with non-invasive carcinoma. A section from the posterior lip (Fig 13) showed the non-invasive carcinoma again covering the portio but here (Fig 14) there was also a tongue of apparently fresh invasion extending from it into the stroma. The non-invasive portion on the surface (Fig 13) was identical in appearance with the biopsy specimen taken 3 years (Fig 10) and 2½ years (Fig 11) previous to the patient's death and it likewise shows no mitoses. In contrast the cells comprising the invasive tongue are larger, more "active" in appearance and quite a few mitoses are readily found. Other sections through the posterior lip of the cervix show somewhat similar tongues of invasion and in addition the body of the cervix contains many bundles of the same carcinoma (Fig 15). Thus we have a case of asymptomatic carcinoma of the cervix in which invasion from the pre-existent non-invasive lesion probably began an estimated 2 to 4 months before the death of the patient. Unfortunately an autopsy could not be done on this case and we do not know if there were any metastases or extensions of the growth into the parametrial tissue. It is the opinion of her attending physicians that her death was due entirely to refractory pernicious anemia.

CASE 14 (Path 42430) N. I., a 52 year old mother of two children, came to the hospital complaining of joint pains for 9 months and was found to have infectious arthritis. She was referred to the gynecology department for a pelvic check up with regard to a possible focal infection there. Examination showed that the cervix was about normal in size, shape and consistency. The anterior lip was smooth but the posterior lip was slightly adherent to the posterior vaginal wall and these adhesions were injected and bled slightly following examination. Biopsy specimens were taken from both lips. The microscopic section showed two fragments of cervical tissue one of which was covered on one side with normal stratified squamous epithelium and a very short length of thin non-invasive carcinoma. This patient was given radium directly to the portio and

is alive and well. Recent examination has shown no evidence of cervical carcinoma.

CASE 15 (Path 43321, 43366 and 43481) L. C., a 46 year old Russian Hebrew woman who had had one child and two abortions, came to the hospital May 6, 1936 complaining of metrorrhagia for 3 days 1 month before. She had had a subtotal hysterectomy at the age of 25 years and she had not menstruated since. Examination disclosed obesity, a hypertension of 220/150 and diabetes. The cervical stump was found to be small of normal shape and consistency and the portio was smooth except for a small circumscribed eroded area on the posterior lip which bled on examination. Several biopsy fragments were taken from the cervix and the microscopic slide contained several of these fragments of cervical tissue and a few small fragments of non-invasive potential carcinoma. She was given radium and was alive and well when last heard of in December, 1936. Further attempts to locate her have proved fruitless.

CASE 16 (Path 44092) J. S., a 62 year old nulliparous married Hebrew woman, came to the hospital November 5, 1936 complaining of very slight metrorrhagia for 8 months. On examination the cervix was found to be small, firm, of normal nulliparous contour and the portio was smooth except for several small areas of erosion on both the anterior and posterior lips. Several biopsy fragments of tissue were taken. The microscopic slide showed some fragments of cervical tissue and a strip of typical early non-invasive potential carcinoma 3 millimeters long. As can be seen in Figure 16 the anaplasia is very marked. The nuclei are greatly varied in shape, size and staining density. There are 10 mitoses per high power field. The basal layer is intact and consists of about three layers of spindle cells. Then about half of the thickness of the epithelium is made up of round or oval nucleated transitional cells and superficially these change over and somewhat resemble spinal cells. This latter change consists of a horn-like appearance and increased prominence of the cytoplasm with the nuclei becoming more generally oval but not decreasing in size. In this particular case there is a thin superficial layer of atrophic cells in which the nuclei are small, usually oval and take a dense dark stain. In most sections these cells cannot be found as they usually slough off as soon as they become atrophic. The transitional type of cell predominates although there is some semblance of stratification remaining. The mitoses are evenly distributed between the three viable layers and several are found in cells practically at the surface which is never seen in benign hyperactivity. This woman was given radium and is alive and well without any symptoms suggestive of cervical carcinoma.

CASE 17 (Path 44279) V. K., aged 61 years the mother of 5 children, came to the hospital December 14, 1936 complaining of uterine descensus for 3 months. Examination showed a relaxed vaginal outlet and a second degree uterine descensus. She had

vative potential "carcinoma" of the cervix is essential for accurate diagnosis. In the first place the component cells exhibit those signs generally accepted as characteristic of malignant cells. The nuclei, instead of showing the uniformity seen in normal stratified squamous epithelium, present a total absence of uniformity; they may be as much as six times the size of their neighboring nuclei, and may be round, oval, flattened, or slightly curved or twisted. Some nuclei will take practically no stain at all and their chromatin will stand out prominently like a lattice-work over a window; their nucleoli usually stain a bit darker and are relatively larger than those in the nuclei of benign cells. Other nuclei may be hyperchromatic, taking a dense "black" visually impenetrable hematoxylin stain. There may be all degrees of staining density between these two extremes, and there may be some intranuclear variations as well. The important point is that the nuclear staining densities bear no relation whatever to the size of the nuclei. In normal cells the larger the nucleus the lighter the stain and vice versa; in the malignant ones there may be an extremely large "black" nucleus in a cell which lies adjacent to one containing a pale staining nucleus one-sixth its size. There may be occasional large cells with a dozen nuclei in them. The cytoplasmic cell borders generally are not easily discernible and the cells lie in such a close-packed heterogeneous confusion that one receives the impression that there are a relatively greater number of nuclei per high power field than in normal epithelium. The presence of large darkly stained round or oval nuclei in cells on the surface of the growth is characteristic of this superficial "carcinoma," and the compact spinal cell outer layer is nearly always absent. The stratification of the cells normally seen in squamous epithelium is frequently absent although some definite semblance of it may remain.

The border between the normal epithelium and the "carcinoma" is nearly always sharp, and while in some cases it may be perpendicular, it is usually and characteristically of a 45 degree obliquity, the superficial portion leaning toward the new-growth. The basal

layer consists usually of more or less spindle shaped cells closely lined up in a single intact layer. Although there may be the same changes in the contour of the basal layer as are found in normal squamous epithelium, e.g., shallow tongues of cells dipping into the stroma, complete epidermization of a superficial gland, etc., the stroma must not be invaded. No specific changes in the elastic tissue of the stroma beneath these growths can be demonstrated (27).

These "carcinomatous" cells, as Best's stain will show, do not contain the glycogen found in the spinal and some superficial transitional cells in normal stratified squamous epithelium. There may be a characteristic lymphocytic infiltration in the stroma beneath and in that extending just beyond the border of the growth. The growth activity, as manifested by the relative number of mitoses per high power microscopic field, in our cases does not bear any definite relation to the relative degree of anaplasia of the cells. We wish especially to stress this fact. Many times we have observed as high as 6 mitoses per high power field in a perfectly benign tongue of epithelium in the process of growing into a superficial gland during the repair of an inflammatory cervical condition. In a rapidly advancing and enlarging cancer the cell multiplication rate must of necessity be very high, and a correspondingly large number of mitotic figures per high power field will naturally be found; here their presence is undoubtedly of some aid in making the microscopic diagnosis of malignancy. As a rule the presence or absence of mitotic figures in a non-invasive potential "carcinoma" of the cervix has been of little or no diagnostic value, and in the final analysis the diagnosis can be made only when the anaplastic nuclear changes and non-uniformity of cell arrangement described herein are present.

DEFINITION AND SIGNIFICANCE OF NON-INVASIVE POTENTIAL "CARCINOMA" OF THE CERVIX

Non-invasive potential "carcinoma" of the cervix is a lesion composed of anaplastic epithelial cells which apparently arises spontaneously in a "growth center" at the junc-

junction of the cylindrical and squamous epithelium, and he has stressed this fact. This is further borne out by the finding of 11 of our non invasive potential "carcinomas" at the same junction, despite the fact that half of our lesions were found in biopsy fragments. Five of our "carcinomas" were found relatively localized to childbirth lacerations. We wish to draw attention to the fact that Smith and Pemberton's (17) 3 cases of early cervical "carcinoma" which later became invasive were found in tissue removed during trachelorrhaphy.

The microscopic pictures of these 18 cases were essentially similar in that the cells all showed typical anaplastic changes, all of the growths were non invasive and had lost most of the stratification seen in normal squamous epithelium, and all stood out rather sharply from the adjacent benign epithelium.

Case 2, in which the "carcinoma" became invasive after 8 years, and Case 13, in which invasion began about 3 years after biopsy, present some evidence that these non invasive "carcinomas," as Schiller believes, are potentially invasive. Smith and Pemberton's 3 cases are of similar significance. Since only 2 of our cases developed into clinical "cancers," one of which was later directly fatal, it might appear that the potential invasiveness of these lesions is questionable. However, as was stated above, in 7 of our cases all of the lesion was apparently removed. Of the 11 others 2 later developed into an invasive growth. Five of the cases in which biopsy was done were recognized as "carcinoma" and were given adequate radium treatment. Of the 4 cases remaining 2 patients were given thorough cervical cauterization following biopsy and in 1 of these all of the growth might well have been removed by the extensive stripping of the squamous epithelium from the portio and the curettage of the canal of the stump. Thus leaves 2 non invasive potential "carcinomas" apparently unaccounted for. Cases 5 and 11. We have not been able to follow Case 5 and in Case 11 the patient was alive and well when last heard from in July 1936.

The trachelorrhaphy specimen removed from Case 2, June 30 1919 showed non invasive "carcinoma," and when she was seen on

February 28, 1928, 8 years and 8 months later, she had an advanced carcinoma of the cervix. It had then been symptomatic for 4 months and when Stahler's mathematically evolved 27 month asymptomatic postinvasive period (28) is added it gives a 67 month invasive growth period to this tumor. In subtracting this from the total time interval a known non invasive existence of 8 years and 13 months is established. Case 13 showed early asymptomatic carcinoma in the posterior lip of the cervix at the time of death, 3 years after the first biopsy was taken. From the extent of the growth we might assume that invasion had taken place from 2 to 4 months before death, in which case we establish a known non invasive period of 2 years and 9 months for the original superficial lesion. By similar calculations Smith and Pemberton's (17) Case 1 had an established 3 year and 13 month non invasive period, with a 107 month invasive growth phase. If, on the basis of 6 months being the average duration of symptoms in large groups of cases (6) we assume 87 month invasive phases for his other 2 patients, Case 2 would have a non invasive period of 4 years and 03 months, while Case 16 would have one of 5 years and 43 months. Thus, from the data on these 5 cases, we find that the established known non invasive periods vary from 2 years and 9 months to 8 years and 1 month.

In our Case 11, in which the biopsy specimen taken in 1930 showed non invasive potential "carcinoma," the patient has as yet received no treatment and was well and without suggestive symptoms in July, 1936 exactly 6 years later. The 2 biopsy examinations in our Case 13 (Figs 10 and 11) show the same "level" of anaplasia and activity. When they are compared to a portion of the superficial growth (Fig 13) on the same cervix 3 years later a striking resemblance is still apparent even though by this time invasion has begun from the surface lesion about 2 millimeters away.

THE DIAGNOSIS OF NON INVASIVE POTENTIAL "CARCINOMA" OF THE CERVIX

tion of the squamous and columnar epithelium of the portio of the cervix. It lies within the usual domain of the normal stratified squamous epithelium and has remained relatively localized in a few accurately observed cases for from 3 to 8 years after which it may break through the basement membrane and invade and destroy the stroma of the cervix, having then become clinically a cancer.

The fact that some of these lesions apparently do not become invasive cancers suggests that possibly all are not potential "carcinomas." However, the possibility of the destruction of these superficial growths during their several years dormancy by the necroses and erosions of trauma and intercurrent infections looms rather formidably when carefully considered.

If all clinical cervical carcinomas are preceded by this non invasive phase, then routine biopsy of all cervixes even once a year might be a guarantee against the development of cervical cancer. Although we feel that in our Case 13 we have been able to demonstrate fairly well the growth continuity through the non invasive to the invasive phase we cannot say definitely that the invasive carcinoma in our Case 2 developed from the non invasive growth discovered 8 years previously. As W. G. MacCallum has stated "It is natural that the development of the carcinoma should be connected with the original change but it does not seem quite proven." (8) However, if a patient without symptoms is found repeatedly to have a growth of Escherichia coli in cultures of the urine from one kidney and after a period, has an acute flare up of pyelitis in that kidney, the urine giving a heavy growth of the same organism we naturally assume that the original bacillus was the cause of the acute inflammation.

Among the obvious questions raised by a consideration of these lesions are the following: Is every cervical cancer preceded by a non invasive phase of one or more years? Will every non invasive potential "carcinoma" of the cervix eventually invade the stroma if the woman lives long enough and the growth is not destroyed? What are the factors determining the breaking through of the stromal defenses by the anaplastic epithelial cells? If

some of these growths are not potentially invasive could they be differentiated from those that are? These and other queries on the subject will be answered only when many more of these cases are assembled and carefully studied.

SUMMARY

1. Cancer is the second most frequent cause of death in the western world, cancer of the uterus is responsible for one third of the cancer deaths in women. 90 per cent of uterine cancer arises in the portio of the cervix and is thus easily accessible for examination and study.

2. The most favorable statistics from the treatment of cancer when it is limited to the portio of the cervix show a 52 per cent cure while not more than 20 per cent of all cervical cancers have a 5 year cure.

3. Schottlaender and Kermanner (1912) and Schiller (1927) have described and called attention to a form of superficial non invasive cervical "carcinoma." Schiller considers and treats it as definite carcinoma.

4. The authors present 18 cases for which one of them (C. S. S.) has proposed the name "non invasive potential 'carcinoma' of the cervix."

5. In 1 patient (Case 2) the "carcinoma" remained non invasive for 8 years and 1 month, following which it developed into a clinical carcinoma and finally caused the death of the patient. A second patient (Case 13) died of pernicious anemia 3 years after the first biopsy examination revealed a non invasive potential "carcinoma." Serial sections of this cervix revealed that invasion had taken place shortly before death.

6. Non invasive potential "carcinoma" of the cervix is defined and its diagnosis is discussed as well.

7. The authors hope that similar studies of the material in other pathological laboratories will be carried out for when many of these cases are thus unearthed and studied we will be able to draw more valuable conclusions and to throw light on the as yet unanswerable questions on this subject.

We wish to thank Dr. Thomas S. Cullen, Dr. Emil Novak, Dr. Walter Schiller, Dr. W. G. MacCallum and Dr. R. T. E. for their help and advice they have given us in the preparation of this paper.

has been carried out with increasing frequency.

Forty-two of the 45 cases herein reported, were operated upon by us, 3 by other members of this surgical service. Thus, by close collaboration and frequent exchange of opinion, we developed the present operative technique and general mode of management of cases of acute pulmonary abscess. Of vital importance has been the co-operation of the physicians of our institution, who, noting the results which have been obtained in these cases, now request early surgical consultation.

In this communication our 45 cases shall be analyzed for the purpose of presenting, partly in detail and partly in outline, their varying etiology, their clinical and roentgenographic features, the operative problems and findings, the operative sequelæ, and the results of operative treatment.

Classification. Incidence For purposes of analysis and classification, the cases have been divided into two groups, unperforated and perforated. Thirty-four cases (Group A) were unperforated in the sense that the abscess was confined to the pulmonary parenchyma. In 11 cases (Group B), the complication of perforation into the pleura with pyopneumothorax existed prior to operation.

In our series the higher incidence of pulmonary abscess in males is to be noted (29 males, 16 females). An explanation will be offered in a succeeding paragraph. The youngest patient was 2 years of age, the oldest was 70. Thirty of the 45 cases occurred during the fourth, fifth, and sixth decades of life, the lowest incidence being noted at the extremes of life.

Location of lesions In the 45 cases, the right lung was involved in 32, the left in 12, and both right and left in 1. A single abscess was present in 40 of the 45 cases. In 15 of these, it was located in one of the upper lobes; and in 20, in one of the lower lobes. In 5 cases it involved contiguous portions of two adjacent lobes by direct extension across an interlobar fissure. There were 5 cases in which more than 1 abscess existed. Of these, 3 had 2 abscesses lying immediately adjacent to each other, the lesions being situated in the upper lobe in all 3 instances. (We regard these as

cases of solitary abscess in which more or less irregular extension into the adjacent pulmonary parenchyma had occurred.) In the fourth case (Case 37) there were 3 widely separated abscesses in the right lung. The last case (Case 45) presented several bilateral abscesses.

The point is that the great majority of patients had *single* lesions, a fact which supports the "*aspiration*" rather than the "*embolic*" theory of origin of putrid abscess of the lung. If the *embolic* mechanism were common, the pulmonary lesions frequently would be *multiple*, *widespread*, and *bilateral*. It is interesting, in this connection, to note that in the 1 case in this series (Case 45), in which an embolic mechanism properly could be invoked, the pulmonary lesions *were* multiple, widespread, and bilateral. A second fact, which suggests strongly that aspiration is responsible for the production of putrid abscess of the lung, is the much higher incidence of right sided as compared with left sided lesions in this series. The direct pathway from the trachea into the right main bronchus in contrast with the less direct one into the left main bronchus, would account for the preponderance of right sided lesions on the basis of aspiration.

Etiology. The etiology was definite in only 19 cases, as follows: tonsillectomy in 8 (2 under local anesthesia); extraction of teeth in 2 (both under local anesthesia); operations under general anesthesia in 2; incision of a peritonsillar abscess in 1; epileptic seizure in 1; acute tonsillitis in 1; spillover from a chronic pulmonary abscess in 1; sepsis after therapeutic abortion in 1; and laceration of the esophagus in 2. In these last 2 cases the pulmonary abscess was the result of direct extension of infection from the mediastinum into the adjacent lung.

In the 26 remaining cases the etiology was "uncertain." In a recent article, Stern¹ of this institution reported his investigation concerning the cause of putrid abscess of the lung in a series of cases of obscure etiology. In 84 per cent of cases in which the etiology was not obvious, he found gross gingivodental infection, and unusually large deposits of dental

ACUTE PUTRID ABSCESS OF THE LUNG

II An Analysis of Forty-Five Consecutive Operative Cases

HAROLD NEUHOF, M.D. and ARTHUR S. W. TOUROFF, M.D., F.A.C.S.,
New York, New York

IN a recent publication¹ we presented evidence in favor of operation in the *acute* stage of putrid abscess of the lung, based upon a study of the pathological and clinical features of the disease as observed in a large series of cases in all stages. Operative indications were discussed, our operative methods were described in detail, and the results obtained in the surgical treatment of 37 consecutive acute cases were outlined. We defined an "acute" abscess arbitrarily, on the basis of time alone, as one of not more than 6 weeks' duration from the time of onset of pulmonary manifestations. Some of the points which were emphasized and which have a bearing on the present communication, are as follows: (1) An understanding of the pathology of acute abscess of the lung constitutes the foundation of correct treatment, and in particular of correct operative treatment. (2) Certain pathological features such as the superficial location of the abscess within the lobe and the presence of overlying pleural adhesions, indicate the feasibility of operation in the acute stage. (3) The inflammatory process is well localized in the early phase. (4) In the later phases it becomes widespread and secondary changes occur in the surrounding pulmonary parenchyma and bronchial tree. These changes are responsible for the lower incidence of cure and the higher incidence of morbidity and mortality in the subacute and chronic cases. (5) Acute cases may be classified as 'mild' or 'grave'. Spontaneous subsidence may occur, less often in the latter than in the former. In those cases in which the process does not subside fatal complications develop early in the course of the disease or they pass into the chronic

phase. (6) The seriousness of putrid abscess of the lung can be appreciated only if the manifestations of the chronic phase and the complications with their mortality, are borne in mind. (7) Although clinical manifestations usually settle the question of operative intervention in individual cases, it can be stated, in general, that the great majority of patients with "grave" lesions should be subjected to operation in the acute stage. (8) The operative method which we advocate consists essentially of a single stage procedure in which the lesion is entered through overlying pleural adhesions, unroofed and packed. (9) Exact diagnostic localization of the lesion is a prerequisite for the operative methods which we employ. In the absence of precise pre-operative localization of the abscess, the operation as described is not recommended.

The present paper is based upon a study of 45 consecutive operative cases of acute putrid abscess of the lung,² treated in accordance with principles stated in our previous communication. These patients represent the total number treated by operation in a series of more than one hundred cases of acute putrid pulmonary abscess admitted to the Mount Sinai Hospital. Thus every acute case that has come under observation has not been operated upon. On the other hand, it is to be emphasized that in no instance was operation withheld from a gravely ill patient for fear of increasing the operative mortality rate.

We began to operate upon patients with acute pulmonary abscess in 1925. In the beginning operation was performed rarely and was reserved for patients who were desperately ill. In recent years, however, as our surgical indications have broadened, operation

²Since this paper was prepared for publication, 23 additional patients have been operated upon with satisfactory results in 7 and death in 1 several months after operation from pulmonary complications not referable to the operated upon (and healed) acute pulmonary abscess.

GROUP A—ACUTE PUTRID ABSCESS OF LUNG—Continued

Name, age, sex, admission No.	Etiology Duration before admission	Pre operative course, special features	X-ray	Bronchoscopy	Location of lesion In hospital before operation	Operative procedure and findings	Postoperative course (in hospital), special features	Inter course	Result
6 T S 1911 322,870 Male 37	Unknown 3 wks	Septic course, high fever, very rapid pulse, prostration Rapid enlargement of lesion	Extensive infiltration in upper part of R L L posteriorly	Poultice, apical branch R L L	Apical segment of R L L 10 days	One stage Local anesthesia Paravertebral approach through 7th rib and transverse process. Pleural adhesions. Very large cavity unroofed	Uneventful Discharged 3 wks after operation	Uneventful Bronchial fistula maintained for 5 weeks	Well 19-year follow up Symptom free Normal x ray
7 M C 1911 320,127 Female 16	Post tonsillectomy (general anesthesia) 11 days	High fever, septic course, rapid increase of pulmonary cavitation. Profuse expectoration	Diffuse pneumonic infiltration medial portion of base of R L L with cavity formation	Small amount of foul pus, posterior branch R L L	Medial segment R L L (mediastinophrenic aspect) 8 days	Two stages 1st stage Local anesthesia Posterolateral approach through 6th rib No parietal pleural adhesions present. Pleura opened and explored. Adhesions found in lower lobe under surface of lower lobe and diaphragm. Tendon shut off from free pleura by suture and packing	Uneventful except for irregular fever for 3 wks Discharged 33 days after operation	Uneventful Bronchial fistula maintained for 2 mos	Well 3½ year follow up Symptom free Normal x ray
8 J M 1911 328,417 Male 59	Indeterminate (poor dental and oral hygiene) 18 days	High fever, night sweats Rapid loss of weight	Uncomplicated pleural effusion in lateral half of chest apex to base	Not performed	Posterolateral segment R L L 5 days	One stage Local anesthesia Posterolateral approach through 7th rib. Pleural adhesions present. Large cavity unroofed. This lesion was unroofed compared with the empyema seen by x ray. Pleura aspirated in 6th interspace. Foul pus obtained. 6th rib resected and large putrid empyema evacuated. No communication between abscess of lung and empyema. Not a case of perforated lung abscess	Uneventful Discharged 21 days after operation	Uneventful Bronchial fistula maintained for 2 wks	Well 3 months follow up Failed to return thereafter. When last seen was symptom free. Wound healing. X ray negative except for slight residual pleural thickening

GROUP A—ACUTE PUTRID ABSCESS OF LUNG—Continued

Name, age, admission No.	Sex	History Duration before admission	Pre operative course, special features	X ray	Bronchoscopy	Location of lesion In hospital before operation	Operative procedure, and findings	Postoperative course (in hospital), special features	Inter course	Result
15 1031 365,580 Female 2	Male 36	Indeterminate (poor dental hygiene) 1 wk	Proliferative hemoptysis at onset	Dense shadow in right portion of chest. No cavity visible	Found pus, an abscess in the right bronchus L.U.L.	Axillary segment L.U.L. 7 days	One stage. Avertin G.O. in thorax. Posterior approach through 4th rib. No pleural adhesions found. Pleural adhesions found at lower level. Pleural adhesions 5th rib resected. Pleural adhesions 1 in cavity in lung unroofed. Several accessory loculations present.	Uneventful. Discharged 12 days after operation	Uneventful. Bronchial fistula maintained for 2 mos	Well. 3 yr follow-up. Symptom free. Normal x ray
16 1031 376,581 Female 2	Male 36	Indeterminate (poor dental hygiene) 4 wks	Unimproving course. High fever. Marked toxemia. Rapid enlargement of cavity	Dense pneumonic infiltration—lateral portion of L.U.L. Several fluid levels	Not performed	Axillary segment L.U.L. 1 day	One stage. Local anesthesia. Axillary approach through 5th rib. Free pleural adhesions cut. Adhesions adjacent to pleural adhesions. Lung surface to thoracic parietal pleura unroofed. Large cavity unroofed. After first operation, reoperation.	Postoperative fever. Prostration. Non-foul expectoration. X-ray revealed unroofed abscess lying posterior to the drained cavity	Satisfactory except for occasional bloody expectoration during early course	Successful 1 mos after operation. Bronchial fistula was being maintained. Normal x ray and symptom-free at time of death
17 1031 365,580 Female 2	Male 36	Post tonsillectomy (general anesthesia) 10 days	Septic fever 101-103° F. Marked anapathy	Infiltration entire R.L.L. apex to base. Several fluid levels. 1 largest cavity 2 in diameter	Found pus, an abscess in the right bronchus R.L.L.	Anterior segment R.L.L. and adjacent R.M.L. 5 days	One stage. Ether anesthesia. Thoracotomy approach through 4th rib. Pleural adhesions cut. Large cavity unroofed. Free pleural adhesions cut. Pleural adhesions immediately cut. Opening made with pack. Several adjacent pulmonary loculations unroofed.	Uneventful. Large clean pulmonary defect closed by plastic operation 3 wks after original operation. Discharged 3 wks after and operation, with wound healed.	Uneventful	Well. 2 year follow-up. Symptom-free. Normal x ray
18 1031 376,581 Female 2	Male 36	Indeterminate (poor dental hygiene) 3 wks	High septic fever. Chills, prostration, profuse night sweats. Progressive coughing. Extensive perforation	Large cavity L.U.L. apex to base. Intense inflammatory consolidation surrounding pulmonary infiltration	Found pus, an abscess in the right bronchus L.U.L.	Axillary segment L.U.L. 7 days	One stage. Avertin G.O. in thorax. Posterior approach through 6th rib. Pleural adhesions 1 in cavity unroofed.	Postoperative bronchopneumonia (non putrid) of L.L.L. Discharged 6 wks after operation	Uneventful. Bronchial fistula maintained for 3 1/2 mos	Well. 2 yr follow-up. Symptom-free. Normal x-ray and bronchogram

Name, yr, adm, sion No	Sex	Etiology	Pre-operative course, special features	X-ray	Bronchoscopy	Location of lesion	Operative procedure and findings	Postoperative course (in hospital), special features	Later course	Result
21 S F 1935 386,358	Female	Post tonsil- ectomy (local an- esthesia) 2 wks	Typical	Pneumonic infil- tration meso- portion of base of R L L	1 oral pus, mesial branch of R L L	Mesial segment of R L L, and (mediastino- phrenic aspect) 9 days	One stage Avertin G O an- esthesia. Posterolateral approach through 10th rib No parietal pleural adhe- sions present. Pleural cavity opened and explored. Pleural adhesions present between under surface of lower lobe and diaphragm. Lesion shut off from free pleura by suture and pick- ing. Cavity unroofed.	High fever, toxic psy- chosis. Sterile hydro- pneumothorax. Dis- charged 10½ wks after operation.	Uneventful Bronchial fis- tula maintained for 1 wk after leaving hospital.	Well 1½-year fol- low-up. Symptom- free. X ray normal.
22 G F 1935 386,980	Male	Indetermi- nate (poor dental and oral hy- giene) 1 wk	Unusually pro- fuse sputum 20-30 oz daily. Sputum odorless	Dense shadow lower part of R U L. In mesial part is a 2 in cavity with fluid level	Small amount of focal pus, para-vertebral branch of R U L and apical branch of R L L	Lower segment of R U L, and adjacent R L L 8 days	One stage Avertin G O anes- thesia. Posterior para- vertebral approach through 6th rib. Pleural adhe- sions. Large bullous cavity partially in R U L, and partially in R L L, un- roofed.	Uneventful. Large cleft in lesion in lung closed by plastic operation 7 wks after original operation. Discharged 17 days after second operation with wound healed.	Uneventful	Well 1½ year fol- low-up. X-ray normal. Bron- choscopy negative.
23 M McL 1935 386,583	Female	Post tonsil- ectomy (general anesthesia) 2 wks	Fulminating course, chills, high fever, rapid loss of weight	Cavity with fluid level 1½ in x of R U L. Post- eriorly	Not performed	Apical segment of R U L 1 day	One stage Avertin G O anes- thesia. Posterior para- vertebral approach through 6th rib. Pleural adhe- sions. 3 in cavity un- roofed.	Uneventful except for slight bleeding at first dressings. Discharged 1 wks after operation.	Uneventful Bronchial fis- tula maintained for 10 wks	Well 1½ year fol- low-up. Symptom- free. X ray normal.
24 S S 1915 391770	Male	Unknown 9 days	Fulminating course, high fever, pro- fuse sputum, 40 spms and rapid en- largement of cavity	Infiltration with portion of L U P just above inter- costal fissure. Two irregular cavities present 1½ in	Granulation tissue in L U L from chills. No secretion ("shift off" lesion) 1½	Axillary segment of L U L 1 day	One stage Avertin G O anes- thesia. Axillary approach through 4th rib. Pleural adhesions not present. Pleural cavity opened and ex- plored. Pleural adhesions present at a higher level. Lung sutured to parietes. 4th rib resected. Dense pleural adhesions present at this site. Large multi- locular cavity unroofed.	Uneventful. Discharged 1 wks after operation.	Uneventful Bronchial fis- tula maintained for 1 mos	Well 1½ year fol- low-up. Symptom- free. Normal x ray
25 L A 1915 388,003	Male	Post tooth extraction (local an- esthesia) 3½ wks	Very profuse expectora- tion. Rapid enlargement of cavity. Marked toxicemia	Extensive area of consolidation up- per part of R L L contain- ing a 2 in cavity with fluid level	Not performed	Posterolateral segment of R L L Operated upon on admission	One stage Avertin G O anes- thesia. Posterolateral ap- proach through 8th rib. Pleural adhesions. 3 in cavity unroofed.	Uneventful. Discharged 13 days after operation.	Uneventful Bronchial fis- tula maintained for 5 wks	Well 1½-year fol- low-up. Symptom- free. Normal x ray
26 T McK 1916 388,797	Male	Indetermi- nate (poor dental and oral hy- giene) 16 days	Typical	1 in cavity with fluid level, axillary region. Lung moderate sur- rounding infiltri- tion	Not performed	Posterolateral segment L L L 1 days	One stage Avertin G O an- esthesia. Posterolateral approach through 6th rib. Pleural adhesions. Cavity unroofed.	Uneventful. Discharged 16 days after operation.	Uneventful Bronchial fis- tula maintained for 2 mos	Well 1½-year fol- low-up. Symptom- free. Normal x ray

GROUP A—ACUTE PUTRID ABSCESS OF LUNG—Concluded

Name, year, admission No.	Sex, age	Etiology, Duration before admission	Pre operative course, special features	X ray	Bronchoscopy	Location of lesion In hospital before operation	Operative procedure and findings	Postoperative course (in hospital), special features	Later course	Result
11 1916 309251 Female 31	Spillover from chronic putrid abscess L.U.L.	10 days	Frequent hemoptyses	Cavity with fluid level axillary portion of L.L.L.	Foul pus, postero-lateral branch L.L.L.	Posterolateral segment of L.L.L. 3½ wks	One stage. Avertin G O anesthesia. Postero-lateral approach through old incision. Pleural adhesions 1.5-in. cavity in lower lobe unroofed	Subsequent drainage of chronic putrid empyema derived from original putrid abscess of lung. Discharged 7½ wks after operation	Uneventful. Bronchial fistula maintained for 10 wks	Well 1 year follow-up. Symptom free
12 1916 102,959 Male 31	Posttuberculous (general anesthesia)	1 mo	Frank hemoptysis	Area of infiltration near vertebra column 7th to 9th ribs posterior side. No fluid level	Not performed	Apical segment R.L.L. 5 days	One stage. Avertin G O anesthesia. Paravertebral approach through 7th and 8th ribs. Bilateral pleural adhesions. Pleura entered and explored. Dense adhesions present more medially. Lung approximated to parietes. 2-in. cavity unroofed	Uneventful. Discharged 1 wks after operation	Uneventful. Bronchial fistula maintained for 5 wks.	Well 1 year follow-up. Symptom free
13 1917 372,531 Female 52	Laceration of esophagus by chicken bone	5 wks	Persistent pain in chest, weakness, fever, foul sputum, and loss of weight	Dense infiltration, mesial half of R.U.L. 1½ in. cavity at level of 4th and 5th ribs posteriorly. Pneumothorax with 33 per cent collapse of rt lung	Foul pus, apical branch of R.U.L.	Abscess of posterior mediastinum with extension into R.U.L. of lung 1 wk	Two stages. 1st stage. G O anesthesia. Paravertebral approach through 1st, 2nd, and 3rd ribs. Inadequate pleural adhesions. Pleura opened and packed locally. Second stage, 9 days later. G O anesthesia. Median sternotomy. Abscess of lung then exposed and unroofed. Both lesions packed	Postoperative toxic psychosis	Uneventful. Bronchial fistula maintained for about 1 wks	1½-year follow-up. Except for pain in operative scar, patient is symptom free. X ray negative
14 1932 351,311 Female 10	Laceration of esophagus by meat bone	11 days	Septic course, toxic psychosis, dyspnea, and rapid pulse. Copious foul sputum	Infiltration mesial portion of R.U.L. apex to 2nd rib anteriorly. With-in infiltrated area a fluid level extending from chest wall to a point beyond the midline	Foul pus, apical branch of R.U.L.	Large abscess of anterior, middle, and posterior mediastinum with extension into R.U.L. of lung. Operated upon admission	One stage. G O anesthesia. Paravertebral approach through 5th and 6th ribs. Large mediastinal abscess entered and evacuated. Abscess of lung exposed. Both lesions packed	Uneventful. Patient discharged 12 weeks after operation	Uneventful. Bronchial fistula maintained for 4 mos	Well 2½-yr follow-up. Symptom free. X ray negative

situated Among these the involvement of 2 or more contacting bronchopulmonary segments was revealed in a few instances. In 2 cases the abscess was shut off from the communicating bronchus, and in these, bronchoscopy confirmed the presumptive diagnosis of a "shut-off" lesion. The single error in localization of the abscess by bronchoscopy led to an operative approach at an incorrect site (Case 10).

The amount of foul pus encountered at bronchoscopic examination ranges from very small amounts to large quantities. The technique whereby the source of foul pus can be identified with precision, even when the bronchial tree on the involved side is more or less completely flooded, can be acquired only by those who are especially interested in, and frequently examine, such cases. Skillful bronchoscopic examination was particularly valuable in the diagnosis of 2 cases (Cases 9 and 22) in which the *sputum was not foul*, for it disclosed not only the presence but also the precise origin of *foul pus*.

Bronchoscopy is *not* indicated in cases of perforated abscess of the lung, because operation usually is imperative and localization of the lesion rarely offers difficulties. It was performed, however, in 1 of our 11 perforated cases, an instance in which the diagnosis of perforation was not made prior to operation.

Concerning the 14 unperforated cases of abscess of the lung in which diagnostic bronchoscopy was not performed, 9 of the patients were considered too ill for bronchoscopy, or were operated upon as emergencies. In 2 instances, an incorrect diagnosis of perforation into the pleura was made. In the 3 remaining cases precise localization of the abscess was simple, and the existence of a foreign body or an endobronchial lesion seemed quite unlikely.

Duration of illness The duration of illness of the cases of perforated abscess now will be discussed. Before doing so we wish to emphasize that we are discussing only cases in which a substantial pulmonary abscess is present, and do not include cases of small "cortical" abscess with perforation. In the latter, the symptoms are essentially those of the complicating pleural infection and not those of pulmonary abscess. Thus, in the majority of our

patients, the expectoration of foul pus and other manifestations of abscess of the lung continued after perforation had occurred. It can be stated at once that the diagnosis of perforation was found at operation to be incorrect in some of the cases, and, conversely, that pleural penetration was not suspected in some instances in which it was found at operation.

Of the 11 perforated cases, 2 had had symptoms of pulmonary abscess for less than 1 week before admission; 2 had been ill for 1 to 2 weeks, 4 had been ill for 2 to 3 weeks; and 3 had been ill for 4 to 5 weeks.

Seven were operated upon as emergencies on admission because the existence of perforation was recognized, 2 were operated upon in the first, and 2 in the second week of observation in the hospital. In 2 of the 11 cases (Cases 37 and 44), perforation occurred undoubtedly during the patient's pre-operative stay in the hospital.

An analysis of the known (or assumed) time of perforation in the 11 cases leads to some interesting conclusions. In 2 cases, perforation occurred in the second week, and in 6 cases in the third week of illness. Two others were known to have had pleural invasion in the third or, at the latest, in the fourth week; and in the last case, perforation *probably* occurred in the fourth week. In other words, perforation into the pleura occurred in the second or third week in most of the cases. A second conclusion to be drawn from our analysis is that the existence of *localized perforation* cannot always be recognized before operation. Finally, perforation can occur during hospital observation as well as before admission.

Of the 34 unperforated cases, the duration of illness before admission to the hospital was: up to 1 week, 2 cases; 1 to 2 weeks, 13 cases; 2 to 3 weeks, 7 cases; 3 to 4 weeks, 9 cases; 4 to 5 weeks, 2 cases; fifth week, 1 case.

The duration of illness during hospital observation before operation varied somewhat, but it will be noted that the great majority of the patients were operated upon in the first week of hospitalization. The figures are as follows: operation on admission, 3 cases; in the first week, 23 cases, in the second week, 6 cases; and in the third and fourth week, 1 case each.

tartar The conclusion reached by him was that abscess of the lung in cases of "uncertain" origin, often was derived from teeth or gums by aspiration. Of our 26 cases of acute abscess in which the etiology was "uncertain," 17 presented gross gingivodental infection. For the reasons advanced in Stern's paper we concur in his view that these cases are of gingivodental origin. In 9 instances the etiology was entirely obscure and such cases are often referred to as of pneumonic origin. No differences in clinical course or in pathological features were discerned in these cases as compared with those of definite etiology. Furthermore on x-ray examination the pulmonary infiltration which preceded cavitation was no more extensive than in cases of known etiology. For these and other reasons referred to elsewhere, we believe that pneumonia is not the etiological factor in acute abscess of the lung of obscure origin.

It would lead too far afield to discuss the varied etiology of the 45 cases in relationship to the question of the aspiratory versus the embolic theory of causation of putrid pulmonary abscess. However an examination of the tabulation of the etiology of these cases indicates that embolism played no rôle with 1 (Case 45), or possibly 2, exceptions (Case 37).

An interesting sidelight on gingivodental infection as a cause of putrid abscess of the lung is offered by the fact that pulmonary abscess of "uncertain" etiology occurred among adults alone. In all of the children in our series, the cause of the pulmonary abscess was obvious. Since severe gingivodental lesions are encountered very rarely among children the importance of the oral status in the etiology of abscess of the lung in adults becomes evident.

Roentgenographic features The characteristic roentgenogram of the chest in cases of acute abscess discloses a single localized cavity in the lung with a well defined fluid level, and a surrounding narrow zone of pulmonary infiltration. However, considerable variation from the typical picture is often seen. Thus, the abscess cavity may be filled completely with pus and detritus, and no fluid level may be visible. In such instances the shadow cast by the filled cavity merges with and is indistinguishable from the surrounding pulmonary

infiltration. As a result, there is a fairly dense shadow like that of pneumonic consolidation. At times small areas of rarefaction may be noted in the midst of this infiltration. In other instances there is a wide, instead of a narrow, surrounding zone of increased density although a well defined cavity with or without a contained fluid level is seen. In such cases we have found that the abscess generally corresponds in size to that of the major portion of the area of "pulmonary infiltration" as noted on the roentgen film.

In only 7 of our 34 cases of non perforated acute abscess of the lung, were the roentgenographic features typical in accordance with the definition contained in the first sentence of the preceding paragraph. In these 7 cases the cavity ranged in diameter from about 2 to 4 inches. In the 27 remaining cases the roentgen findings varied as follows: Extensive pulmonary infiltration without evidence of cavitation, 6 cases, extensive infiltration containing single or multiple areas of rarefaction, 19 cases, and extensive infiltration containing a single cavity 2 to 4 inches in diameter, 2 cases. It is significant, we believe, that these atypical findings were encountered most often in cases in which the clinical course was severe.

The characteristic roentgen film of perforated abscess of the lung is that of limited or widespread empyema or pyopneumothorax; more commonly the latter. Because of the comparatively large size and the density of the pleural effusion the details of the causative pulmonary lesion usually are obscured. However in 5 of our 11 cases the pleural lesion was so situated in relationship to the pulmonary abscess that both could be identified in the roentgen film.

Bronchoscopic examination¹ The extraordinary accuracy of properly conducted diagnostic bronchoscopy is evident from an inspection of our case analyses, with particular reference to the operative findings. Bronchoscopy was performed in 20 of the 34 unperforated cases. In 17 of the 20, bronchoscopic examination located precisely the bronchopulmonary segment or segments in which the abscess was

¹All bronchoscopic examinations are performed by members of the laryngological service of Dr. Rudolph Keamer.

GROUP B—ACUTE PUTRID PERFORATED ABSCESS OF LUNG—Continued

Name, age, admission No.	Sex	Age	History before admission	Pre operative course, special features	X-ray	Bronchoscopy	Location of lesion in hospital before operation	Operative procedure and findings	Postoperative course (in hospital), special features	Later course	Result
10 C.H. 1912 315,222 Female 10		3 wks	Indeterminate (poor oral hygiene)	Typical of putrid abscess of lung with later development of severe pleural infection	Circumscribed area of pneumothorax middle third of right chest. Lung is infiltrated and compressed above this region. Infiltration in R.L.T. with small pleural effusion	Not performed	Perforated abscess of R.L.T. Encapsulated putrid interlobar and parietal pyopneumothorax. Operated upon on admission	<i>One stage</i> Local anesthesia through 3rd rib. Drainage of interlobar and parietal encapsulated pyopneumothorax. Exposure of perforated abscess on upper surface of lower lobe. Pulmonary and pleural lesions picked	Uneventful. Discharged 16 days after operation	Uneventful. Bronchial fistula maintained for about 1 mo	Well 2-yr follow-up. Symptom-free
10 H.L. 1913 376,988 Female 20		3 wks	Postmenstrual (for therapeutic abortion)	Typical of putrid abscess of lung with development of severe pleural infection. Chronic rheumatic carditis. Pulmonary abscess. Mitral stenosis	Dense infiltration of medial portion of R.U.P. and thickening of pleura along interlobar fissure. No abscess cavity visible	Not performed	Perforated abscess of R.L.T. Putrid encapsulated interlobar pyopneumothorax. Operated upon on admission	<i>One stage</i> Local anesthesia. Posterior approach through 7th and 8th ribs. Drainage of interlobar encapsulated pyopneumothorax. Exposure of perforated abscess on upper surface of lower lobe. Pulmonary and pleural lesions picked and operation 2 days after first operation. <i>One stage</i> Local and G-O anesthesia. Mediastinal approach through 8th rib. Drainage putrid pyopneumothorax evacuated	Cessation of cough and expectoration. Continued improvement. X-ray 2 days after operation revealed an encapsulated anterior pyopneumothorax	Uneventful. Bronchial fistula maintained for 5 mos	Well 2½-yr follow-up. Symptom-free. X-ray and bronchogram negative
15 A.R. 1915 382,256 Female 70		10 days	Unknown	Typical of putrid abscess of lung with early development of pleural infection	Generalized enlargement of heart. Pleural effusion—lower third of it chest 2 in cavity with fluid level in lung, situated posteriorly near border of heart	Not performed	Perforated abscess of L.L.T. Putrid encapsulated posterior pyopneumothorax. 3 days	<i>One stage</i> Local anesthesia. Postero-lateral approach through 9th rib. Drainage of posterior encapsulated pyopneumothorax. Unroofing of perforated lung abscess. Pulmonary and pleural lesions picked	Two episodes of coronary thrombosis and several small hemoptyses due to minor pulmonary infarctions	Uneventful. Bronchial fistula maintained for 3 wks	Well 1½-yr follow-up. Symptom-free. X-ray negative
13 C.D. 1915 381,900 Female 15		5 wks	Indeterminate (poor oral hygiene)	Typical of putrid abscess of lung with later development of severe pleural infection. Diabetes mellitus	Large pyopneumothorax rt chest with 50 per cent collapse of lung. Abscess of lung with small fluid level situated posteriorly	Not performed	Perforated abscess of R.L.T. Multiple encapsulated putrid pyopneumothoraces. Operated upon on admission	<i>One stage</i> Avertin, G-O anesthesia. Postero-lateral approach through 8th rib. Drainage of multiple encapsulated localities of putrid pyopneumothorax. Exposed and widely unroofed. Pulmonary and pleural lesions picked	Uneventful. Discharged 7½ weeks after operation	Uneventful. Bronchial fistula maintained for 2 mos	Well 1½ yr follow-up. Symptom-free. X-ray negative

GROUP B-1 CUTL PUTRID PERFORATD ABSCESS OF LUNG

[illegible]

Finally, the figures for the total duration of illness before operation are as follows: up to 1 week, 1 case, to 2 weeks, 4 cases; to 3 weeks, 10 cases; to 4 weeks, 7 cases, to 5 weeks, 7 cases; to 6 weeks, 5 cases

The comparatively short duration of illness before admission in the majority of the cases, together with the necessity of early operation in most instances, are indices of the severity of the illness in the preponderance of patients in this series. Of the small group of patients operated upon toward the end of the 6 week period of total illness, some came to operation because of persistence rather than severity of symptoms. In others, the postponement of operation until the sixth week was due to the incorrect assumption of satisfactory progress.

Pre-operative course In the common or so called "typical" case of acute abscess, the clinical manifestations are mild or moderately severe. Thus, the temperature averages around 100 to 101.5 degrees, and cough is moderate. Expectoration is foul, sputum averages about 4 ounces daily and is bloodstreaked from time to time. The general condition is apt to remain fairly good. Of our 34 unperforated cases, only 11 conformed essentially to this clinical picture. In 4 others the clinical course, although only moderately severe, was complicated by episodes of frank hemoptysis. In the 19 remaining cases the manifestations were severe, the clinical course being classified as fulminating in 4, septic in 10, and toxic in 5. The 4 fulminating cases had spiking temperature ranging from 101 to 105 degrees, severe chills (in 3 of the 4), pulmonary excavation extended rapidly, and the general clinical course was one of rapid deterioration. In the 10 cases characterized as septic, pulmonary excavation was also extensive and progressive, fever was high and irregular, but there were no chills and deterioration was not so rapid. The 5 toxic cases ran fairly high fever; however, the outstanding clinical feature was profound prostration and apathy.

A complete analysis of symptomatology will not be given in this paper. However, because of its diagnostic significance, reference should be made to the variations which occurred in one of the important manifestations of the disease, namely, the sputum. As stated pre-

viously, the sputum in "typical" cases is foul, is slightly bloodstreaked from time to time, and averages about 4 ounces daily. Of the 34 unperforated cases, 19 had typical sputum. The remainder presented the following variations: unusually profuse sputum (20 to 30 ounces per day) in 6, unusually profuse but odorless in 2, foul but very scanty in 1, large hemoptyses on one or more occasions in 6.

The pre-operative course in each of the 11 perforated cases was that of the severely toxic or septic type of putrid pulmonary abscess. There were no mild cases. A discussion of the phenomena which characterize perforation, and of the diagnostic criteria of pleural invasion, will not be presented in this paper. However, a few facts gleaned from an analysis of our cases may be stated. The outstanding clinical feature of perforation into the pleura is not only an ominous change in the condition of the patient, but also the suddenness with which it occurs. The physical signs suggestive of fluid, or of fluid and air in the pleura, are definite aids in the diagnosis and are to be contrasted with the vague physical signs usually present when the abscess is confined to the lung. It is assumed by many that the expectoration of foul sputum ceases when an abscess perforates into the pleura. While this may be true in the case of perforation of a small cortical abscess, it is not the rule in rupture of the comparatively large abscess which is the subject of this paper. Thus, the expectoration of foul pus continued in 8 of our 11 cases.

Indications for operation Early in our experience, operations were performed for acute putrid abscess of the lung solely because of imperative indications. In recent years, however, the indications for operation gradually have been broadened so that at the present time there exist, in our opinion, elective as well as imperative indications.

Operation was imperative, by any criteria, in about one-third of the unperforated cases. Thus, there were 11 cases in which an operative attempt at saving of life appeared urgent, because of a hyperacute, fulminating course with or without chills, or a course characterized by severe toxemia and profound asthenia. In the 11 cases of perforated abscess of the lung, operation was obviously imperative.

Finally, the figures for the total duration of illness before operation are as follows: up to 1 week, 1 case, to 2 weeks, 4 cases, to 3 weeks, 10 cases; to 4 weeks, 7 cases, to 5 weeks, 7 cases, to 6 weeks, 5 cases.

The comparatively short duration of illness before admission in the majority of the cases, together with the necessity of early operation in most instances, are indices of the severity of the illness in the preponderance of patients in this series. Of the small group of patients operated upon toward the end of the 6 week period of total illness, some came to operation because of persistence rather than severity of symptoms. In others, the postponement of operation until the sixth week was due to the incorrect assumption of satisfactory progress.

Pre-operative course In the common or so called "typical" case of acute abscess, the clinical manifestations are mild or moderately severe. Thus, the temperature averages around 100 to 101.5 degrees, and cough is moderate. Expectoration is foul, sputum averages about 4 ounces daily and is blood-streaked from time to time. In the 10 cases characterized as septic, pulmonary excavation was also extensive and progressive, fever was high and irregular, but there were no chills and deterioration was not so rapid. The 5 toxic cases ran fairly high fever; however, the outstanding clinical feature was profound prostration and apathy.

A complete analysis of symptomatology will not be given in this paper. However, because of its diagnostic significance, reference should be made to the variations which occurred in one of the important manifestations of the disease, namely, the sputum. As stated pre-

viously, the sputum in "typical" cases is foul, is slightly bloodstreaked from time to time, and averages about 4 ounces daily. Of the 34 unperforated cases, 19 had typical sputum. The remainder presented the following variations: unusually profuse sputum (20 to 30 ounces per day) in 6, unusually profuse but odorless in 2, foul but very scanty in 1, large hemoptyses on one or more occasions in 6.

The pre-operative course in each of the 11 perforated cases was that of the severely toxic or septic type of putrid pulmonary abscess. There were no mild cases. A discussion of the phenomena which characterize perforation, and of the diagnostic criteria of pleural invasion, will not be presented in this paper. However, a few facts gleaned from an analysis of our cases may be stated. The outstanding clinical feature of perforation into the pleura is not only an ominous change in the condition of the patient, but also the suddenness with which it occurs. The physical signs suggestive of fluid, or of fluid and air in the pleura, are definite aids in the diagnosis and are to be contrasted with the vague physical signs usually present when the abscess is confined to the lung. It is assumed by many that the expectoration of foul sputum ceases when an abscess perforates into the pleura. While this may be true in the case of perforation of a small cortical abscess, it is not the rule in rupture of the comparatively large abscess which is the subject of this paper. Thus, the expectoration of foul pus continued in 8 of our 11 cases.

Indications for operation. Early in our experience, operations were performed for acute putrid abscess of the lung solely because of imperative indications. In recent years, however, the indications for operation gradually have been broadened so that at the present time there exist, in our opinion, elective as well as imperative indications.

Operation was imperative, by any criteria, in about one-third of the unperforated cases. Thus, there were 11 cases in which an operative attempt at saving of life appeared urgent, because of a hyperacute, fulminating course with or without chills, or a course characterized by severe toxemia and profound asthenia. In the 11 cases of perforated abscess of the lung, operation was obviously imperative.

analysis of operative cases of *acute* abscess offers the evidence in a comparatively small series. Additional supportive evidence is offered, however, by the findings in a much larger number of cases of *chronic* abscess. Accordingly, we maintain that overlying pleural adhesions are an inevitable accompaniment of putrid abscess of the lung. Adhesions were found at operation in every case of unperforated acute abscess, regardless of how early in the course of the disease operation was performed. Furthermore, the adhesions were sufficiently firm and widespread to agglutinate the apposed pleural surfaces, and thereby permit safe entry of the abscess in one stage. (Cases 7 and 9 are exceptions for obvious reasons)

However, the operative exposure of adhesions sometimes was not a simple matter, and it is probably because adhesions are not always disclosed at the primary incision of the pleura that many observers have questioned our contention that adhesions always are present. Despite painstaking attempts at precise localization, adequate agglutinating adhesions were not found at the site of initial rib excision in all of our cases. Analyzing the 38 operations, adhesions occupying the entire operative field, to the complete exclusion of the free pleura, were encountered in 27. In 7 others, because of slight errors in localization or in placement of the incision, adequate adhesions were found not directly beneath, but immediately adjacent, to the primary operative exposure. (As stated in our previous communication, the entry of the free pleural cavity, directly adjacent to adhesions, no longer constitutes a bar to the performance of a single stage procedure.) There was one gross error in localization, already referred to, and in this case (Case 10), no adhesions were found at the site of operative approach. The absence of adhesions was recognized, and accordingly the pleura was not opened. Adequate adhesions were encountered at a second operation, when the operative approach was made at the correct site a few days later. Disclosure of adhesions, in or adjacent to site of operative approach, at 34 of 35 operations (31 patients), is the best commentary on the accuracy with which acute abscess of the lung can be localized.

Well developed adhesions also existed in the 3 remaining cases, but were not parietal and therefore could not possibly be present at the site of operative approach. In 1 of these (Case 9), the abscess faced an interlobar fissure. In this instance, the adhesions agglutinated the apposed surfaces of the lobes and sealed the fissure about the abscess. In the last 2, the abscess faced the under surface of the lower lobe. In this region, agglutinating adhesions were situated between the under surface of the lobe and the adjacent surface of the diaphragm. This picture presented itself in our Cases 7 and 21.

In the 11 perforated cases, adhesions lying directly over the abscess were of course destroyed in the process of penetration of the abscess into the pleural cavity. It is interesting to note, however, that some attachment of the lung to the parietes in the region of the abscess still persisted in a number of cases at the time of operation.

Entry of the free pleural cavity. The free pleural cavity was entered inadvertently at only 1 of the 27 operations in which there were *parietal pleural adhesions at the site of operative approach*. In this instance (Case 15), in which a child was operated upon under light general anesthesia, the pleura tore, apparently as the result of the patient's straining, after the abscess had been incised. The free pleural cavity was entered inadvertently shortly after rib excision in 4 cases (Cases 5, 14, 20, and 30) and this was *attributable to faulty technique*. (However, the fact that the pleural cavity could be entered so readily was evidence also that there were no adhesions or only scanty adhesions at the immediate site of the primary operative approach.) The pleural opening at once was enlarged in these cases for purposes of exploration.

The free pleural cavity was entered intentionally in 7 cases. Reference already has been made to 3 of these (Cases 7, 9, and 21), in which no parietal adhesions were present because the abscess faced the interlobar fissure or the diaphragm. In the 4 other cases (Cases 13, 24, 32, and 33), the free pleural cavity was opened in order to search for adhesions which were absent at the immediate site of operative exposure.

There remain 23 cases of unperforated abscess in which the indications for operation were considered "elective." Assuredly, a difference of opinion concerning these cases will exist, the generally held view being that abscess of the lung in the acute stage is a non-operative lesion. Although emphasizing that we do not operate in cases of acute abscess of the lung when the lesion is small and the clinical course satisfactory, we wish to state that our operative indications have been widening as the result of increasing confidence in the outcome of operation when performed with the technique we have developed. In our opinion the elective operative indications to be mentioned are tenable only upon application of the principle of accurate pre-operative localization of the lesion and the use of the type of operative procedures which we advocate. We do not hesitate to express the opinion that high mortality and morbidity as well as incomplete results are almost inevitable if methods generally employed at present time in surgical treatment of abscess of lung are applied to cases of acute abscess.

With due regard to the statements contained in the preceding paragraph, our elective indications for operation are: (1) a septic or severely toxic clinical course (bordering on imperative indication), (2) the absence of a tendency toward spontaneous subsidence, (3) an apparently stationary lesion as noted in successive roentgenograms coupled with a moderately severe clinical course, (4) an increase in size of the lesion accompanied by increasing clinical manifestations, (5) a more or less "shut off" lesion or the development of a more or less 'shut off' state in a previously "open" lesion, (6) a dangerously situated lesion, in the 'cardiac' lobe for example, (7) unusually large lesions, (8) the roentgenographic evidence of pronounced pleural reaction suggesting impending or actual perforation of the abscess.

With increasing experience we have become less and less inclined to defer operation if there is doubt as to the satisfactory progress of a case.

THE OPERATION

An outline of the operative procedures which were employed in our 45 cases will be

found in the appended tabulation. The details of technique of operation have been described elsewhere,¹ and will not be discussed in this paper. However, reference will be made to certain aspects of operation which in our opinion, have a significant bearing on the results.

Whether the choice of *anesthesia* is a factor in the results which have been obtained can not be ascertained from a study of our cases. Thirteen of 34 operations for unperforated abscess were performed under local anesthesia. The remainder were carried out under gas-oxygen anesthesia (rarely with the addition of ether). In recent years avertin, supplemented when necessary by gas-oxygen, has been employed. On the other hand, local anesthesia has been used more often than general in the perforated cases.

The reasons for our advocacy of the *one stage operation* have been fully set forth elsewhere. Of the 38 operations (34 patients) for unperforated abscess, 34 were one stage procedures. In 2 instances (Cases 7 and 9) two stage operations were performed because the abscess situated on the under surface of the lower lobe faced the diaphragm. The 2 remaining patients (Cases 5 and 33) early in our experience were operated upon in 2 stages because the free pleural cavity had been opened by accident adjacent to adhesions at the first stage. (At the present time these 2 cases would probably be operated upon in one stage.) All the perforated cases were operated upon in one stage. Later drainage of secondary loculi was carried out in 3 instances to which reference will be made.

The localization of the site of the abscess by pre-operative studies was the sole guide to the placement of the *thoracic incision*. As has been indicated elsewhere we advocate no 'stand-ard' or 'routine approach'. Thus, of 33 operations (34 patients) for unperforated abscess, an avillary approach was made in 6, anterior thoracic in 2, paravertebral in 16, posterolateral in 10 and anterolateral in 4.

The subject of *adhesions overlying the abscess* appears to be the most debated aspect of presentations on abscess of the lung which we have made at various times and places. This

spite of drainage of the abscess at the second stage, and subsequent drainage of the pleural infection, the patient died. At postmortem examination, the lesions found within the right lung and pleura were sufficient to account for death, but whether a cerebral embolus also existed was not determined because of a limited autopsy. This case represents a surgical death which occurred early in our experience, and which we regard as probably avoidable with present surgical methods.

As to the second fatal case (Case 28), the patient was admitted to the hospital 9 days after incision, without anesthesia, of a peritonsillar abscess. Cough and profuse foul expectoration had been present for several days prior to admission, but the unusual clinical feature was a septic course with irregular, spiking temperature and repeated, severe, shaking chills. On admission, the patient was suffering from profound toxemia and toxic psychosis. Successive x-ray films taken before admission revealed a rapidly enlarging abscess involving much of the right lower lobe. The repeated chills and profoundly septic state led to the additional diagnosis of septic thrombophlebitis of a large branch of the pulmonary vein. This appeared to be the most ominous feature of the case. At operation, on the day after admission, a huge pulmonary abscess was evacuated, unroofed, and packed, in one stage. The operation was without incident. Cough and foul sputum ceased, but septic fever and chills continued, and death occurred on the fourth day after operation. The assumption is warranted that in this instance, death was due to a continuation of sepsis and not to operation.

Secondary operations. In a number of cases, secondary operations, oftentimes minor procedures, were performed for various purposes. In the unperforated group, there were 4 cases in which drainage of additional loculi was performed (Cases 3, 14, 20, and 30), the drainage being established through the existing operative wound in 3 of the 4 cases; a putrid empyema was drained in 1 case (Case 9, the fatal case already referred to); plastic operations for early closure of large cavities were carried out in 3 cases (Cases 15, 22, and 27). It should be noted that the latter were opera-

tions of choice, performed for the purpose of shortening the duration of open wounds.

In the perforated group, additional undrained pleural collections were operated upon in 2 instances (Cases 35 and 40); an additional unperforated abscess of the lung was drained in 1 case (Case 37); and minor revision of an existing surgical wound was performed in order to permit more direct drainage in 1 case (Case 43).

Duration of postoperative hospitalization. There is a rather widely held view that serious complications often follow operation for abscess of the lung, and that the period of postoperative hospitalization is inordinately long. The fact is, as already pointed out, that serious postoperative complications were rare. As a corollary, the postoperative stay in the hospital usually was not unduly prolonged. Of the unperforated cases, more than half left the hospital in the first month after operation and most of the remainder left in the second month. The stay of the perforated cases was longer, in a few instances, because of treatment required for large empyema cavities.

Duration of maintenance of bronchial fistula and open wound. The management of the bronchial fistula, a vital part of postoperative treatment, has been discussed elsewhere.¹ The point to be stressed is that closure of the bronchial fistula, always present after an adequate operation for abscess of the lung, should be under control of the surgeon. The fistula is then permitted to close only after all clinical evidence of anaerobic infection has disappeared, after pulmonary infiltration is no longer visible in the roentgenogram, when expectoration is absent or minimal and, if doubt exists, after bronchoscopy has been performed with negative findings.

It has been asked whether difficulty ever has been encountered in closing the bronchial fistula. Difficulties are encountered occasionally in cases of chronic abscess of the lung when one or more fistulas have been present for a considerable period of time. After operation for acute abscess of the lung, however, the problem is not how to close, but rather how to keep open, a fistula which tends to close prematurely. In the majority of our

It should be especially stressed that the pleural entry, whether planned or accidental, took place early in the course of operation (with the single exception already noted—Case 15). Because of this fact there was but one complicating putrid empyema following an operation for unperforated abscess (Case 9), and thus occurred after the first stage of a deliberately performed two stage operation.

Some features of the pathology at operation The superficial situation of the lesion within the lobe of the lung, a fundamental characteristic of putrid abscess which was pointed out in a former communication,¹ goes hand in hand with the presence of overlying pleural adhesions. In each of the 34 unperforated cases, the abscess was entered after traversing a practically avascular shell of compressed lung which measured about one quarter of an inch in thickness. The superficial situation of the pulmonary lesion in perforated cases is self evident, and probably constitutes the most important reason for the occurrence of early perforation.

One of the arguments which we advanced in favor of operation in the acute stage of putrid abscess of the lung was the tendency of the lesion in many of the more severe cases to assume at a comparatively early date some of the pathological features of chronic abscess. Thus, of our 34 unperforated cases, only 18 (little more than half) presented the solitary, unilocular cavity which is characteristic of the early acute phase. Of the lesions in the 16 remaining cases 8 were distinctly bilocular and 8 were multilocular (not multiple). In each of the 11 perforated cases the lesions were unilocular. This perhaps was to be expected because early evacuation of the abscess into the pleura probably reduced the likelihood of further extension of the lesion within the substance of the lung.

The only additional feature of the pathological findings at operation, to which we shall refer here, is the bronchial fistula. One or more freely blowing fistulas was found opening into the cavity in every case. In a few instances in which the fistula was not apparent at operation, because it was plugged with detritus or blood, it was seen at the first dressings.

Postoperative complications The clinical course of our 45 patients, from the time of operation to the time of discharge from the hospital, can be analyzed briefly. In 28 cases recovery was uneventful. In the 17 remaining (13 unperforated and 4 perforated) the post operative course presented complications of varied nature and severity. For the sake of completeness all are included, although several were of a minor nature, others existed prior to operation, and still others appeared to be independent of the operative procedure.

The complications in the 34 unperforated cases (38 operations) were as follows: toxic psychosis, 2 cases, undrained adjacent abscess, 2 cases, undrained adjacent abscess with toxic psychosis, 1 case, sterile hydro pneumothorax and toxic psychosis, 1 case, mild bronchopneumonia (non putrid), 1 case, spillover putrid lung abscess, 1 case, thrombophlebitis of a branch of the pulmonary vein, 1 case, bleeding from the wound at the first dressings, 2 cases. None of these complications was fatal, and few were serious in the sense that they endangered life. Two deaths occurred after operation. These will be discussed separately.

The 4 complications in the 11 perforated cases were as follows: bland cerebral embolus with spontaneous recovery, 2 cases, coronary thrombosis and pulmonary infarction, 1 case and multiple encapsulated non putrid empyemas, 1 case. There were no deaths in the perforated group.

Discussion of deaths As stated in the preceding section there were 2 deaths in the series both occurring in unperforated cases. In 1 case (Case 9) the patient had a single abscess which lay partially within the right middle and partially within the right lower lobe as the result of extension across the sealed-off interlobar fissure. Because of the unusual location of the lesion adhesions were present only between the middle and lower lobe, and between the lower lobe and the diaphragm, there being no parietal adhesions of the lung to the chest wall. For this reason a two stage operation was undertaken. Between the first and the second stage, the patient developed evidence of pleural infection, toxic psychosis (and cerebral embolism?) In

fulminating in 4, septic in 10, and toxic in 5. It was of the severely toxic or septic variety in all cases of perforated abscess.

The outstanding clinical feature of perforation into the pleura was not only an ominous change in the condition of the patient, but also the suddenness with which it occurred. The presence of physical signs of empyema or pyopneumothorax was a definite aid in the diagnosis of perforation, and contrasted with the indefinite physical signs usually found in unperforated abscess of the lung.

Although operation is not advocated in acute abscess when the lesion is small and the clinical course satisfactory, the authors' operative indications have been widening. As a result, elective as well as imperative operative indications are described. Operation was classified as imperative in all perforated cases because severe and oftentimes spreading infection existed, and spontaneous recovery seemed most unlikely. In 11 unperforated cases, operation was imperative because the course was fulminating and hyperacute, or was characterized by severe toxemia. In the 23 remaining unperforated cases, the indications for operation were elective. The authors' elective indications are (1) septic or severely toxic clinical course (bordering on imperative indication), (2) absence of any tendency toward spontaneous subsidence, (3) apparently stationary lesion (in successive roentgenograms) coupled with a moderately severe clinical course, (4) increase in size of the lesion accompanied by increasing clinical manifestations, (5) more or less "shut off" lesion, or the occurrence of a more or less "shut off" state in a previously "open" lesion; (6) potentially dangerous situation of the lesion, in the cardiac lobe for example, (7) unusually large lesions, (8) roentgenographic evidence of pronounced pleural reaction suggesting impending perforation of the abscess.

With 4 exceptions, all operations were performed in one stage. The one stage operation is advocated by the authors only when the exact localization of the abscess by pre-operative studies has been carried out. The principles of operation consist essentially in the unroofing and the wide packing of the abscess cavity.

Pleural adhesions overlying the abscess invariably were present, regardless of how early in course of the disease operation was done.

In 38 operations (34 patients) for unperforated abscess, adequate adhesions occupying the entire operative field at the initial site of rib excision were encountered 27 times. In 7 others, adhesions were found immediately adjacent to the primary operative exposure. In 1 case, no adhesions were found at the initial operative site because of an error in localization. In the 3 remaining cases adhesions, although well developed, were not situated parietally because of the unusual location of the abscess (interlobar, supradiaphragmatic, etc.).

The free pleural cavity was entered inadvertently during only 1 of the 27 operations in which there were parietal pleural adhesions at the site of operative approach. Of the remaining cases, the free pleura was entered accidentally, shortly after rib excision, in 4 cases. It was opened in 7 cases for purposes of exploration.

In all cases, only a thin avascular shell of lung lay between the most superficial portion of the abscess and the overlying sealed off pleura. In 18 cases, a solitary unilocular cavity, characteristic of the early acute phase, was encountered. In 16, the cavities were already bilocular or multilocular. In each perforated case, the pulmonary lesion was unilocular. Bronchial fistulas were present in all cases.

Recovery was uneventful in 28 cases. In 17, there were complications which, for the most part, were not serious. Bronchial fistulas were permitted to close only after all discernible evidence of infection had disappeared—8 weeks in the majority of cases.

There were two postoperative deaths. One was due to pleuropulmonary suppuration. The second was due to the continuation of a sepsis which existed prior to operation. Of the 43 remaining patients 40 were cured according to the criteria stated in the text: (1) healed wound; (2) freedom from pulmonary symptoms; (3) absence of roentgenographic evidences of pulmonary infiltration. In the 3 remaining cases, the period of follow-up was too short to speak of cure, but all were progressing toward cure when last examined.

cases, fistulas were permitted to close within 8 weeks of operation. Since these fistulas were purposefully maintained by packing or by tube, the wounds closed in all cases soon after drains were discontinued. There were 3 patients in whom fistulas were maintained for long periods—7 months, 1 year, and 2 years, respectively. In the first, the cavity was of unusually large size and was obliterated slowly. The second patient insisted upon wearing his tube for a year because he had had recurrence of manifestations when his fistula was permitted to close shortly (prematurely) after operation. In this case, there remains a cutaneous dimple into which a fine probe can be introduced. Because of an oversight, the bronchial fistula was maintained by a tube for 2 years in the third case. It is of interest to note that the wound closed promptly after the tube was removed.

Bronchial fistulas also were present in all of the perforated cases after operation. Fistulas were maintained for periods up to 5 months, the average being about 7 weeks. The wounds generally were closed within a few weeks of the time of bronchial closure. As in the unperforated cases, the wounds closed completely in all cases.

Results of treatment. In evaluating the results of treatment, our criteria of cure are strict. No patient is considered cured unless pulmonary symptoms have disappeared completely, pulmonary infiltration is absent on roentgenographic examination, and the wound is healed. Bronchoscopy and bronchography, if performed, also must be negative. Cure, according to these criteria, usually occurs early and is lasting. There were 2 deaths to which reference already has been made. Of the 43 remaining patients, 32 were in the unperforated group and 11 in the perforated.

Of the 32 unperforated cases, 20 were followed for periods ranging from 1 to 10 years. Complete cure occurred in 11. (In Case 4, death occurred from carcinoma of the stomach 3 years after operation and the lungs were negative at postmortem examination.) The 3 remaining cases were doing well and apparently progressing toward cure when their follow up was terminated as follows: 1 case, after 4 months, suicide; 1 case, after 3 months, death

following operation for strangulated hernia; 1 case, after 3 months, disappeared from observation. The last was the only instance in which our follow up has been incomplete.

The 11 perforated cases have been followed for periods ranging from 1½ to 7 years. All are cured.

SUMMARY

Forty-five consecutive operative cases of acute putrid abscess of the lung treated in accordance with principles described by the authors in another communication, are analyzed. In 34 cases the abscess was confined to the pulmonary parenchyma. In 11 cases the abscess had perforated into the pleura prior to operation.

A single abscess was present in the great majority of cases. The right lung was involved more than twice as often as the left. These facts, in addition to others stated in the text, tend to support the aspiration theory of causation of pulmonary abscess.

The etiology was definite (tooth extraction, tonsillectomy, etc.) in 19 cases. It was entirely obscure in 9. The 17 remaining patients suffered from gross gingivodental infection which, for reasons stated in the text, was regarded as the source of the pulmonary abscess.

The typical roentgenographic features of acute abscess of the lung were present in the minority of cases. Atypical features were encountered most often in the severe cases.

Diagnostic bronchoscopy located with great accuracy the bronchopulmonary segment or segments in which the abscess was situated.

The duration of illness before hospitalization varied from several days to 5 weeks. The majority of patients entering the hospital in the second to fourth week. The complication of perforation of the abscess into the pleura took place most commonly in the second or third week of illness. The relatively short duration of illness before admission, in the majority of cases, together with the necessity of early operation in most instances, indicated the severity of the disease in the preponderance of patients in this series.

Typical clinical manifestations of acute putrid abscess of the lung occurred in only 11 patients. Hemoptysis was an outstanding feature in 4 cases. The clinical course was

TABLE I

Sugar	75	75	75
Sodium chloride	485	485	485-495

1 to 2 weeks. The patient with vomiting of 7 months, on admission had no acetone in the urine, a hemoglobin of 70 per cent, and remained only 6 days. Occasionally patients vomit intermittently throughout pregnancy without the necessity of entering the hospital. In general, the length of time in which vomiting had persisted before the patient entered the hospital had no definite relation to the severity of her condition nor to the response to treatment. This agrees with recent reports (26).

The average duration of pregnancy on admission was 13.9 weeks and only 63.8 per cent were 3 months and under. This was due to the long duration of vomiting in many cases.

The blood pressure was not materially affected. There was a tendency for the pressure to be slightly lower after treatment, although in numerous cases there was some increase. There was a distinct rise to 146 systolic in 2 cases of low reserve kidney and in 2 cases of late vomiting of pregnancy.

The hemoglobin was definitely increased on admission. In most of the severe cases it was 90 per cent or above (Sahli method used). The average was 87.3 per cent. After treatment there was a drop to an average of 76.5 per cent. The increased hemoglobin was no doubt due to the marked dehydration and concentration of the blood. This appears to be of some diagnostic significance as to the severity of the symptoms but by no means is it always indicative. Some patients with a hemoglobin of 90 to 95 were cured merely by frequent small meals and in 1 patient with an admission hemoglobin of 90 it was necessary to induce abortion. Generally when the hemoglobin was low, it denoted less dehydration and the symptoms were readily amenable to treatment.

The value of blood chemical findings is not fully appreciated. They are often said to be of little use in hyperemesis gravidarum. Yet

Fig. 1. Chart showing age and parity.

frequently one obtains valuable information and assistance in properly treating individual cases. Many reports are based on a single or admission determination. Most of our patients have repeated or serial determinations which allow a better picture of the progress and response to treatment.

In normal pregnancy there is an alteration in the metabolism and in certain of the blood constituents. The normal values as determined by Stander are shown in Table I. In hyperemesis there is a further change.

Harding (9), Dieckmann and Crossen, Haden and Guffy, Stander and others (5, 15), have found an increased non-protein nitrogen and uric acid in cases of vomiting, especially in the severe cases. By taking serial blood specimens and plotting curves, there is found to be a more or less definite drop following active treatment with fluids (Fig. 2). This is sometimes preceded by a short rise. In cases in which only dietetic measures are used, the drop is not so noticeable. The average non-protein nitrogen (Fig. 3) was 28.6 and the average after the initial drop was 24.6. Some patients in the later months of pregnancy, and possibly before abortion, have a rising curve in spite of active treatment. This is more noticeable in the uric acid curve than in the non-protein nitrogen (Fig. 5).

The uric acid usually follows the non-protein nitrogen (Figs. 2 and 4). Some of the

A STUDY OF HYPEREMESIS GRAVIDARUM WITH SPECIAL REFERENCE TO BLOOD CHEMISTRY

OSCAR GLASSMAN, M D, New York, New York

IT is generally agreed that hyperemesis gravidarum is an exaggerated or pernici-ous form of "morning sickness" or nausea and vomiting of pregnancy. Its etiology is not known and although our methods of treatment have gradually improved we have no way of determining which patients will fail to respond to treatment. A critical study of the usual response to treatment may throw some light on these cases.

Generally the cases are classified as neurotic, reflex, and toxic. Many investigators believe that the neurotic type will respond readily to treatment whereas the toxic type does not. Solomons, as well as most present day writers does not believe in the reflex type and he utilizes the Fouchet test¹ to distinguish the toxic from the neurotic. If the Fouchet test is positive, provided there is no albumin in the urine, the case is considered toxic and if the test is negative, the case is classified as neurotic. Van Wyck states that no satisfactory distinction can be made between the toxic and the neurotic vomiting. Plass considers them all neurotic and states he does not know how to differentiate those individuals who will die. Because so many patients respond to suggestive therapy it is natural to suppose that some or all are neurotic. Stander believes that from a clinical study and chemical findings in the blood and urine as well as from experimental work on animals, all cases of vomiting of pregnancy have a toxic basis. The underlying toxemia may be obscured by a predominating neurosis. Accordingly we classify all cases of hyperemesis gravidarum with the toxemias.

There were 86 patients with hyperemesis gravidarum admitted to the New York Hospital in 12,005 admissions—an incidence of 0.71 as compared to 1.21 of Cruikshank.²

From the Department of Obstetrics and Gynecology, Cornell University Medical College and the New York Hospital.

¹An oxidation test for bilirubin. *Compt. rend. soc. de biol.* 1917, 80: 816.

of Costa, and 0.66 of Peckham. According to Pick, 1 in 1,000 and according to Williams 1 in several hundred pregnant women develop hyperemesis.

In this series were included only those patients who were admitted to the wards during their pregnancy and sufficiently studied as to weight, blood chemistry, and water balance—50 in all. Three of these had two admissions and 1 had four admissions. The cases were not divided as to severity. All cases in which patients required hospitalization were considered severe enough to be included in the study. The various theories as to etiology and treatment will not be considered.

The average age was 27.0 years (Fig. 1). There were a greater number of primiparae but no increase in elderly primiparae. The multiparae averaged 1.48 children. Quigley found no increased nausea and vomiting in elderly primiparae, and Misset found no difference in incidence between primiparae and multiparae but he did find that with nausea and vomiting in the first trimester the incidence of late toxemia increased. Schultze, Rhonhof and others (8) find primiparity a definite factor.

There were only 2 negroes, 1 Porto Rican and 1 Mexican in our series. The average number of colored patients in the entire clinic is only 12.1 per cent (19). In a group from Baltimore (26) hyperemesis was equally divided between black and white. Theobald points out the rarity of toxemias of pregnancy in Siam and other countries in the far East. Holman in reviewing the literature concerning hyperemesis gravidarum among various classes, notes that there is little evidence of this condition among the aborigines or so called uncivilized people.

The period of vomiting before entering the hospital varied from a few days to 7 months. However with severe vomiting it was necessary that the patient enter the hospital within

Fig 4. A composite curve of the blood uric acid determinations. This does not depict the early drop as is shown in many of the individual cases.

cases had very little change but, except for an initial small rise, the majority have a distinct fall. It appears that in some cases which will not respond to treatment (Fig. 7) and in certain cases of late vomiting of pregnancy (Fig. 5) the uric acid tends to rise. In the latter cases it may indicate liver damage or even a mild yellow atrophy. Harding and Van Wyck (10), however, suggest that the vomiting of late pregnancy may have its origin in some salt and water disturbance, both sodium bicarbonate and sodium chlorides causing redistribution of water.

Low sodium chloride values are reported in hyperemesis by Stander (40), Harding (9), Haden and Guffy, and Dieckmann and Crossen. In the present series the average sodium chloride on admission was 489 which is essentially normal (Fig 8). There was some tendency to an increase but the change was not great. One case had an extremely low sodium chloride, 365. One had 427 and another 435. Peckham reports an average of 480.9 and 2 patients with less than 400. Haden and Guffy report a case with blood chlorides of 300 and Harding and Van Wyck (12) report a case with blood chlorides of 290, both responding to sodium

chloride therapy. This in itself reveals the value of blood chemical studies in the treatment of individual patients.

The blood sugar (Fig. 9) was fairly constant and apparently agrees with that of most investigators who find a normal or slightly lowered blood sugar (4, 6, 37). Peckham finds

Fig 5 Shows rising non-protein nitrogen and uric acid in late vomiting of pregnancy despite active treatment. Labor was medically induced 2 weeks before term. Case No. 42822

Fig 2 Showing the usual early drop in non protein nitrogen and uric acid. Note the disappearance of acetone in the urine and the rise in weight with improvement. Case No 68307

Fig. 4. A composite curve of the blood uric acid determinations. This does not depict the early drop as is shown in many of the individual cases.

cases had very little change but, except for an initial small rise, the majority have a distinct fall. It appears that in some cases which will not respond to treatment (Fig. 7) and in certain cases of late vomiting of pregnancy (Fig. 5) the uric acid tends to rise. In the latter cases it may indicate liver damage or even a mild yellow atrophy. Harding and Van Wyck (10), however, suggest that the vomiting of late pregnancy may have its origin in some salt and water disturbance, both sodium bicarbonate and sodium chlorides causing redistribution of water.

Low sodium chloride values are reported in hyperemesis by Stander (40), Harding (9), Haden and Guffy, and Dieckmann and Crossen. In the present series the average sodium chloride on admission was 489 which is essentially normal (Fig. 8). There was some tendency to an increase but the change was not great. One case had an extremely low sodium chloride, 365. One had 427 and another 435. Peckham reports an average of 480.9 and 2 patients with less than 400. Haden and Guffy report a case with blood chlorides of 300 and Harding and Van Wyck (12) report a case with blood chlorides of 290, both responding to sodium

chloride therapy. This in itself reveals the value of blood chemical studies in the treatment of individual patients.

The blood sugar (Fig. 9) was fairly constant and apparently agrees with that of most investigators who find a normal or slightly lowered blood sugar (4, 6, 37), Peckham finds

Fig. 5. Shows rising non-protein nitrogen and uric acid in late vomiting of pregnancy despite active treatment. Labor was medically induced 2 weeks before term. Case No. 42822.

Fig 6 Although the non protein nitrogen and uric acid respond well to treatment showing early drop the patient did not respond clinically and therapeutic abortion was done. However as will be noted the acetemuria was not controlled. Case No 123862

a normal sugar in the mild cases but an increased sugar in the severe cases. Titus found a low sugar and believes carbohydrate deficiency to be the chief underlying factor in pregnancy toxemia. However, a markedly perverted carbohydrate metabolism is well recognized (37) and glucose is generally given because it spares protein and fortifies the liver.

The carbon dioxide curves are very interesting and show wide fluctuations (Fig 10). That the acid base equilibrium is not very stable in normal pregnancy is shown by MacNider who found that in normal pregnant animals there is a definite tendency for the acid base equilibrium of the blood to become disturbed and concludes, from a large series of experiments, that, associated with gestation, there is a definite tendency toward failure to maintain a normal acid base equilibrium. In normal pregnancy there is a reduced alkali reserve (42), as shown by lowered alveolar carbon dioxide tension (13) and a decreased carbon dioxide of the serum (18, 22, 32, 39). Oard and Peters revealed that this lowered alkali reserve was due to the decrease in the fixed base and not to an increase of acids. This was cor-

roborated by Stander (42) who found the hydrogen ion concentration within normal limits but due to the decreased serum bicarbonate there was a "compensated alkali or carbon dioxide deficit" rather than a true acidosis. Voza showed that the decreased alkali reserve was more marked during the first stage of pregnancy and that 300 cubic centimeters of 10 per cent glucose or 10 units of insulin did not change it.

Peckham found a marked variation in the carbon dioxide combining power of the blood in vomiting of pregnancy. Our average carbon dioxide combining power was 45.3 volumes per cent and varied between limits of 27.7 and 64.5. The wide fluctuations may be due to the unstable acid base equilibrium and two opposing factors, one being the starvation acidosis and the other, due to loss of hydrochloric acid and electrolytes in the vomitus, producing an alkalosis. It has also been suggested that the rapidity of change may be of greater significance than the absolute level of the carbon dioxide combining power, as occurs with blood sugar changes in reference to hypoglycemic convulsions (20, 23). Frequent carbon dioxide determinations are therefore, very necessary.

The serum proteins were not determined. Van Wyck considers them of prognostic significance. A high protein determination, with few exceptions, he thinks is a good prognostic sign. Low protein and dehydration signifies a long duration of symptoms with destruction of protein and serious prognosis.

The weight curve appears to be of definite value. Few clinics weigh the patients after admission to the hospital. Yet this is probably more important than the pulse rate in these patients. It is difficult to determine how much weight the patient has lost when she enters the hospital as the figure given by her is often unreliable unless she has been carefully observed. In this series it was given as from 10 to 30 pounds. Peckham reports 6 patients with a loss of weight over 30 pounds, but the loss of weight on admission apparently had no relation to the response to treatment.

Our patients are now weighed every day or on alternate days. The scale is wheeled to the bedside. If the patient is very ill she can be

Fig 7 There is a gradual increase in non-protein nitrogen and uric acid. Note the absence of initial drop, and continued loss of weight. Therapeutic abortion was necessary. Case No 93434

Fig 8 Sodium chloride. The heavy dotted lines are curves of cases requiring therapeutic abortion

Fig 9 Blood sugar

Fig 10 Carbon dioxide combining power

lifted onto the stretcher scale and weighed with little or no disturbance. On admission the patient is already dehydrated, has lost considerable weight, and the subsequent loss is usually important. Figure 11 reveals the weight curves of 17 patients. The average curve generally has an initial rise due to the intravenous fluids administered. It then gradually subsides and with improvement of the patient it begins to rise. In 3 cases in which therapeutic abortion was necessary, the weight curve continued to drop (Figs 6, 7, 11). One patient lost weight rapidly but as the acetonuria cleared up after hypodermoclysis,

and as the blood chemical findings indicated that the patient was reacting favorably, we were not alarmed.

A conspicuous and almost constant finding on admission to the hospital is acetonuria (Table II). This was present in 40 cases and absent in 5 cases. In the latter cases the condition was comparatively mild and required no intravenous therapy. Two patients showed no acetone on admission but did show a trace shortly thereafter. These two patients were each given intravenous injections of glucose. Small amounts of glucose given to starving animals will cause the appearance of a great

number of acetone bodies in the urine (38). Ketosis as it affects the human organism, however, is not entirely the same as in other species; rats and other animals are very resistant to the development of ketosis (16).

A diet poor in carbohydrates leads to the excretion of acetone bodies in normal pregnant women whereas on an identical diet the non-pregnant women will show no acetone (29, 30). Schmidt and Wingen noted that the large carbohydrate requirement of pregnancy is met by conversion of fat to glycogen and that acid by-products are likely to appear. In hyperemesis, as in starvation, the protein is spared to the very last while the fat is being burned. The fat content of the blood increases and acetone bodies appear in the urine. The acid bodies of the blood are increased in the vomiting of pregnancy according to various observers. Runge and Juhl observed increased amino acids, Loeser reports increased lactic acid, and Bokelmann and Bock found an increase in "acetone bodies."

That the acetone in the urine is not the immediate cause of the vomiting has been clearly shown by Harding (10) who placed pregnant patients on a high fat diet, and found that acetone appeared in the urine, but that none of the patients developed vomiting. There is a close association, however. Thalheimer, Waters, and others observed that the vomiting ceased with the absence of ketonuria. This usually takes place but often the acetonuria persists for a few days after the vomiting has ceased or the vomiting persists with negative acetone findings. However, in the latter condition, the acetone usually reappears within a short time if the vomiting continues.

From a consideration of the facts stated, the value of blood chemistry in hyperemesis gravidarum is at once evident. An extremely low chloride, sugar, or carbon dioxide value can be readily corrected. Mistakes of com-

Fig. 11. Weight curves

mission, as exemplified by the following report, can be obviated. Titus relates a case, in which a patient with almost continuous vomiting, acidosis, and dehydration was admitted to the hospital. A blood specimen was taken before the intravenous injection of glucose and it revealed a blood sugar of 230.

One cannot determine the prognosis by any one procedure or finding. It is necessary to take into account various factors. Often the prognosis is facilitated by observing the response to treatment. The objective factors in this study which are somewhat indicative of this response are the curves of the non-protein nitrogen and uric acid, the weight curve, and acetonuria.

It would seem that in the proper treatment of these patients, blood chemical studies are essential. The acidosis must be controlled and by the proper evaluation of the blood findings and weight curve, one can better arrive at a decision as to whether or not interruption of pregnancy is indicated. We consider retinal hemorrhages (40, 45) as absolute indications for interruption of pregnancy. The presence of jaundice is a further indication of the severity of the disease.

SUMMARY AND CONCLUSIONS

1 We classify all cases of hyperemesis gravidarum as toxemia.

2 The incidence in the woman's clinic of the New York Hospital is 0.71 per cent.

3 The average age in this series is 27.9 years and there is an increase in incidence in primiparæ but no apparent increase in elderly primiparæ.

4 Hyperemesis gravidarum is relatively infrequent in negroes.

5 The length of time in which vomiting persists, the duration of the pregnancy, the pulse rate, and the blood pressure have no definite relation to severity of the condition.

6 A high hemoglobin appears to be of some diagnostic significance and as a rule denotes marked dehydration.

7 The non-protein nitrogen content and the uric acid content may be increased but show a sharp drop after treatment with intravenous fluids. In some cases of late vomiting of pregnancy and in some patients who do not respond to treatment the non-protein nitrogen content and the uric acid content tend to rise.

8 Blood chlorides and sugar values are usually within the normal limits. A few patients show extremely low values but respond to therapy.

9 There is a marked fluctuation in the carbon dioxide combining power of the blood with great tendency to acidosis.

10 Acetonuria is a conspicuous finding and although not the immediate cause of vomiting, control by proper therapy is important.

11 The value of blood chemical studies in the rational treatment of hyperemesis gravidarum is at once evident.

12 Prognosis is dependent upon the following: the hemoglobin values, the weight curve, the presence or absence of acetonuria, the blood chemistry determinations, and the effect treatment has on these factors.

13 Among the indications for interruption of pregnancy are continued loss of weight with rising non-protein nitrogen and uric acid, retinal hemorrhages and marked jaundice.

THE OBSTETRICAL SHOULDER TRAUMA

Dr OSCAR SCAGLIETTI, Bologna Italy

THE term, "birth palsy" signifies all clinical manifestations which may be observed after trauma to the shoulder during delivery. The term is misleading. The sequelae of shoulder trauma show that in the majority of cases the lesion does not involve the nerve trunks of the brachial plexus. The clinical material of the Istituto Rizzoli permits, according to Putti, the following classification of cases of "birth palsy."

Obstetrical trauma of shoulder joint	{ Simple distortion
	{ Complicated epiphyseal separation of upper end of humerus
	{ Fracture of clavicle
Obstetrical paralysis	{ Upper type
	{ Lower type
	{ Total type
	{ Associated atypical forms

There are also mixed forms which involve ment of nerve roots and of the joint ends. These cases show the most complicated clinical picture.

This classification is of great practical value because, as stated by Putti, the clinical picture of the obstetrical trauma should not be confounded with obstetrical paralysis.

From 1899 to June, 1935, 199 cases of obstetrical shoulder lesions were observed in the Istituto Rizzoli; 171 cases were hospitalized, 128 were seen and given ambulatory treatment.

Statistically, it is demonstrable that the obstetrical shoulder lesions are more frequent in males (55.27 per cent) than in females (44.72 per cent), more often unilateral (93.46 per cent) than bilateral (6.53 per cent). The right side was involved in 62.81 per cent, the left in 30.65 per cent.

During delivery in the more common type of head presentation the right shoulder is pressed more often and longer against the pubic arch, which explains the more frequent involvement of the right side. In breech presentations, the obstetrical lesion is bilateral in the majority of cases (6 cases).

From The Istituto Ortopedico Rizzoli. Prof. Dr. Vittorio Putti, director.

In none of the cases was heredity a factor. Obstetrical shoulder lesions are acquired during delivery.

In the 199 cases, there were 62 cases of obstetrical joint lesions, 22 cases of obstetrical paralysis, 14 cases were mixed forms. (The 101 ambulatory cases could not be classified). This shows that joint lesions occur more frequently than the other forms and that the general opinion that obstetrical shoulder lesions are of nervous origin is not correct.

In this article, it is our purpose to discuss only the complicated obstetrical joint trauma, the lesion most frequently encountered in our series (53 cases). Although most of these cases came to clinical observation relatively late after injury, it was possible to determine that the primary lesion in all cases was an epiphyseal separation at the upper end of the humerus.

Our clinical and radiographic knowledge of epiphyseolysis in the newborn is not very extensive. Inasmuch as the clinical symptoms after epiphyseolysis are essentially the same as after obstetrical paralysis (functional disability and internal rotation contracture of the arm), these two essentially different lesions have been considered as the same. Poh has contributed valuable experimental, anatomical, and clinical data concerning the epiphyseal separation of the upper end of the humerus. We are here mainly interested in the roentgenological findings of the obstetrical shoulder trauma. On this basis, it will be possible to explain the after effects of the complicated obstetrical shoulder trauma.

The x-ray picture taken in an early stage of the shoulder lesion is entirely negative. There are no changes in the upper end of the humerus. The first positive signs appear with the formation of periosteal callus in the form of a cloudy shadow around the upper end of the humerus (Fig. 1). Toward the third month, however, when the bony nucleus appears in the head of the humerus, a more precise statement can be made as to whether there was a

Fig 1 Sixteen day old boy Typical picture of bilateral periosteal epiphyseolysis with periosteal callus formation around metaphyses Breech presentation, delivered by manual extraction

partial or complete epiphyseolysis with or without displacement of the upper end of the humerus (Fig 2). Before the third month, some cases may show mild structural changes in the metaphysis, suggestive signs of traumatic lesion.

The exact diagnosis of a traumatic shoulder lesion is of great value. If there is no displacement of the epiphysis, almost complete cure can be expected without any involvement of the joint. If there is displacement, the clinical and roentgenological syndrome of obstetrical shoulder trauma will develop. Cases without displacement of the upper fragment show 4 to 5 months after birth some circumscribed enlargement of the diaphysis with periosteal callus undergoing resorption. These structural changes gradually disappear entirely and the shoulder joint remains intact. However, if there has been displacement of the cartilaginous epiphysis, the shoulder joint will show involvement. We believe that these cases do not represent a simple epiphyseolysis, i e, a separation along the epiphyseal line, but a fracture through the cartilaginous epiphysis, which means that the separation is above the

Fig 2 A, Fracture through epiphyseal plate B, Fracture line becomes displaced distally by the physiological bone growth C, Fracture through epiphyseal cartilage. The fracture line is above the epiphyseal plate and there is no displacement by bone growth.

epiphyseal line. This assumption explains why so many cases are without periosteal callus formation during the first few weeks after delivery and why so rarely signs of hematoma or swelling of the shoulder are encountered.

SYMPTOMATOLOGY OF THE SEQUELÆ OF THE COMPLICATED SHOULDER TRAUMA (FIGS 3-7)

On *inspection* (Figs 3-7), one notices internal rotation of the upper arm and consequently pronation of the forearm. The arm is frequently kept slightly abducted with flexion in the elbow. If the abduction in the shoulder is not noticeable on inspection, it is due to the position of the scapula which is tilted with its greater diameter, the lower corner being approximated to the spine, the upper corner prominent under the upper margin of the trapezius muscle. On abduction of the arm, the symmetry of both shoulder blades can be restored.

This symptom is due to joint contracture, to shrinkage of the capsuloligamentous ap-

Fig 3 Eight year old boy Manual delivery with traction on left arm Hypotrophy of deltoid muscle, abduction and internal rotation contracture of left shoulder, + Loss of normal shoulder relief

Fig 3

Fig 4 Six year old girl Manual delivery On external rotation of left arm the upper corner of the scapula appears below the margin of the trapezius. (Scapula sign of Putti)

paratus There are other signs of this contraction Putti noticed that on external rotation of both arms, the upper corner of the scapula appears at the upper margin of the trapezius (scapular sign of Putti, Figs 4, 6) This sign is due to joint rigidity by which all the arm motion is transmitted to the scapula If the arm is abducted, the scapula rotates along its longitudinal axis and becomes elevated (Fig 3)

If the arms are crossed in front by forced adduction, the scapula lies almost in a sagittal plane, the vertebral margin being sharply prominent under the skin (Fig 5)

Fig 5 Four year old boy Forceps delivery Atrophy of right shoulder muscles Internal rotation of arm Shortening of 1 centimeter By adducting the arms (adduction on right side diminished) the vertebral margin of the scapula is brought almost into a sagittal plane

The normal external configuration of the shoulder is lost The arm hangs lower than its mate, the roundness of the shoulder relief has disappeared and sometimes the coracoid process is clearly visible under the skin The loss of shoulder roundness is especially visible when the patient is looked at from above (Putti)

Fig 6

Fig 7 Same case as in Figure 6 Scapula high and hypoplastic Abduction and internal rotation of right arm which is considerably shorter Beginning left convex scoliosis

Fig 8 Horizontal section through shoulder region (schematic) to illustrate the anatomic conditions of the different muscle groups in the sequelæ of obstetrical shoulder trauma. A, left. Normal conditions; B, obstetrical trauma. 1, Deltoid muscle, 2, pectoralis major, 3, infraspinatus, 4, subscapularis, 5, serratus magnus. The obstetrical trauma with the resulting retroversion of epiphysis and the internal rotation of the arm leads to atrophy of the deltoid, 1, pectoralis major, 2, subscapularis, 4, contracted because their points of origin and insertion are approximated. The infraspinatus muscle, 3, is lengthened and under constant tension.

The shoulder muscles are fairly well preserved. They are hypotrophic, but there is not as much atrophy as is observed in nerve lesions. There is almost always present a shortening of the humerus (2 to 3 cm.), quite frequently there is also shortening of the forearm and hypoplasia of the hand. The scapula is always hypoplastic and its vertebral margin is at considerable distance from the thorax; the scapula is much higher, its inferior corner about 2 to 3 ribs higher than the normal side (Fig. 7).

On *palpation*, the head of the humerus is found smaller and displaced backward. It is not in front below the coracoid process but behind the acromial process in retroversion. It is impossible, even by passive motion, to center the head of the humerus into the glenoid fossa. Sometimes, however, on abduction and external rotation, it seems as though the head would slip into place with a little jump when the upper epiphysis passes over the posterior border of the glenoid. In almost all cases, from the third to fourth year of life, a definite step can be noticed in the posterior shoulder region, due to the inclination of the neck of the humerus, which is accentuated in these cases (Fig. 7).

Active motion shows: (1) abolition of external rotation, due to shrinkage of capsule

and shortness of internal rotators; (2) limitation of abduction by about 50 per cent, partially compensated for by motion of the scapula; (3) limitation of flexion and extension. There is considerable joint rigidity which can also be noticed on passive motion (Fig. 8).

The *electric examination* does not reveal nerve lesions, nor muscle degeneration; quite frequently, however, the shoulder muscles are less responsive to faradic and galvanic currents, the result of inactivity. There is no disturbance of sensation.

Roentgen anatomy. The sequelæ of complicated obstetrical shoulder trauma have a typical x-ray appearance which permits early differentiation from pure obstetrical nerve lesions. The bony nucleus of the head of the humerus may appear later on the affected side. Typical cases show it displaced laterally over the outer half of the metaphysis; quite often it is slightly elevated from the inner side and it is always hypoplastic.

We tried to find out whether the lateral displacement of the epiphysis was only apparent and entirely due to the internal rotation. Figure 9 shows roentgenograms of a normal humerus in different projections. B is a view taken in moderate internal rotation. There is hardly any lateral displacement of the epiphysis. C is taken in forced internal rotation

Fig 9 Normal left humerus of 3 year old boy. A Roentgenogram in neutral rotation B In internal rotation C In total internal rotation The epiphyseal bony nucleus does not rub any more over the inner half of the metaphysis but is displaced laterally overlapping the shadow of the greater tuberosity the metaphysis has lost the normal roof shape and appears narrowed

and reveals some lateral displacement. However, such a degree of internal rotation is never observed after obstetrical trauma and still the lateral displacement of the epiphysis is by far more marked in these cases. We deal therefore with a real displacement of the epiphysis which becomes more marked by internal rotation (Vannini).

If one takes roentgenograms of the shoulder joint in axial (craniocaudal) direction, one obtains pictures of great value (Fig 10). Normal pictures reveal the epiphysis opposite the glenoid fossa and overlapped by the shadow of the acromion. In cases of obstetrical shoulder trauma the epiphysis is always displaced clearly backward from the glenoid cavity and behind the shadow of the acromion. The glenoid is not always visible because the arm can not be brought into full abduction.

Fig 10 Schema of axial projection of shoulder joint.

The axial view of the shoulder should be taken in every case of obstetrical shoulder trauma because it shows whether there exists a displacement of the epiphysis with increased angle of declination.

These roentgen findings are typical and can be observed up to about 3 years of age. When the bony nuclei of the tuberosities of the humerus begin to appear, their shadows overlap the epiphyseal nucleus due to the inward rotation of the arm. The backward displacement of the epiphysis is less marked at the age from 8 to 10 and decreases even more as the years go by. However, it never disappears entirely. Simultaneously, the anteroposterior view reveals that the lateral displacement of the epiphysis becomes less, the bony nucleus—due to its hypoplasia and internal rotation—appears deformed, sometimes pear shaped, sometimes triangular or boat shaped.

We are unable to say how the epiphysis gets recentered; it is probably a progressive adaptation by growth and function.

There are also roentgenological signs of involvement of the other joint components. The hypoplasia of the epiphysis makes it appear as though there was a wide separation between epiphysis on one side and glenoid and acromion on the other. Quite frequently, the nuclei of both tuberosities appear later than on the other normal side.

The upper metaphysis of the humerus is smaller and flat instead of cone shaped. An irregular condensation along the epiphyseal line is to be observed in the first year of life.

Fig 11 Boy, $2\frac{1}{2}$ years of age Breech presentation Manual extraction. Marked lateral displacement of the hypoplastic epiphysis. The bony nucleus of the greater tuberosity still absent (present on normal right side). Metaphysis narrowed, sclerotic, with loss of the normal roof-shape. Wide space between glenoid and epiphysis.

Scapula high with atrophy of glenoid. Axial view. Right normal side: 1, Coracoid; 2, acromion; 3, glenoid; 4, acromial end of clavicle; 5, epiphysis of humerus; 6, greater tuberosity. The humeral epiphysis is below the acromion. Strong retroposition of epiphysis: 1, coracoid; 2, acromion; 3, acromial end of clavicle; 4, epiphysis of humerus.

Fig 12 Four year old boy. Delivery by manual traction on right arm. Hypoplasia of epiphysis of humerus. Lateral displacement of bony nuclei of greater tuberosity

and head of humerus. Scapula high, hypoplastic, and anteverted. Axial view shows retroversion of epiphysis: 1, Coracoid; 2, acromion; 3, epiphysis; 4, greater tuberosity.

Fig 13 Angle of declination of neck of humerus Upper and lower end of humerus projected in horizontal plane 1 Trochlea humeri 2 epitrochlea 3 capitulum humeri 4 epicondylus lateralis 5 upper end of humerus 6 glenoid cavity 7 y-y axis of head and neck 8 x-x transverse axis of lower end of humerus The angle between x-x and y-y is the angle of rotation or declination α It is about 20 degrees and opens inward and backward

This irregularity is hard to explain, most likely it indicates a traumatic lesion

The glenoid, up to 3 or 4 years of age, does not differ appreciably in shape and development from the normal. Changes appear around the fourth year of life. First only a slight hypoplasia can be noticed which gradually increases to a real aplasia. This is especially true for the lower half which appears to be cut away. The joint margin is sometimes sclerotic. There is no neck of the scapula. Rather frequently in more severe, inveterate cases (15 to 16 years) the lateral margin of the scapula runs directly into the glenoid. The

Fig 14 Figure 14 15 and 16 show the changes in the configuration of the humerus after obstetrical shoulder lesion. The angle of declination is increased by backward displacement of the axis y-y. The transverse axis of the lower end of the humerus x-x remains in the frontal plane. The contact surfaces between head and glenoid change

aplasia of the glenoid corresponds exactly to that of the acetabulum in cases of congenital dislocation of the hip joint

All these signs are associated with a general hypoplasia of the scapula, only the coracoid process and acromion appear larger, which fact is due to the oblique view in which the roentgenogram is taken (inclination of the scapula)

The clavicle very often shows signs of a fracture in the middle third with callus formation in the first months of life, later with

Fig 15 If the increase of the angle of declination B is associated with an internal rotation of the transverse axis of the lower end of the humerus x-x the head has contact with the scapula only with its anterolateral pole. The epiphysis is turned backward and the greater tuberosity is in front. Such are the findings at surgical intervention

Fig 16 The epiphysis of the humerus regains normal contact with the glenoid after the capsule has been cut and the extremity turned outward. The transverse axis of the lower end of the humerus x-x shows marked external rotation because there is no change in the angle of declination, B. To re-establish normal anatomic conditions it is necessary to break the continuity of the humerus between epiphysis and diaphysis and to turn the lower fragment inward thus decreasing the pathologic angle B to the normal angle α

irregular sclerosis in the middle third. It is hypoplastic, shorter and, in some cases, its S-curve is accentuated. Due to the elevation of the scapula it may appear turned forward

SURGICAL ANATOMY

Muscles The contraction of the subscapularis muscle (frequently also of a small part of the pectoralis major) commonly limits external rotation. It is almost always present in cases over 6 years of age, but may be absent in younger individuals. There may also be a shortening of the coracobrachialis and of the short head of the biceps which explains the slight flexion contracture of the elbow (Fig. 8).

Capsule If there is no contracture of pectoralis and subscapularis muscles, the obstacle to external rotation is represented by the thickened, contracted joint capsule. Even after myotomy of the pectoralis and subscapularis muscles, external rotation is not complete. To obtain full external rotation, it is necessary to cut the joint capsule. The main reason for the internal rotation of the arm is the shrinkage of the anterior portion of the joint capsule. In the same way, the abduction contracture is principally due to contracture of the upper portion of the joint capsule and of the scapulohumeral ligament. There are also small adhesive bands at the joint margins in the upper and front parts of the shoulder joint.

Head of humerus. After incision of the joint capsule, one finds that the joint surface of the humerus is not in contact with the joint surface of the glenoid, neither with acromion and clavicle, but that it is displaced backward, retroverted and partially dislocated. In the typical position of internal rotation, the head of the humerus is in contact with the glenoid only with its anterolateral pole. If one brings the arm in external rotation and extension, a definite sound of reduction can be heard, and the head is brought into contact with the glenoid cavity and fills the subacromial space. On further forced external rotation, the head of the humerus slips out of the capsule, resulting in an infracoracoid dislocation of the shoulder and presenting itself for full inspection. The epiphysis is much smaller, deformed, either pear-shaped or gland-shaped. Some

cases show circumscribed small areas of atrophy of the joint cartilage. The epiphysis is retroverted, displaced also medially along the metaphysis, and the angle of inclination is increased.

The *glenoid* shows the main changes in the lower half and along its anterior margin. It is hypoplastic, flattened, and, instead of being in a sagittal plane, it appears more in front. Its margin is frequently absent. Its visibility during surgical intervention is rather limited.

COMMENTS ON CAUSES OF DISPLACEMENT

From the findings on the operating table, we tried to reconstruct the anatomic conditions as they occur after the shoulder trauma. *The most constant and characteristic change is the deformation of the angle of declination*¹. The angle of inclination is involved to a minor degree.

Figure 13 shows that the normal angle of declination is behind the transverse axis of the lower end of the humerus. If this is the case, the head of the humerus is in normal contact with the glenoid.

If the angle of declination increases by a backward displacement of head and neck of the humerus (the transverse axis of the lower end of the humerus remaining in the frontal plane), the contact surfaces between glenoid and head of humerus change (Fig. 14). If the declination increases by internal rotation of the transverse axis of the lower end of the humerus, those anatomical relations will be encountered as we found in our roentgenological and anatomical investigations: the head of the humerus will be brought in contact with the glenoid with its anterolateral pole. The epiphysis will be displaced backward, the greater tuberosity will be in front (Fig. 15).

After the joint capsule has been cut and the arm brought in external rotation, the epiphysis has normal contact with the glenoid, but the angle of declination remains unchanged and the axis of the lower end of the humerus will be rotated completely outward.

To re-establish normal anatomical conditions, which means to bring back in a frontal

¹The angle of declination is formed by the axis of the upper end of the humerus in relation to the transverse axis of the lower epiphysis, it is about 20 degrees, open backward and inward. The angle of inclination is formed by the axis of the shaft of the humerus and the axis of head and neck. It is about 130°-140°.

Fig 13 Angle of declination of neck of humerus. To re-establish normal anatomic conditions it is necessary to break the continuity of the humerus between epiphysis and diaphysis and to turn the lower fragment inward thus decreasing the pathologic angle B to the normal angle α

lateral displacement and retroversion of the epiphysis; (3) the complete absence of nerve lesions (electrical examination negative).

TREATMENT

During the first 2 years of life, the treatment is a conservative one for functional re-education. To prevent contracture in internal rotation, a shoulder spica cast is applied in abduction of 60 to 70 degrees and in maximal external rotation. The cast is changed after 1 month to increase external rotation. After two or three corrective casts, the joint and muscle contracture is usually overcome and a good degree of external rotation is obtained. A removable splint is then applied and physical therapy (heat, massage, exercises) started.

After the second year of life, the treatment must be surgical to correct the anatomical changes. According to Putti, the surgical treatment is characterized by two steps (1) myotomy and the capsulotomy of Sever, and (2) rotation-osteotomy of Putti (Fig. 17). The osteotomy is performed at a second operation in all cases in which retroversion of the epiph-

ysis has taken place, while in milder cases, the procedure of Sever is sufficient.

SUMMARY

1. Obstetrical shoulder lesions can be classified in three groups: (a) obstetrical joint trauma, (b) obstetrical paralysis, (c) mixed form (paralysis plus trauma).

2. Electrodiagnosis and roentgenological examination permit differentiation between joint trauma, paralysis, and the mixed form.

3. Obstetrical joint trauma is most frequent lesion observed. It leads to epiphyseal separation at the upper end of the humerus with characteristic clinical and roentgenological manifestations, to an inward and backward displacement of the upper fragment with an increase of the angle of inclination and declination.

4. The treatment of the sequelæ of the obstetrical shoulder lesion is surgical. In cases with retroversion of the epiphysis two operations have to be performed (1) the capsulotomy of Sever and (2) the rotation osteotomy of Putti.

FIG. 17. Humerus after obstetrical shoulder trauma. A Neutral rotation epiphysis in retroposition B Complete external rotation, epiphysis is in normal contact with glenoid C Rotation osteotomy of Putti to bring the lower end of the humerus in a frontal plane

plane the transverse axis of the lower end of the humerus while head and neck remain in normal position, it is necessary to interrupt the continuity of the humeral diaphysis (Putti) (Fig. 16). By this the inner rotators of the shoulder will be relaxed, the external rotators are put under tension (Fig. 8).

It is of interest to know whether at the time of the epiphyseolysis the epiphysis rotates externally (Kuestner) or internally or whether the epiphysis remains in place and the diaphysis performs the internal rotation.

Our findings speak against Kuestner's hypothesis. If the epiphysis rotated outward and the diaphysis remained still, after consolidation internal rotation of the arm would bring the head of the humerus in full contact with the glenoid. If the epiphysis rotated outward and the diaphysis turned inward, further joint contracture in internal rotation would bring the epiphysis in a frontal plane. However, in all of our cases the epiphysis was completely retroverted and only the anterolateral pole was in contact with the glenoid.

If the epiphysis remains still and the diaphysis turns inward, the olecranon would have to come in a frontal plane to give a retroversion of the epiphysis. This has never been observed, even in rather severe cases.

It is therefore more justified to assume that after the epiphyseolysis a primary displacement of the epiphysis takes place backward and inward. Only this assumption explains all the findings.

To explain how, after trauma, the characteristic internal rotation of the arm develops, one has to consider the distribution of agonistic and antagonistic muscle groups. Upon the upper fragment, in the sense of external rotation, act the infraspinatus, teres minor, and in part, the supraspinatus muscles (the latter is mainly an abductor), in the sense of internal rotation only the subscapularis acts. No muscle can bring the lower fragment in external rotation while internal rotation can be brought about by the action of the pectoralis major, latissimus dorsi, and teres major.

Thus, Kuestner's hypothesis, that the upper fragment turns outward the diaphysis inward, would be based upon considerable muscle imbalance. Against it, however, speak clinical and roentgenological observations.

We believe that the primary cause of internal rotation is the defense position in the injured arm assumes (in the newborn exactly in the same way as in the adult), which means the arm is rested against the chest for immobilization and prevention of pain.

This primary cause is followed by secondary causes which help to stabilize the deformity: contracture of internal rotators and of the capsuloligamentous apparatus. Also the pronation of the forearm (due to gravity) helps to augment the deformity as the years pass by.

One could think that the displacement of the epiphysis is gradually acquired during the persisting contracture in internal rotation. However, against this speaks (1) the displacement of the bony epiphysis which is more marked in the first 2 to 3 years and later on there is improvement instead of aggravation, (2) the absence of displacement in cases of pure obstetrical paralysis even if by muscle contracture the arm is kept in internal rotation.

DIAGNOSIS

The diagnosis of the obstetrical shoulder joint lesion is based upon (1) the typical symptomatology characterized by rigidity of the shoulder joint, (2) the roentgenogram with

boilable varieties) which are manufactured in the United States, Austria, France, Germany, Great Britain, Holland, and Spain. The material comprised 14 brands of American made, and 22 brands of foreign made sutures. These brands, as well as all those examined during my previous investigations, were of current manufacture, and all of the firms were actively engaged in making and selling sutures when my purchases were made.

A total of 589 lots comprising 7,168 sutures was examined. Following the procedure adopted in all my previous catgut research, at least four sutures from each lot were first subjected to complete chemical analyses to determine the nature and amount of any chemical compound with which the sutures might be impregnated. Then, at least eight sutures of the same lot were tested in accordance with the bacteriological technique (5) previously outlined; except that the test organism now being used for controlling the growth-promoting properties of the culture medium is *Clostridium lentoputrescens*, since this is a slow-growing organism and most exacting in its anaerobic requirements.

The bacteria found in the non-sterile sutures were obtained in pure culture by the poured plate method, colonies were fished and the culture re-plated until pure culture was obtained. Anaerobic cultures were studied on freshly prepared cystein meat infusion agar plates. These plates were incubated at 37 degrees C. in jars in which anaerobiosis was provided by alternately exhausting with a vacuum pump and rinsing with pure carbon dioxide, after the method employed by Hartsell and Rettger. This process was repeated three times, and the jars sealed after the final exhaustion. Identification of the various bacteria was made in accordance with the procedures outlined in Bergey's *Manual of Determinative Bacteriology*, fourth edition, 1934; Ford's *Textbook of Bacteriology*, and Spray's "Tentative Key" (12). These comprised a study of (a) morphology; (b) spore formation and position, (c) cultural characteristics on solid and fluid media; (d) liquefaction of gelatin, (e) fermentation of various sugars; (f) production of indol, and (g) reduction of nitrates.

RESULTS

Of the 36 brands of catgut sutures examined, 15 brands, or 41 per cent, were found to be non-sterile. Of the 589 lots tested, 161 lots or 27 per cent contained non-sterile sutures.

From the non-sterile catgut sutures, 36 spore-forming bacterial species were isolated and identified; including 5 sporulating anaerobes (*Clostridium bifermentans*, *Clostridium fallax*, *Clostridium histolyticum*, *Clostridium sporogenes*, and *Clostridium welchii*), together with 31 aerobic and facultative spore-forming bacilli. Classification of this latter group into species presented a real problem, since the genus *Bacillus* has been overburdened with inadequately described species. As a result, the allocation of strains to the proper species within this bacterial genus is difficult and often uncertain. From the work done, it seems that most of the strains are closely related and belong either to the species *Bacillus mesentericus* or to *Bacillus megatherium*. However, other strains very closely resembled *Bacillus brevis*, *Bacillus cereus*, *Bacillus circulans*, *Bacillus cytaseus*, *Bacillus laterosporus*, *Bacillus mycoides*, *Bacillus polymyxa*, *Bacillus terminalis*, and *Bacillus vulgatus*. None of the strains conformed to all the cultural characteristics of *Bacillus subtilis*, as described by Bergey, which accounts for the absence of this species.

All the aerobic and facultative spore-forming bacilli, together with two species (*Clostridium bifermentans* and *Clostridium sporogenes*) of the sporulating anaerobes, are commonly considered non-pathogenic, but the three other species of sporulating anaerobes (*Clostridium fallax*, *Clostridium histolyticum*, and *Clostridium welchii*) are pathogenic.

The principal habitat of these bacteria is the soil; but some of the species are also found in the intestinal canal of man and animals, and some occur in gas gangrene wounds.

Some sutures of some brands of catgut contained aerobic and facultative spore-forming bacilli which are non-pathogenic, while in other sutures of the same lot were found pathogenic, sporulating anaerobes.

Upon chemical analyses of sutures of those brands of catgut which proved to be non-sterile, appreciable quantities of soluble chem-

THE BACTERIAL SPECIES FOUND IN NON-STERILE SURGICAL CATGUT SUTURES

RALPH OAKLEY CLOCK, M D, F A C P Scarsdale, New York

IN previous papers (1, 2, 3, 4) in which the results of my bacteriological researches of surgical catgut sutures were presented, I endeavored to emphasize the inefficiency and unreliability of the so called chemical sterilization of surgical catgut. I demonstrated that several brands of catgut sutures tested by my bacteriological method (5), were non sterile.

Bacteria in raw material Bacteriological examinations of 20 specimens of sheep intestines from Spain, England and Argentina revealed the presence of 13 different species of sporulating anaerobes of the pathogenic and non pathogenic varieties, and these were designated by Piening as follows: (1) *Fraenkel's gas bacillus* (*Bacillus welchii*), (2) *Bacillus novyi* of malignant edema, (3) *para anthrax bacillus* (*Vibrio septique*), (4) *Bacillus histolyticus*, (5) *Bacillus putrificus verrucosus* (*Bacillus sporogenes*), (6) *Bacillus putrificus tenuis* (*Bacillus bifementans*), (7) *Bacillus tertius*, (8) *Bacillus sphenoides*, (9) *Bacillus multifementans*, (10) *Bacillus cochlearius*, (11) *Bacillus tetanomorphus*, (12) *Bacillus tetani*, (13) *Bacillus lichenoides*. All these species except the last one are clostridium forms and, therefore, should have been so designated. The last species (*Bacillus lichenoides*) is not listed among the anaerobes in any standard work on systematic bacteriology, it may be the facultative anaerobe *Clostridium licheniforme* described by Weigmann.

In the United States a study (8) of 83 specimens of raw catgut revealed the presence of pathogenic spore forming anaerobes in 38 of the specimens examined. These comprised three species of gas gangrene organisms: *Clostridium novyi*, *Clostridium septicum* and *Clostridium welchii*.

While these bacteriological investigations of the raw material are of scientific interest, the chief concern of the surgical and hospital professions lies in the possible presence of living

bacteria in the finished product—surgical catgut sutures.

Gas gangrene infections In 1923 and again in 1925, pathogenic sporulating anaerobes were isolated (9) from sutures taken from the same batch of catgut as that used for surgical patients in whom postoperative gas gangrene had developed with fatal issue. The infections occurred in two hospitals in New York City and involved two brands of catgut sutures. The sporulating anaerobes found in these sutures included *Clostridium septicum*, *Clostridium sordelli*, and *Clostridium welchii*.

Bacteria in catgut sutures Regarding the kind of bacteria in contaminated catgut sutures, it has been stated (6) "While it is true that the majority of bacteria which contaminate catgut are non pathogenic anaerobic bacilli, the presence of gas forming anaerobic bacilli or the relatively more serious tetanus bacilli can never be excluded."

In spite of this statement, however, a search of the literature failed to disclose any reference to a systematic study of a large number of brands of catgut ever having been made for the purpose of determining the species of bacteria present in contaminated surgical catgut, and therefore, there did not appear to be any reliable data on which the foregoing statement could be based.

MATERIALS AND METHODS

Because of the widespread interest which my investigations of the sterility of surgical catgut sutures aroused, it seemed desirable to identify the various species of bacteria present in non sterile brands of catgut. Accordingly, during the years 1935, 1936 and 1937, I purchased periodically from various sources in the open market several lots of each kind and variety of catgut sutures (plain, chromic, tanned, Brady catgut, chloramine, copper, iodized, formalized, pyoktann, silver, catgut, etc., including the boilable and non-

West Virginia University School of Medicine, for his assistance in clarifying the nomenclature of the sporulating anaerobes and for his valuable suggestions. Also, to Dr Stanhope Bayne-Jones, Dean and Professor of Bacteriology, Yale University School of Medicine, and to Professor C-E A Winslow, Department of Public Health, Yale University School of Medicine, for their helpful suggestions.

ical compounds were found, and the physical characteristics of these sutures indicated that they had been subjected either to a low degree of heat or no heat

SUMMARY AND CONCLUSIONS

1 A comprehensive bacteriological study extending over a 3 year period was made of 36 brands of American and foreign made catgut sutures, of which 15 brands, or 41 per cent, were found to be non sterile, and of the 589 lots tested, 161 lots, or 27 per cent contained non sterile sutures. This study, therefore, confirms my previous researches of catgut sterility (2, 3)

2 During this study, 36 spore forming bacterial species were isolated and identified. These comprised 5 sporulating anaerobes together with 31 aerobic and facultative spore forming bacilli which grew usually under aerobic conditions but sometimes when cultured anaerobically

3 A significant result of this investigation was that all the bacteria isolated from the non sterile sutures are spore formers

4 The presence of spore forming bacteria in catgut sutures constitutes a potential danger to the patient for two reasons: first, as so ably pointed out by Small, bacterial spores may remain viable although inactive for a considerable period of time during which bacterial activity may occur through tissue damage as a result of mechanical or chemical injury, concurrent infection, or even cold which inhibits phagocytosis, and, second if the sterilizing process does not include heat of a sufficiently high degree and long enough duration to kill the non pathogenic spore formers, it is quite obvious that it cannot be depended upon to destroy those pathogenic species (such as *Clostridium tetani*) which have a higher thermal death point and which may be present in other sutures of the same lot of catgut

5 All except three species (*Clostridium fallax*, *Clostridium histolyticum*, and *Clostridium welchii*) of the bacteria found in non sterile sutures during this investigation are commonly considered non pathogenic. It should be borne in mind however that while some of the sutures of some brands of catgut

contained aerobic and facultative spore forming bacilli which are non pathogenic, yet in other sutures of the same lot of catgut were found pathogenic, sporulating anaerobes

6 Most of the aerobic and facultative spore forming bacilli isolated during this study use a great deal of oxygen for their growth. If these bacteria are present in catgut sutures which are introduced into tissues, they may consume all the oxygen which is present, thus bringing about anaerobic conditions which, in turn, favor the growth of such anaerobes as *Clostridium fallax*, *Clostridium histolyticum*, *Clostridium welchii* and other gas gangrene organisms if they should also be present. Again, while it is probably true that *Clostridium bifermentans* and *Clostridium sporogenes* are commonly non pathogenic when rabbits and guinea pigs are inoculated subcutaneously with pure cultures, nevertheless when catgut sutures containing these sporulating anaerobes are buried in the tissues of surgical wounds, these organisms possibly may prove to be pathogenic

7 Chemical analyses of sutures of the 6 brands of catgut which were found to be non sterile revealed appreciable amounts of soluble chemical compounds. Moreover, their physical characteristics indicated that they had been exposed to a low degree of heat or even none at all. Therefore in the preparation of these non sterile sutures, entirely inadequate heat or none whatever was used for sterilization purposes reliance having been placed apparently upon chemical methods. On the other hand, sutures of those brands of catgut which were found to be absolutely sterile showed every evidence of having been subjected to high heat sterilization. As emphasized in a former paper (1)

"1 The so called chemical sterilization of surgical catgut by any method yet devised is inefficient and unreliable

"2 Carefully controlled heat sterilization is the only uniformly reliable and positive method of sterilizing surgical catgut sutures"

It is a pleasure to acknowledge my gratitude to Mr J. Roger Porter, Laboratory of Bacteriology, Yale University for his advice and valuable assistance in classifying the aerobic and facultative spore forming bacilli isolated during this investigation and to Professor Robb Spalding, Spray Department of Bacteriology and Public Hygiene

technical problem. However, the sphincter of Oddi may be attacked directly. Its musculature may be permanently paralyzed by actual surgical division of its fibers. Transduodenal sphincterotomy may be a comparatively new term in operative nomenclature, but it is not a new procedure because transduodenal choledochotomy for impacted papillary calculi has been done for years and in this operation, division of the sphincter is essential in order to extract the stone. Recently Archibald has reported several cases in which the sphincter was divided for spasm, and del Valle has sectioned it transduodenally for "odditis." This latter condition manifests itself pathologically by the presence of a retracted sphincter which partially obstructs the free flow of bile.

Transduodenal papillotomy is not without risk aside from the immediate postoperative dangers of peritonitis and duodenal fistula because subsequent duodenal deformities due to adhesions may also result in physiological disturbances. Besides the eventual efficacy of transduodenal sphincterotomy for sphincteric spasm can only be evaluated after more information is gained by a careful follow-up of these patients. There are still many questions to be answered. Does division of the sphincter permanently destroy its action?

Fig 1 The sphincterotome with knife blade open. The shaft, which is 16 centimeters long and 4 millimeters in diameter, has a flattened tip measuring 35 by 6 by 2.5 millimeters. The shearing blade which fits into a slot in the tip, has a thickness of 1.5 millimeters and an effective cutting length of 11 millimeters.

Does the scar resulting from this section cause a secondary contraction of the papilla, and does this result in a stenosis with biliary stasis?

Certain of the obvious objections to transduodenal sphincterotomy may be eliminated by endocholedochal sphincterotomy. Recently the results of dividing the sphincter through the common bile duct by means of a sphincterotome (Fig 1) in cholecystectomized dogs were published (2). The operation which was perfectly feasible, effected a definite reduction in the function of the sphincter mechanism and was not followed by any evidence of ascending infection of the biliary tract. This procedure was then tried on a series of cadavers. Its safety was demonstrated as far as

ENDOCHOLEDOCHAL SPHINCTEROTOMY

RALPH COLP M D F A C S and HENRY DOUBILET, M D, New York New York

PHYSIOLOGICAL disturbances of the sphincter of Oddi bear an important relationship to certain types of acute pancreatitis, gall bladder disease, the post cholecystectomy syndrome, the dyskinesias of the biliary tract and some forms of transient jaundice. Spasm of the sphincter which is a basic factor in the production of these pathological states, has recently been demonstrated by roentgenologic x ray studies of lipiodol injections of the choledochus (2, 7), together with pharmacological studies of the intraductal pressure recorded kymographically, according to the method described by Katz.

It is extremely important, therefore, in order properly to treat many of the aforementioned conditions that spasm of the sphincter of Oddi be relieved either temporarily or permanently. It is well known that some of the patients with sphincteric spasm respond readily to medical therapy especially those cases which presumably have their origin in either endocrine disturbances or imbalances of the sympathetic nervous system. Other patients have been definitely benefited by rest, dietetic measures and duodenal lavage. But quite often these conservative measures fail and the persistence of severe and distressing symptoms make surgical intervention imperative. It is in those cases especially, when careful surgical exploration fails to disclose any gross pathological alterations that attention should be focused upon a dyskinesia of the sphincter of Oddi as the possible cause of the symptomatology.

There are several surgical procedures which may be employed to relieve this localized muscular spasm.

Forceful dilatation of the sphincter obtained by the passage of graduated sounds through the common duct into the duodenum will undoubtedly paralyze the musculature for a long time. This simple method advo-

cated by many appears rather crude and traumatic. It has been complicated by an ascending anaerobic infection from the duodenum and deaths from Welch infections due to *Bacillus welchii*, have been reported.

Biliary duodenal intubation accomplishes practically the same result as instrumental dilatation. The indwelling tube insures not only a free internal drainage of bile, but by its mechanical presence maintains a persistent dilatation of the sphincter until the spontaneous elimination of the tube. This method advocated by Duval and Walzel, aside from certain technical difficulties, does not seem particularly dangerous, especially if a tube of large caliber is used and sufficient of its length protrudes into the intestine. The method, however, has never gained great popularity.

There is another procedure which is advocated. Many European surgeons when confronted with dilatation of the choledochus associated either with impacted calculi, or sphincter spasm or papillary stenosis, prefer an anastomosis between the common duct and the duodenum eliminating entirely the sphincter mechanism and shortcircuiting the flow of bile. The operation of choledochoduodenostomy is attended by certain dangers. One of the most important of these, theoretically at least is an ascending infection from a duodenal reflux. In spite of the fact that gas-roentgenological x ray studies in these cases often reveal the presence of barium in the common bile the clinical incidence of ascending infection is quite rare. This has been verified by the reports of Sasse, Floercken, and Peterman who have used choledochoduodenostomy in a large series of cases.

All of these surgical procedures, however, have certain definite disadvantages. Dilatation of sphincter and biliary duodenal intubation are only temporary measures because eventually the sphincter will regain its tone and periodic muscular spasms may recur. Choledochoduodenostomy as a cure for simple sphincter spasm presents rather a difficult

Figs 6 left and 7 Lipiodol studies before (Fig 6) and after (Fig 7) the administration of morphine in a patient whose kymographic studies are recorded in Figure 3. Note that both in Figure 4 (manometric resistance 165 millimeters) and in Figure 6 (manometric resistance 160 millimeters), the terminal ends of the hepatic ducts are visualized to an equal extent. The spasm produced by morphine in the intact sphincter of Oddi (Fig 7) raised the resistance to such a height (370 millimeters) that the very fine biliary radicles were visualized before lipiodol entered the duodenum.

ectomy, she made an uneventful recovery and was discharged June 18, 1933.

She remained well but for a short time when she began to experience episodes of pain which were described as rather characteristic. A few days previous to the onset of the attack, the patient experienced severe hunger. The pain then started in the right lower quadrant, radiating around the right side to the back, and upward to the right shoulder and arm. There was nausea but no vomiting. The pain lasted for a short time and either terminated spontaneously or was relieved by an injection of morphine sulphate, at times $\frac{3}{4}$ of a grain being required (nitroglycerine was without effect). After the attack subsided, there was residual tenderness in the right upper quadrant and along the course of the colon, and pruritus which was followed by a generalized urticaria. Jaundice was never noticed.

During the past year, the patient also complained of menstrual disturbances in that her periods occurred irregularly every 2 or 3 weeks. The bleeding occasionally was slight and lasted a few days and at other times it was more profuse, and persisted from 10 to 12 days. It was noted too, that her weight increased from an average of 150 to about 175 pounds.

Because of the patient's unusual sequence of symptoms, it was decided to hospitalize her for a period of observation. She was readmitted to the Beth El Hospital on February 15, 1937. The following laboratory reports were of significant value:

Blood chemistry, February 17, 1937, showed: serum albumin, 4.3 milligrams per cent; serum globulin, 2.4 milligrams per cent; total serum protein, 6.7 per cent; glucose, 0.86 milligrams per cent; urea, 11.5 milligrams per cent; creatinine, 1.2 milligrams per cent; cholesterol, 110 milligrams per cent; cholesterol ester, 54 milligrams per cent.

Galactose tolerance test, February 19, 1937, showed: blood sugar—fasting, 0.87 milligrams per cent; $\frac{1}{2}$ hour, 0.95 milligrams per cent; 1 hour, 0.93 milligrams per cent; $1\frac{1}{2}$ hours, 0.94 milligrams per cent; 2 hours, 0.40 milligrams per cent; urinary sugar negative in all 5 specimens.

Glucose tolerance test, February 20, 1937, showed: blood sugar—fasting, 0.72 milligrams per cent; $\frac{1}{2}$ hour, 0.95 milligrams per cent; 1 hour, 0.96 milligrams per cent; $1\frac{1}{2}$ hour, 0.93 milligrams per cent; 2 hours, 0.90 milligrams per cent; urinary sugar negative in all 5 specimens.

Bile drainage—A and C bile was obtained, but no B bile. Microscopic examination showed no cholesterol crystals or other abnormal constituents.

Gastric analysis with alcohol test meal showed:

	Free hydrochloric acid	Total acidity
Fasting	1	16
$\frac{1}{2}$ hour	58	76
1 hour	26	40

Blood count showed, 12,800 white cells; polymorphonuclears, 63 per cent; lymphocytes, 37 per cent.

Figs. 4 (left) and 5 (right) fluoroscopic study 21 days after sphincterotomy. The resistance of the common duct sphincter was so low (Fig. 4) that the terminal portions of the hepatic ducts and the upper end of the choledochus were not outlined before lipiodol entered the duodenum. Following the administration of morphine (Fig. 5) the duodenal wall was clearly seen to become spastic, compressing the intramural portion of the choledochus. The resultant increase in the resistance was slight, since only the terminal portion of the hepatic ducts was visualized before lipiodol entered the duodenum. These studies confirm the results of the kymographic tracings (Figs. 8 & 9, 10).

visible injury to the duodenum and pancreas was concerned. The method was recently tried clinically.

The following case, presumably one in which the clinical picture was due to periodic episodes of sphincter spasm is of interest because the attacks apparently were relieved by endocholedochal sphincterotomy.

L. C. a married female 24 years of age was referred to me by Dr. I. A. Feder of Brooklyn, New York, to whom we are indebted for her history and laboratory studies. She was first admitted to the Beth El Hospital, Brooklyn, New York, on August 5, 1932, and discharged during November, 1932. Her past history was practically negative except that for 2½ years following her second pregnancy, she had experienced attacks of right upper quadrant pain which radiated to the back and right shoulder.

The present illness began rather abruptly with high fever, chills, delirium and rigidity of the neck. The physical examination revealed findings suggestive of typhoid fever, which all laboratory data confirmed. During the fourth week of her illness the temperature instead of subsiding continued in an intermittent fashion. The patient complained of severe pain in the right upper quadrant of the abdo-

men, and on physical examination a mass was noted in this region. There was no jaundice and the white blood count was normal. In spite of the fact that the patient was critically ill, a laparotomy was performed under spinal anesthesia on September 14, 1932.

An enormously distended partially necrotic gall bladder with a pericholecystic abscess completely enveloped by omentum was found. There was a stone in the cystic duct. A cholecystotomy was made and a cigarette drain was inserted to Morrison's pouch. Cultures of pus from the gall bladder were positive for *Bacillus typhosus* and *Staphylococcus albus*. The postoperative course was rather stormy, and although at one time there were clinical signs of subphrenic abscess, the condition subsided spontaneously. The patient was finally discharged with a biliary fistula, which eventually closed in 2 months' time.

The patient then began to experience attacks of severe biliary colic which were relieved only when the fistula spontaneously reopened with the free discharge of bile and pus. Because of the repeated episodes, the patient was admitted to the Brooklyn Jewish Hospital for exploration May 30, 1933. The operation which was performed under spinal anesthesia revealed a chronically inflamed gall bladder with stones in the cystic duct. The common duct was probed and found free. Following a cholecy-

Figs 6 left and 7 Lipiodol studies before (Fig 6) and after (Fig 7) the administration of morphine in a patient whose kymographic studies are recorded in Figure 3. Note that both in Figure 4 (manometric resistance 165 millimeters) and in Figure 6 (manometric resistance 160 millimeters), the terminal ends of the hepatic ducts are visualized to an equal extent. The spasm produced by morphine in the intact sphincter of Oddi (Fig 7) raised the resistance to such a height (370 millimeters) that the very fine biliary radicles were visualized before lipiodol entered the duodenum.

ectomy she made an uneventful recovery and was discharged June 18, 1933.

She remained well but for a short time when she began to experience episodes of pain which were described as rather characteristic. A few days previous to the onset of the attack, the patient experienced severe hunger. The pain then started in the right lower quadrant, radiating around the right side to the back, and upward to the right shoulder and arm. There was nausea but no vomiting. The pain lasted for a short time and either terminated spontaneously or was relieved by an injection of morphine sulphate, at times $\frac{3}{4}$ of a grain being required (nitroglycerine was without effect). Bile drainage—A and C bile was obtained, but no B bile. Microscopic examination showed no cholesterol crystals or other abnormal constituents.

Gastric analysis with alcohol test meal showed:

	Free hydrochloric acid	Total acidity
Fasting	1	16
$\frac{1}{2}$ hour	58	76
1 hour	26	40

Blood count showed, 12,800 white cells, polymorphonuclears, 63 per cent, lymphocytes 37 per cent.

Fig 8 Kymographic record of the resistance of the sphincter of Oddi 10 days after endocholedochal sphincterotomy. The resistance was found to measure 130 millimeters of water. Following intraduodenal instillation of dilute hydrochloric acid the resistance rose to 145 millimeters falling to the original level in 10 minutes. The hypodermic injection of morphine caused the resistance to rise to 145 millimeters at which level it remained for the duration of the experiment.

Fig 9 Typical kymographic tracing in a patient in whom the sphincter had been left intact. The original resistance (160 millimeters of water) rose to 255 millimeters following the local application of dilute hydrochloric acid. The spasm produced by morphine raised the resistance to 370 millimeters of water.

Wassermann and complement fixation tests were negative. Basal metabolic rate was -22 . Roentgenogram of the sella turcica was negative. Examination of the right upper quadrant by flat x-ray plate showed a peculiar linear shadow density about $\frac{3}{4}$ inch long. Its cause could not be made out.

After her discharge from the Beth El Hospital February 26, 1937 she was given thyroid and pituitary gland extracts without relief. In view of the repeated attacks of pain exploratory laparotomy was advised since it was felt that the patient was suffering either from periodic attacks of spasm of the sphincter of Oddi or possibly a common duct stone.

The patient entered the Mount Sinai Hospital on March 25, 1937 and was discharged April 11, 1937.

An exploratory operation was done under avertin supplemented by gas oxygen and ether anesthesia on March 26, 1937. The liver and gall bladder bed appeared normal. There was no evidence of a cystic duct. The common bile duct which was normal throughout its course did not appear dilated and on aspiration was found to contain clear golden yellow bile. The stomach, duodenum and pancreas which were clearly visualized were normal. The uterus was retroverted but normal in size and shape. The adnexa felt normal. There were many intra-peritoneal adhesions which were divided in order to expose the common bile duct adequately. By means of the Hoffman punch a biopsy specimen was taken from the liver and pancreas. (These were sube-

Fig 10 The tracing from the patient in whom the sphincter of Oddi was sectioned (Fig 2) superimposed upon the tracing in a patient with an intact sphincter (Fig 3) The difference in the levels of the tracings clearly shows the small part played by the duodenal musculature and the important part played by the sphincter of Oddi, especially after the local effect of hydrochloric acid and the effect of morphine

quently reported as showing no significant changes.) The common bile duct was incised between Allis clamps and, probed without difficulty, and did not contain any calculi. The sphincterotome (Fig 1) was introduced into the common bile duct and through the sphincter into the duodenum. The knife was opened and the instrument withdrawn until it firmly infringed upon the sphincter. The knife was closed, thus dividing the sphincter without difficulty. The instrument was withdrawn, and the piece of tissue which had been punched out was removed from beneath the blade and sent to the pathological laboratory for study (Figs 2 and 3). A T tube was inserted into the common bile duct and sutured about the tube with four interrupted chromic sutures. Two rubber dam drains were placed to the region of the common duct, one above, and one below the tube. The abdomen was closed in layers using chromic throughout, with silk and pincettes for the skin.

Postoperative course There was an immediate postoperative rise of temperature to 103 degrees. This gradually fell to normal on the fifth day. There was free drainage of bile through the choledochostomy tube on the second day, at which time the return from an enema revealed a normal stool containing abundant bile. Lipiodol studies (Figs 4, 5, 6, 7) and manometric studies after the method of Katz (Figs 8, 9, and 10) which are herewith recorded, were then made on the tenth and eleventh days after operation. The T tube which was removed on the twelfth day was not followed by any further discharge of bile. The patient was discharged on the sixteenth day.

The patient has been seen repeatedly, the last examination taking place on February 23, 1938. She had been perfectly well and has had no recurrence of her previous attacks.

It seems fair to assume that the attacks resembling biliary colic described by the patient, were presumably due to spasm of the sphincter of Oddi. This conclusion is further verified by the operative findings and the fact that following endocholelechoal sphincterotomy, the attacks ceased. The cause of the spasm is open to question. The period of hunger preceding the episodes of pain, the increased tolerance to sugar as noted in the glucose and galactose tolerance tests (the latter almost a typical course of a true hypoglycemia), the menstrual disturbances, the gain in weight, and a low basal metabolic rate, point to an endocrine disturbance as the most likely etiological factor in the production of the muscular irritability. Conservative therapy, i.e., treatment by the administration of glandular extracts, was without effect. There is no doubt that the sphincter was divided endocholelechoally because the specimen removed by the sphincterotome revealed biliary and duodenal mucous membrane and some

CLINICAL SURGERY

HALLUX VALGUS

HARRY C STEIN, M D, F A C S, New York, New York

THE perplexing and intriguing problem of 'bunions' has been attacked from many interesting and diverse angles by both foreign and American investigators

Despite the many excellent contributions in the literature many necessary anatomical and physiological details, however, seem not always to have been sufficiently considered. This is especially true in the rôle of the sesamoids.

The writer having reviewed a number of cases operated upon at various clinics, undertook an independent investigation of the subject. Etiological, anatomical, physiological, pathological, pathophysiological, radiographic, and clinical data were considered in the light of a predominantly physiological rather than a plastic surgical repair.

An operative procedure which seems best to meet the surgical indications was evolved.

ETIOLOGY

In walking, as described by Hiss, the weight of the body converges from the "cuboid" (weight bearing) stream to join the "scaphoid" (walking) stream, and the combined load is finally distributed along the under surface of the great toe. Any factors, extrinsic or intrinsic, tending to shift this load more medially on the big toe, favor the development of hallux valgus.

Extrinsic factors include high heeled, pointed, short or poorly fitted shoes, and short or toe-constricting hose.

Among the more common intrinsic factors are torsional deformities involving the thigh, leg or foot, faulty foot posture, flat foot, adducted supinated forefoot, excessively high arch with compensatory forefoot pronation, overaction, spasm, or contracture of the adductor hallucis muscle, imbalance between peroneus longus and tibialis anticus muscles, excessive varus or short first metatarsal bone, congenital or acquired defects, or excessive rounding of the head of the first metatarsal, hyperextensibility at the metatarso-internal cuneiform or internal cuneiform-scapoid joints, and accessory scaphoids.

From the Hospital for Joint Diseases, service of Harry Finkelstein, M D

The deformity primarily is merely a functional postural adaptation; later it becomes structural in character.

ANATOMY

Sesamoid bones These play a most important rôle not only in the development but also in the surgical correction of hallux valgus. It is essential to bear in mind that: (1) These bones are intracapsular. They articulate by means of convex facets on their superior surfaces, with corresponding longitudinal grooves on the inferior aspect of the first metatarsal head. (2) They are contained in the double tendon of the flexor brevis muscle which inserts (via conjoined tendons) into opposite aspects of the base of the proximal phalanx (Fig 1). Thus they move in whatever direction the great toe moves. This partly accounts for their displacement in hallux valgus. (3) Held together by the glenoid ligament they move as one bone. (4) Together they form a movable groove for the protection of the flexor longus hallucis tendon. They are situated more posteriorly when standing and anteriorly when the toe is dorsiflexed, as in walking. (5) The outer margin of the lateral sesamoid affords attachment for the powerful adductor obliquus tendon just before it merges into the formation of the conjoined tendon (Fig 1).

First metatarsal bone 1 There is a normal varus of this bone of between 8 and 12 degrees, due to the obliquity of its articulation with the internal cuneiform bone. This adds strength to the longitudinal arch. This articulation, in addition, permits of about 10 to 15 degrees of lateral, and a lesser degree of vertical mobility thus adding flexibility to the arch.

2 When the forefoot is supinated varus of the metatarsals is relatively increased. On pronation, it diminishes. This affects the inner four metatarsals (Fig 2). Normally, voluntary adduction of the forefoot is combined with inversion (supination), abduction, with eversion (pronation). The resistance of the ground in walking, as referred to by Steindler, may induce secondary compensatory detorsional changes in the position of the forefoot. Thus, in flat foot the forefoot eventually becomes supinated. The converse is true in high arch.

muscle (Figs 2 and 3), and the x ray findings following lipiodol injection and the kymographic tracing bear witness to its division. In spite of the fact that the sphincter had been divided, the duodenal musculature and the obliquity of the entrance of the common bile duct through its wall acted as an efficient protecting valve against the reflux of duodenal contents (Fig 5). Clinically, the patient has remained in good health and has been free of attacks of colic following the division of the sphincter of Oddi.

Fig 3 a, Transverse section through head of normal first metatarsal bone b, Similar section in a case of hallux valgus a a', Sesamoid bones, c, b, b', conjoined adductor hallucis tendon, n, abductor hallucis tendon, f, flexor brevis tendons, u, capsule, y, head of second metatarsal bone, s, fibrocartilaginous capsular thickening, z, overlying bursal sac, l, l' lateral ligaments

The abductor hallucis muscle, in addition to its action in maintaining the alinement of the toe, also has a splinting effect on the first metatarsal bone. Acting in a line parallel to this bone, and using its head as a fulcral point, the abductor hallucis pushes this bone toward the second metatarsal. The adductors, arising from the remaining metatarsal bones, in opposing this action, tend to keep all the metatarsals together and in normal alinement.

This effect also is lost, as the abductor tendon goes plantarward, resulting in the development of metatarsus varus (Fig 6) (Where the fore-foot is supinated, the inner four metatarsals may be involved, as can be seen in Figure 7.) Later there is the occurrence of spreading of the metatarsal heads, and dropping of the anterior arch. Since the metatarsal of the great toe no longer is fixed, the remaining metatarsals likewise are not fixed.

Fig 4 Displacement of adductor and abductor muscle groups and sesamoids in hallux valgus n, Abductor hallucis, f, flexor brevis, b, b', adductor obliquus, c, adductor transversus

With this concept, one may readily understand why in cases of hallux valgus there is usually found the co-existence of metatarsus varus, spreading of the metatarsal bones, depression of the anterior arch and displacement of the sesamoids.

PATHOLOGY

Following are described typical pathological changes to be found in the usual well developed case of bunions.

Fig 5 Lateral displacement of sesamoids in hallux valgus

Fig 1 Normal arrangement of abductor and adductor muscle groups of great toe *f* flexor brevis muscle two heads *n* adductor hallucis *b b* adductor obliquus two heads *c* adductor transversus

3 The articular cartilage covering the first metatarsal head continues for about $\frac{3}{8}$ inch over its lateral surfaces. This cartilage forms a gliding mechanism for the obliquely placed collateral ligaments.

4 The tibialis anticus and peroneus longus tendons insert into opposite aspects of the base of this metatarsal. These maintain its physiological balance.

PHYSIOLOGY

As emphasized by McBride the great toe is maintained in normal forward alignment by the physiological opposing action of the abductor and adductor muscle groups. These insert by means of conjoined tendons into opposite aspects of the base of the proximal phalanx (Fig 1). The abductor group comprises the medial head of the flexor brevis and the abductor hallucis muscles. The adductor group consists of the lateral head of the flexor brevis, the adductors obliquus and transversus.

This opposing action is possible only so long as the abductor tendon retains normal position in its groove on the inferomedial aspect of the metatarsal head (Fig 3a). (This tendon is here blended with the capsule.)

Fig 2 Left High arch with compensatory forefoot pronation. Right Same foot in inversion (supination). Note change in direction of four inner metatarsals.

Pathological physiology. In the development of hallux valgus as a result of the pathophysiological forces the abductor tendon migrates. It moves from its groove on the inferomedial aspect of the first metatarsal head plantarward beneath the inferior margin of the head then lateralward. It lodges in the groove for the medial sesamoid. Here it becomes firmly wedged, resulting in a fixed eversion of the great toe (Figs 3b and 4). The sesamoid bones are thus crowded laterally. The medial one goes into the groove for the lateral sesamoid and the lateral one into the interspace between the first and second metatarsal heads (Figs 3b 4 5). This lateral subluxation is augmented by pull of the obliquus tendon via its lateral sesamoid attachment (Fig 4).

In its displaced position the opposing action of the abductor (to the adductors) is lost. It now acts as a flexor and evor of the great toe. The unopposed adductors and the bow string (long short flexor and extensor tendons), all tend to increase the hallux valgus deformity.

The medial portion of the capsule, the internal lateral ligament and the slightly squarred lateral margin of the metatarsal head offer resistance to these deforming forces. In most instances, however, this is inadequate and soon overcome. During this interval the apparent paradoxical condition of pronounced metatarsus varus with eversion of the toe and displacement of the sesamoids without a corresponding hallux valgus deformity may be found.

Fig 9 Drawing of skin incisions. The eversion of the great toe is indicative of displacement of the abductor tendon into the groove for the medial sesamoid

4. In advanced and long standing cases, there are secondary adaptive bony changes of the metatarsal head. These consist mainly of hypertrophy and "squaring" of its medial margin. This may be sufficiently marked to cause lateral shifting of the entire articular surface (Fig 10)

5. In arthritic cases, there may be hypertrophy and lipping of the articular margins and sesamoids

The so called "exostosis" removed at operation is usually a myth. On examination, it is found to consist essentially of a section of the inner margin of the normal or hypertrophied cartilage covered head, plus a segment of the markedly thickened, dense, fibrocartilaginous capsule, and the thin, overlying bursal sac. Roentgenographically, what clinically appears to be an exostosis directly under the skin, is found to be a dense, soft tissue enlargement (Fig 8)

The "enlarged" joint, so commonly referred to in connection with these cases, is essentially an over-prominence of the head, due to the metatarsus varus, accentuated by the capsular thickening and the valgus position of the toe. The bony component of this enlargement is relatively small

SURGICAL CONSIDERATIONS

From a surgical viewpoint, the problem of hallux valgus is similar to that of club foot or any

Fig 11 *t*, Modified Silver capsular flap incision, *r*, abductor tendon

Fig 10 Hypertrophy of the mesial margin of the first metatarsal head, especially on the right side, sufficient to cause almost the entire articular surface to face laterally

contractural deformity. The primary deforming elements are found on the contracted side

The surgical requirements include: (1) on the lateral aspect, thorough division of the contracted deforming structures, (2) on the medial aspect, bursectomy plus capsuloplasty fashioned to replace the abductor tendon and correct the eversion and valgus of the toe, (3) removal of any obstructing bone from the metatarsal head

The contracted structures on the lateral aspect consist of (1) adductor obliquus attachments to the lateral sesamoid, (2) the external lateral ligament, (3) the capsule between the two structures, (4) frequently, the lateral head of the flexor brevis muscle

Their division is of primary importance. It permits unresisted correction of the valgus deformity and allows the sesamoids to slip into place. A main causative factor in recurrence is

Fig 12 Capsular flap in position of correction *a'*, Medial sesamoid, *n*, abductor tendon; *p*, position of capsular flap before correction; *s*, position of capsular flap following correction and suture. Note the replacement of the abductor tendon. Correction of eversion of the great toe

Fig 6 Varus of first metatarsal bones. Note marked in crease in space between first and second metatarsal heads indicating corresponding elongation of transverse inter metatarsal ligament

Lateral aspect 1 The capsule here is contracted in its longitudinal and transverse diameters. That part between external lateral ligament and external sesamoid is especially involved (Fig 3b)

Fig 8 Note the marked thickening and increased density of the capsule overlying the bunion joint and the relatively small bony component of this enlargement

Fig 7 Varus of the inner four metatarsal bones. Note the comparatively slight spreading between the first and second metatarsal heads on the right side in spite of the marked first metatarsus varus

2 The external lateral ligament is fore shortened

3 The external sesamoid is displaced laterally and slightly dorsally into the interspace between the first and second metatarsal heads. Here it is firmly anchored by the contracted oblique attachment, as well as the contraction of the capsule above its lateral margin (Figs 3b and 4)

4 The lateral head of the flexor brevis is contracted

Medial aspect 1 The capsule here is the seat of marked fibrocartilaginous thickening. Overlying this is a thin walled bursal sac (Fig 3b)

2 The tubercle of origin of the internal lateral ligament is somewhat hypertrophied

3 The abductor tendon is displaced inferiorly and laterally dislodging the sesamoids (Figs 3b and 4)

Associated changes 1 The great toe is maintained in a position of valgus eversion, and slight downward subluxation (Fig 9)

2 There is an exaggerated varus of the first metatarsal with a corresponding spreading and elongation of the transverse intermetatarsal ligament between it and the adjacent head (Fig 6) (Frequently however especially in cases of supinated forefoot the inner four metatarsal bones go into varus together Fig 7)

3 The metatarsal head is inverted in relation to the toe

Fig 16 a and b, Roentgenograms of both feet before operation, c and d, after operation, e and g, photographs of both feet before operation, f and h, after operation

the lateral sesamoid is prevented from retracting, (3) control of the sesamoids via the great toe, so essential for their reposition, remains intact

Similarly, the various plastic and fusion operations at the base of the first metatarsal for bony correction of its varus are objectionable in ordinary cases for the following reasons (1) they result in diminished strength and flexibility of the longitudinal arch—especially the function of the ball of

the big toe—, (2) unless fusion is accomplished at an exact angle, the ball of the big toe is caused to remain either too high or too low, with consequent secondary static disturbances, (3) an undesirable convergence of the first and second metatarsal bones may result; this is especially true when the varus involves all inner metatarsal bones (Fig 7), (4) adequate spontaneous correction usually occurs after the valgus and eversion

Fig 13 a and b Both feet before operation c and d Both feet after operation Note the spherical first metatarsal heads the replacement of the sesamoids the im-

proved relationship of the first metatarsal internal cuneiform joints and the diminished metatarsus varus

eliminated This procedure alone without any additional work on the medial aspect has yielded satisfactory results (Fig 17c) This has been noted especially in cases of recurrence due to their inadequate division at the original operation

Cases with secondary hypertrophic changes of the medial margin of the metatarsal head acting as a bone block against complete correction, require removal of the obstructing one This restores congruity of the articular surfaces

In cases in which severe osteo arthritic changes have taken place with lateral shifting of the articular surface (Fig 10) the more radical resec-

tion operations are to be considered However if the symptoms are localized to the bursal region the more conservative operations directed at alleviation of pain only are preferable

The writer has found it inadvisable and rarely necessary to sever the conjoined adductor tendon from its insertion into the base of the proximal phalanx The capsular incision to be described plus complete division of the lateral sesamoid attachments of the obliquus tendon and occasionally the lateral head of the flexor brevis answer the same purpose, i.e. of permitting unresisted correction of the valgus of the great toe This procedure has the advantages (1) that the lateral muscle balance of the toe is preserved (2)

Fig 14 Attachments of the usual two obliquus heads to the lateral margin of the lateral sesamoids Dotted line indicates line of incision for separating these structures from this sesamoid a Lateral sesamoid b adductor obliquus heads c adductor transversus muscle f flexor brevis hallucis l external lateral ligament m medial incision x line of severance of adductor attachment to lateral sesamoid

Fig 15 Semi-oblique view to show deeper structures Dotted area d indicates severance of obliquus attachments from lateral sesamoid Note proximal head of obliquus b only is divided completely The heavy dotted line indicates line of hockey stick incision through lateral ligament and capsule between it and underlying sesamoid a Sesamoid b adductors obliquus c adductor transversus h hockey stick incision l lateral ligament

A second, dorsally curved, incision is now made on the medial aspect of the joint (Fig 9), thus exposing the bursa, the thickened fibrocartilaginous capsule, and the displaced abductor tendon.

The bursal sac is excised. A modified Silver capsular flap is so fashioned as to permit fore-shortening of the elongated capsule, derotation of the everted toe, and replacement of the displaced abductor tendon (Figs. 11 and 12).

Before anchoring this corrective flap into position, the head of the metatarsal is inspected. If hypertrophy along its medial margin is sufficient to act as a bone block against complete correction of the valgus, or to result in undue joint tension after correction, the obstructing bone only, (mostly dorsomedially), is chiseled away. As far as possible, the ball of the toe, the groove for the medial sesamoid, and the inner cartilaginous rim at the periphery are conserved. The tubercle of origin of the internal lateral ligament, if enlarged, as well as any osteophytic processes, is removed.

If, after correction of the valgus, the extensor tendons are short, these may be corrected by triple subtotal sections (Figs 3c and d).

Holding the toe in the desired degree of correction and in neutral position, the capsular flap is now anchored snugly. Silk sutures are preferable (Fig 12). Overcorrection is avoided. Freedom of mobility should be possible before and after the anchoring sutures are applied.

The skin incisions are closed, and dressings and adhesive support are applied. No plaster-of-Paris cast is necessary.

Postoperative care includes active exercises. Weight bearing is permitted after 2 weeks. A Jones bunion splint is worn at night for several months. Static foot disturbances are treated and properly fitting postoperative bunion last shoes are prescribed.

REPORT OF CASES

A series of fifteen cases have been operated upon by this method, first utilized in 1933. Three illustrative cases are presented.

CASE 1. E. L., aged 42 years, with painful bunions of 7 years' duration (Figs 16, a and b, and c and g). The procedure described was performed on both sides. Figures 16c and d, f and h show postoperative corrections. Note the corrected position of the sesamoid bones. Result 1 year after operation was very satisfactory.

CASE 2. M. T., aged 12 years, with painful bunions of 1 year's duration (Fig 17a and b). This procedure was performed on the left side (Fig 17c). On the right side, nothing but division of the oblique tendon from the sesamoid and the capsular incision was done. Satisfactory correction was maintained in a 1 year follow-up study (Fig 17d).

CASE 3. L. H., aged 15 years, painful bunions of 1 year's duration. The procedure described was performed

on both sides. Satisfactory correction was maintained in a 3 year follow-up study (Figs 13, c, d).

SUMMARY AND CONCLUSIONS

Some of the more pertinent features of the etiology, anatomy, physiology, pathological physiology, and pathology of hallux valgus have been outlined. This included: (1) a conception of the mechanism of the development of hallux valgus deformity, (2) the importance of the abductor hallucis tendon in maintaining the integrity of the forefoot, (3) the rôle of the contracted structures on the lateral aspect, and especially the oblique attachments to the lateral sesamoid in the causation and in the recurrence of the deformity, (4) a discussion of the "exostosis" myth.

The importance, in the surgical correction of hallux valgus, of replacement of the sesamoids, after their preliminary thorough mobilization has been stressed.

An operative procedure, which, in the author's opinion, seems best suited to meet the surgical requirements, has been described and illustrative cases presented.

The author wishes to express his indebtedness to Dr. L. Haboush for his assistance in the experimental work, and to Mr. George Asness for illustrations and diagrams.

Fig. 17 a and b Both feet before operation c and d after operation

of the toe has been overcome, and the sesamoids replaced (5) the 'bony deformity' at this joint in most instances, is more apparent than real. It is dependent on the degree of inversion of the fore foot, the angle at which the x rays are taken and the altered relationship of the joint surfaces (Figs 13a, b, c, d).

Operations of this nature are reserved for those comparatively rare cases in which a definite bony deformity, or the presence of an intermetatarsal bone as described by Truslow, maintains an unyielding exaggerated varus of this metatarsal.

OPERATION

Fungus infection, if present, is preliminarily treated.

Operation is performed preferably under a tourniquet. A longitudinal incision about $1\frac{1}{2}$ inches in length is made on the dorsum of the foot in the interval between the first and second metatarsal heads. This extends from behind the web directly posteriorly (Fig. 9).

Dissection is carried down keeping close to the lateral aspect of the capsule, thus exposing the lateral sesamoid with its oblique attachment, the conjoined tendon, and the lateral head of the flexor brevis muscle.

With the joint line as a guide, the external lateral ligament with the part of the capsule intervening between it and the lateral sesamoid is divided by a 'hockey stick' incision (Fig. 15).

This is begun by dividing the external lateral ligament at the joint line, carried downward, then posteriorly, in the interval between the lower margin of the head and the lateral sesamoid and extended well back.

The attachments of the oblique tendon to the now exposed lateral sesamoid are thoroughly divided. The hindmost fibers must be included. These usually are attached to its posterior tip as a separate bundle (Fig. 14). (The attachment of the conjoined tendon to the base of the proximal phalanx distally, and the red fibers of the flexor brevis muscle proximally, act as guides to insure its complete division.) The conjoined tendon gains length. Frequently the lateral head of the flexor brevis also requires division. This should be performed proximal to its sesamoid attachment. A definite give can be felt when the binding structures at the posterior sesamoid tip are released. It is but rarely that a triple subtotal section of the oblique tendon is found to be necessary.

Unresisted correction of the valgus without any tendency to spring back, or undue joint tension is now possible. The sesamoids slip into place voluntarily.

The heads of the first and second metatarsals are now approximated by means of a heavy silk or fascial suture. This is taken through the opposing aspects of their capsular bases, or through adjoining drill holes.

THE VALUE OF DELAYED SINGLE PEDICLE SKIN FLAPS IN PLASTIC REPAIR OF THE SCALP

WARREN B DAVIS, M.D., F A C S, Philadelphia, Pennsylvania

AN extensive raw surface in the scalp area, whether due to a deep burn, some degree of avulsion or other severe trauma, is usually healed with difficulty. Blair, Brown, and Byars have secured splendid results by their method of using thick split grafts. For avulsion of the scalp W. D. Haggard regards Thiersch and Reverdin or pinch grafts the only ones applicable. In an avulsion case, A. G. Banks found Thiersch grafts to be only partly successful, and later used a caterpillar graft from the abdomen to the forearm, thence to the scalp successfully. In an avulsion case, G. F. Mitchell closed a denuded area of the cranium 6 inches in diameter by the use of a series of multiple double pedicle flaps and some small single pedicle flaps.

From the Department of Surgery, Jefferson Hospital
Read at the sixth annual meeting of The Society of Plastic and
Reconstructive Surgery, St. Louis, Missouri, October 22, 1937

In the very extensive scalp defects extending over the vault of the cranium, from one side to the other, one is apt to be content if a healed surface is secured by any method of skin grafting or even grafts plus cicatrization, without particular regard to the cosmetic result obtained, since some type of wig can be utilized to hide a disfiguring result.

If a large scalp defect, however, is limited to one side of the head, one should carefully consider the ultimate cosmetic result when the plan of plastic repair is outlined. In such cases, I strongly advocate the use of one or more delayed single pedicle flaps from the sound portion of the scalp as the major part of the operative procedure, supplemented, if necessary, by buried pinch grafts Thiersch or split grafts, to cover any remaining wound surface. The area from which a large delayed pedicle flap has been swung, should be

Fig 1

bone and periosteum became covered with a thin layer of vascular granulations which had a tendency to develop a very delicate unstable cicatricial surface which partly, or sometimes completely, disappeared during the menstrual periods.

In the planned repair, a pedicle flap, 2 inches wide, was outlined over the left side of the top of the head, extending from the occipital region to a point just posterior to the frontal hairline. Measurements insured sufficient length for it to be swung across the midportion of the wound later and sutured to the skin margin anteriorly. The flap was elevated, *both* ends being left attached, then replaced, and sutured into its original position. One week later the anterior attachment was divided, the flap elevated to the occipital attachment, and again replaced and sutured. After another week's delay, the flap was elevated, swung across the midportion of the burned area, and sutured into position. A free full thickness skin graft, the exact size of the pedicle flap, was taken from the abdomen and used to cover the area from which the delayed flap had been removed. At the time of the primary loosening of the flap, small pinch grafts, taken from the thigh, had been buried in the thin granulation tissue above and below the area to be occupied by the flap. All areas healed well, as shown in Figures 2 and 3.

During the following 3 months, it was observed that the healing in the area below the pedicle flap was not entirely stable, small points melting away at menstrual periods, serous fluid oozing out for 3 or 4 days then healing again. This did not occur on the area above the flap covered area. To secure satisfactory scalp tissue to cover the unstable area, a twice delayed single pedicle flap was then prepared in the midline of the posterior portion of the scalp, in the same manner as that used for the first flap, extending from the crown of the head to the margin of the scalp in the cervical area. One week after the second elevation of the flap, the thin unstable epithelium was removed from the area below the first flap, and the second flap placed in position and sutured. By widely undermining the skin margins about the area from which the second flap was taken, and by making a lateral incision at the upper and lower extremities of the raw surface, rectangular flaps were formed, and,

by means of traction sutures, were advanced sufficiently almost to cover the raw area. All areas healed promptly and have remained stable (Figs 4 and 5). It has been interesting to observe that the hair on the transplanted flaps has grown more rapidly and is more lustrous than that on the rest of the scalp.

The functional results have been entirely satisfactory, the cosmetic results are as shown in Figures 6 to 8. The patient is happy with the perfectly comfortable scalp and freedom from the necessity of any artificial covering or wig.

The method outlined is favored for these reasons:

1. A delayed pedicle flap develops an adequate blood supply, thus is more certain to live than is any type of free graft.

2. The thickness of the new scalp is nearer normal and does not develop atrophic spots on the surface.

3. Any surrounding scar tissue is more stable than it would be around any type of free graft.

4. The outline of the flaps can be planned so as to give symmetry in the distribution of hair bearing scalp surface, thus insuring better cosmetic results.

"The disease occurs much more frequently in men than in women, almost in the relation of 75 per cent in males to 25 per cent in females." In our study of 549 cases compiled since 1926 the relation is 85 per cent in males to 15 per cent in females

AGE

Regarding age an analysis of 364 cases, including 164 cases reported in this paper, reveals that the majority of cases occur in the interval between 40 and 60 years. Adding our figures to those of Brunn (4), making a total of 940 cases, 65 per cent were between 40 and 60 years. This was also reported in a study of 96 cases at the Mayo Clinic where 61 per cent were found to be between 40 and 60 years of age. In our group of primary carcinoma of the bronchus, the range in age at the time of admission to the hospital was from a minimum of 33 years and 7 months to a maximum of 68 years and 1 month, the average or mean age being 45 years and 7 months. The range in ages at time of onset of symptoms in a group comprising 140 where onset could be determined with reasonable precision was from a minimum of 32 years and 1 month to a maximum of 67 years and 6 months, the average or mean

age at onset of symptoms being 45 years and no months.

RACE

In this series of 164 cases of carcinoma of the bronchus, 154 were white men and 10 colored. In the 57 cases reported by Rosedale and McKay, 51 were white and 6 colored. Arkin and Wagner had 12 colored patients in their series of 135 cases. Jaffe (14) found that the total incidence of pulmonary carcinoma was higher in the white race than in the colored race, namely, 1.7 per cent of all autopsies in the white race and 1.0 per cent of all autopsies in the colored race.

FAMILY HISTORY

Although the family history was not recorded in 16 cases, in the remaining 148 cases the findings were interesting inasmuch as in 28 cases (31 instances of carcinoma), or 19 per cent, there was a family history of cancer, and in 11 cases (12 instances), or 7.4 per cent, there was a family history of tuberculosis. In 3 cases there was a family history of both tuberculosis and cancer, namely, in 2 cases the mother had died of tuberculosis and the father of carcinoma of the stomach, respectively. In the third case a brother

CARCINOMA OF THE BRONCHUS

A Clinical and Pathological Study of 164 Cases

JUSTIN J. STEIN, M.D. and HOPE L. JOSLIN, A.B., A.M., Hines, Illinois

THE recognition and treatment of primary carcinoma of the bronchus has assumed a role of increasing importance. Although many recent papers report an actual increase in carcinoma of the bronchus, greater diagnostic accuracy, more complete examinations including bronchoscopic study and removal of tissue for biopsy must not be overlooked—also the fact that individuals are now living longer as compared with twenty years ago. Graham (12) states: "The fact that the pathologists are now recognizing more of the small obstructive tumors instead of stopping their examinations at the complications in my opinion accounts for much of the present impression that bronchiogenic carcinoma has actually greatly increased in frequency in recent years. Regardless of whether or not the increase is real or apparent carcinoma of the lung is a relatively common disease."

INCIDENCE

Brunn in a statistical analysis of necropsy reports from 1898 to 1916 found 488 primary carcinomas of the lung in 192,271 necropsies, or 0.24 per cent. From 1916 to 1934 there were 71 cases in 33,308 necropsies or 0.21 per cent. He mentions figures prior to 1900, however, it is difficult to evaluate reports of this period since so little stress was placed upon lung diseases at that time.

Rogers reported 50 cases of primary lung cancer found in 2,209 autopsies done on persons 30 or more years of age at the Pathologico-Anatomic Institute of the University of Vienna from October 1920, to November 1930. The incidence in this group was 2.26 per cent.

Rosedale and McKay reported that in 4,670 autopsies in the period 1915-1934 466 malignant neoplasms of all types were found and of this number 7.5 per cent were bronchiogenic carcinomas.

Jaffe (14) in 1935 reported 871 carcinomas in 6,800 autopsies, of this number 12.47 per cent were carcinomas of the lung. In 1931 in a

statistical analysis of 4,500 autopsies performed between 1915 and 1918 in Vienna, also reported by Jaffe (15), the incidence of carcinoma of the lung among the carcinomas was 10.73 per cent. In these reports the slight increase is more apparent than real.

A study of primary admissions to the Hines Hospital in the 6½ year period from January 1, 1931, to July 1, 1937, reveals a definite increase in primary carcinoma of the bronchus. In Table I are figures comparing the number of primary carcinomas of the bronchus each year with 4 other types of carcinomas as well as with all admissions for carcinomas during a 6 year interval.

This report is based upon an analysis of the clinical features presented by 164 patients having primary carcinoma of the bronchus in whom the diagnosis was established by postmortem examination (100 cases), by histological examination of tissue removed through the bronchoscope (21 cases), by other biopsy examinations (13), or by clinical and roentgen ray evidence (30 cases). In each instance the end result is known constituting a 100 per cent follow up.

SEX

An analysis of 549 cases reported by various authors from the literature shows the ratio of males to females to be 5.6 to 1 respectively.

Regarding this item, Brunn in his statistical analysis of 576 cases published in 1926 states

TABLE I — INCIDENCE OF PRIMARY CARCINOMA OF BRONCHUS

Fig 3c

veterans to various types of gas during the World War has been very thoroughly discussed by Gilchrist and Matz

Although reports have been made stating that tarred streets predispose to the formation of carcinoma of the lung, yet the incidence is just as high where these conditions do not exist. Allen is of the opinion that carcinoma of the lung is no more common among the coal miners of Pennsylvania than in the other population of Pennsylvania

SYMPTOMS

The symptoms of carcinoma of the bronchus are the result of bronchostenosis with its associated pathology, ulceration of the mucosa, or extension of the tumor. Atelectasis is commonly associated with obstruction of the bronchus. Later bronchiectasis develops and abscess formation. As a result of this pathology, there will be pain, cough, dyspnea, and scant or profuse puru-

lent sputum. If a blood vessel is injured as a result of ulceration of the bronchial mucosa, hemorrhage may be produced or the sputum streaked with blood. Chills, fever, and leucocy-

Figs 2a and 2b Anterior and lateral views of bronchiogenic carcinoma showing collapse of the l_{ap} and complete obstruction of left main bronchus just distal to the bifurcation

died of pulmonary tuberculosis and the mother of carcinoma of the bladder. Vague histories, such as "father died of chronic lung trouble" were not included. With more authentic or definite information it is thought the figures might be slightly higher.

OCCUPATION AND ETIOLOGY

Although an exhaustive study was made of the various occupations in this group, no conclusions of any significance could be drawn. At least 75 different occupations were represented, the largest group being farmers or common laborers. Eight, or 5 per cent of the patients had been coal miners but 4 of these also had been employed in other occupations. In addition there were 2 patients whose occupations conceivably might have had some bearing upon the disease. One patient had worked originally as an ore miner, later as a metal polisher and motor assembler. A second patient had been employed for 7 years as an emery polisher inhaling fine particles of emery dust.

Rosedale and McKay state that 75.4 per cent of the patients listed in their group of 57 were employed in occupations requiring exposure to dust or other irritating atmospheric factors. It is

difficult to evaluate properly the part that dust and irritative atmospheric factors play in the etiology of carcinoma of the lung, especially in patients coming from large cities or industrial centers. There have been no conclusive facts shown as yet to prove that the above are of major importance.

Theoretically, trauma is to be taken into consideration in speculating upon etiology. In this series of cases there was no history of injury of any significance. However among these veterans there were 8 who had been subjected to war gas with resulting residuals and complaints of dyspnea, cough, pleurisy, bronchitis, recurrent attacks of pneumonia. In the latter instance one patient stated that in the attacks of pneumonia the left lung had always been the involved lung. Later he developed carcinoma of the left main bronchus. With the exception of 2 cases, both of whom underwent mustard gas poisoning, the type of gas is not mentioned in our histories. One of these patients was the individual previously mentioned who later was employed as an emery polisher so that there are further theoretical complications and conjectures regarding etiology in his case. The entire subject of exposure of

acute bronchitis. In one-third of his patients the onset was not unlike an acute respiratory infection.

Approximately one-third of our patients also described their initial symptom as "heavy cold," "flu," "chill and fever," or had been diagnosed "pneumonia" or "pleurisy." A few additional patients described early symptoms as "asthma" or "bronchitis." In Farrell's cases, the initial symptom had been present a year in more than half the patients before a physician was consulted.

The principal symptoms noted in the cases at this hospital are shown in Table II.

Comparing the symptoms in these cases with those enumerated in other reports, cough, loss of weight, dyspnea, chest pain are most commonly found. However, loss of weight is generally not an early complaint.

The physical and roentgen observations are most often the result of associated pathological conditions, such as bronchitis, abscess, bronchiectasis, pleurisy with or without effusion, atelectasis, et cetera. Quite often the tumor may be obscured by associated pathological conditions and the diagnosis made difficult upon x-ray examination.

The most significant physical findings in our cases are shown in Table III.

ROENTGENOLOGICAL FINDINGS

The findings when typical are that of a unilateral density in the hilum with its apex directed toward the periphery of the lung. Quite often the lateral border of the density blends in with the veil-like shadow of the atelectatic lung resulting from the bronchostenosis. The ribs are narrowed on the affected side, the trachea pulled to that side and the diaphragm elevated. The entire hemithorax is smaller than that of the opposite side. Atelectasis is one of the most common find-

ings in the lung. Occasionally the shadow is distinguished from that of a pleural effusion. When complete obstruction has taken place, the air distal to the tumor is absorbed and the lung collapses. Bronchiectasis may follow the tumor growth is located in the region of the lung, having no connection with the bronchus, causing erosion of ribs or vertebrae, a condition of the terminal bronchioles should be noted (so called Pancoast type of tumor). Recently one of the authors of this paper (JJS, 24) reported a series of 8 cases of carcinoma of the apex of the lung (so called superior pulmonary sulcus type). Six of the cases were in the right apex and 2 in the left apex. Histological specimens were obtained in 5 of the cases, 3 were squamous cell carcinomas and 2 adenocarcinomas. The 3 remaining patients are still living. It is interesting to note that 3 of these cases had been previously diagnosed as tuberculosis and 1 as neuritis.

A large number of the far advanced cases have many associated complicating pathological factors which confuse the picture. Bronchiectasis, abscess cavities, pleural effusion and lymphadenopathies may overshadow the lesion in the hilum. Metastatic lesions in the lung are generally multiple, seldom produce pulmonary symptoms until late, and rarely cause bronchostenosis. That a metastatic lesion may, however, simulate a primary carcinoma of the bronchus was dramatically shown by a case of hypernephroma recently observed by the authors, in which a single metastatic lesion in the lung surrounding an upper lobe bronchus produced a bronchostenosis with the characteristic roentgen-ray findings of a primary carcinoma of the bronchus. The metastatic nodules have a smooth outline as compared with the irregular single shadow of the primary

tosis are caused by the formation of abscesses about the tumor and are generally seen late in the disease. More than half of the patients will have fever at a late stage in the disease.

Funk in reporting 61 cases states the onset of symptoms was usually insidious, although there were also many with sudden pain in the chest, hemorrhage, dyspnea or symptoms resembling

Brunn in a study of 626 case reports, found the heart to be involved in 21 per cent of the cases and the suprarenals in 14 per cent.

The location as finally determined from an examination of autopsied cases demonstrated a greater incidence of cancer in the right bronchus than the left. This corresponds to findings reported by others. The precise location (cases coming to autopsy) is given in Table VI.

Table VIII shows the co-existing diseases or conditions which were found in an analysis of these cases.

With regard to tuberculosis, we are of the opinion that tuberculosis in the presence of carcinoma is a coincidence. It is difficult to believe that either disease causes the formation of the other in the same person. Jaffe (14) found that 7 of his 100 autopsied carcinoma of the lung cases also had tuberculosis. However, there was no case of carcinoma formation from the metaplastic epithelium of an old tuberculous cavity. In many cases of early tuberculosis, the patients consult the physician because of a "generally run-down" feeling, loss of appetite and fatigue following slight exertion, whereas in cases of early carcinoma of the lung the most common symptoms are pain in the chest, cough, and dyspnea.

Syphilis of the lung is rare and quite difficult to diagnose, and such a diagnosis is generally always made by excluding all other possibilities. In 6 of the cases in our series, there was definite evidence of syphilis, but in no case was there evidence of syphilis of the lung.

Brain involvement. All adults having symptoms of involvement of the brain from any cause should have roentgen-rays made of the chest. Jaffe (14) found involvement of the brain in 19 cases in his series of 100 autopsied cases (in 23, brain was not examined). In our series of cases there was clinical or autopsy evidence of cranial metastases in 30 cases. In 4 of our cases there was no history referable to the chest. One of the 4 patients was operated elsewhere for brain tumor because of history of headaches, convulsions, and vomiting. No chest roentgen ray had been made. In an interesting report by Fried and Buckley (9) in 1930, central nervous system metastasis was found in 15 of 37 cases of bronchiogenic cancer. A diagnosis of brain tumor was made in 11 of the 15 cases and intracranial operations performed.

TREATMENT

Since many of the cases were far advanced upon admission to this hospital, irradiation was frequently the only possible choice of treatment. In some instances, this was contra-indicated because of patients' generally poor condition, leucopenia, et cetera.

lesion. If an extensive pleural effusion is present additional films should be made after paracentesis.

HISTOLOGICAL AND PATHOLOGICAL FINDINGS

Often it is quite difficult properly to classify tumors of the lung in that the cellular structure varies a great deal and simulates other forms of malignancy. Samson, in a survey of 100 cases of bronchiogenic carcinoma in which complete autopsies were done, classified the cases as to cell type and found 51 per cent to be adenocarcinoma, 30 per cent squamous celled, and 19 per cent undifferentiated carcinoma. In Farrell's series of 50 cases, 23 were squamous celled carcinomas, 3 adenocarcinomas and 24 undifferentiated carcinomas. In a series of 100 cases specifically studied at Hines Hospital as to cell structure the histological classification was 36 squamous cell carcinomas, 35 adenocarcinomas, and 29 undifferentiated carcinomas.

The major bronchi near the tracheal bifurcation are lined by stratified epithelium. With the decrease in size of the bronchi from the tracheal bifurcation to the periphery of the lung there is an associated decrease in size of the epithelium, the cells of which become thinned out and less spindle shaped. At the ductus alveolaris the cells are cuboidal. The exact origin of the alveolar lining cells has not been determined. Lemon and Higgins (17) consider the alveolar lining cells to be histiocytes and mesenchymal in origin. Fried

TABLE V—BONES INVOLVED

Bone	Number of cases

Femur	3
Humerus	1
Ilium	1
Scull	1

(8) also believes that the alveolar cells are of mesenchymal origin and that "the epithelium of the bronchiole ends abruptly and is followed by the 'naked' walls of the air sacs."

The mucous glands in the wall of the bronchi apparently take their origin from the bronchial epithelium and their ducts are lined with ciliated cells which are continuous with the cells lining the lumen of the bronchus. Since the epithelial elements have the same embryological background all carcinomas of the lung probably arise from the lining cells of the bronchi. Samson has noted that the type of cellular structure in carcinomas of the bronchus depends upon the kind and degree of differentiation attained and not upon the level of origin in the respiratory tract. The cells of the less differentiated basal layer of the bronchus epithelium have the capacity to produce squamous epithelium, columnar epithelium, or undifferentiated round or spindle cells. The 3 types are squamous celled carcinoma, adenocarcinoma and undifferentiated carcinoma.

It is not definitely known just what pathologic processes bronchitis, bronchiectasis and other chronic diseases play in the etiology of carcinoma of the lung. The metaplastic changes which the lining cells undergo in these conditions are for a protective purpose rather than as a forerunner of carcinoma. Similarly when the endometrium is everted the cells become squamous as a protective measure. The great majority of primary carcinomas of the lung arise from the bronchial mucosa. A large percentage of the cases take origin from the epithelium of a bronchus of the first order.

The involvement of various organs as noted in 100 autopsied cases is given in Table IV.

In addition, in unautopsied cases there was clinical or x-ray evidence of brain metastases in 19 cases, of bone metastases in 14 cases, in 3 of metastases to skin—1 of the chest wall—1 of the abdominal wall—1 of the arm, thigh and abdominal wall, 17 of superficial glands, 3 of mediastinal glands, 1 of abdominal glands, 2 of metastases to opposite lung.

The frequency and location of bones involved in 15 autopsied cases having bone metastases are indicated in Table V.

TABLE VI—LOCATION OF CARCINOMA IN LUNG
(100 AUTOPSIED CASES)

Right side	No of cases	Left side	No of cases

Brunn in a study of 626 case reports, found the heart to be involved in 21 per cent of the cases and the suprarenals in 14 per cent

The location as finally determined from an examination of autopsied cases demonstrated a greater incidence of cancer in the right bronchus than the left. This corresponds to findings reported by others. The precise location (cases coming to autopsy) is given in Table VI.

Table VIII shows the co-existing diseases or conditions which were found in an analysis of these cases.

With regard to tuberculosis, we are of the opinion that tuberculosis in the presence of carcinoma is a coincidence. It is difficult to believe that either disease causes the formation of the other in the same person. Jaffe (14) found that 7 of his 100 autopsied carcinoma of the lung cases also had tuberculosis. However, there was no case of carcinoma formation from the metaplastic epithelium of an old tuberculous cavity. In many cases of early tuberculosis, the patients consult the physician because of a "generally run-down" feeling, loss of appetite and fatigue following slight exertion, whereas in cases of early carcinoma of the lung the most common symptoms are pain in the chest, cough, and dyspnea.

Syphilis of the lung is rare and quite difficult to diagnose, and such a diagnosis is generally always made by excluding all other possibilities. In 6 of the cases in our series, there was definite evidence of syphilis, but in no case was there evidence of syphilis of the lung.

Diabetes mellitus	2 (1 autopsy)
Hypernephroma	1 (autopsy)

Brain involvement. All adults having symptoms of involvement of the brain from any cause should have roentgen-rays made of the chest. Jaffe (14) found involvement of the brain in 19 cases in his series of 100 autopsied cases (in 23, brain was not examined). In our series of cases there was clinical or autopsy evidence of cranial metastases in 30 cases. In 4 of our cases there was no history referable to the chest. One of the 4 patients was operated elsewhere for brain tumor because of history of headaches, convulsions, and vomiting. No chest roentgen ray had been made. In an interesting report by Fried and Buckley (9) in 1930, central nervous system metastasis was found in 15 of 37 cases of bronchiogenic cancer. A diagnosis of brain tumor was made in 11 of the 15 cases and intracranial operations performed.

TREATMENT

Since many of the cases were far advanced upon admission to this hospital, irradiation was frequently the only possible choice of treatment. In some instances, this was contra-indicated because of patients' generally poor condition, leucopenia, et cetera.

Surgical extirpation of a centrally located growth must include removal of the entire lung and hilum, as well as the adjacent mediastinal lymph nodes. If the lesion is peripherally located, lobectomy may be sufficient.

Overholt has performed lobectomy upon 19 patients (2 carcinoma, 17 bronchiectasis) with 1 operative fatality, and pneumonectomy upon 11 patients (9 carcinoma, 2 suppuration) with 7 operative recoveries.

In 1933 Graham and Singer (13) stated that there were apparently 6 cases in the literature in which surgical procedures had been carried out the patients remaining either 1 year or more. Of this group 3 of the patients were operated upon by Sauerbruch, 1 by Churchill, 2 by Tudor Edwards, and 1 by Allen and Smith. Only limited portions of lung tissue had been removed. Graham and Singer reported 1 case which they described as being the first case in which the entire lung had been successfully removed at one stage.

In selected cases it is quite possible that the treatment of primary carcinoma of the bronchus through the bronchoscope with a combination of surgical diathermy and radon seeds may prove of value. Surgical diathermy in the treatment of carcinoma of the bronchus and trachea has been described by Kernan, Figs, Vinson and Bowing, Moersch and Bowing, and others.

PROGNOSIS

It is generally agreed that irradiation therapy will produce a palliative effect such as reduction of cough, lessening of pulmonary infections about the tumor, and general clinical improvement. The effect is merely palliative and temporary. However, the patient should receive it whenever possible.

Moersch and Bowing, in their cases in which no treatment was given, found the life expectancy after the microscopic examination had been made to be slightly more than 5 months.

Chandler and Potter found that in 59 patients with pulmonary cancer treated by roentgen ray the survival was 11 months following treatment. In 61 untreated cases the average duration of life was 6 months.

Vinson and Leddy reported 50 patients, who had received roentgen therapy, living and well from 15 months to 4 years after treatment.

In our series of patients treated by irradiation, 73 received roentgen therapy to the chest or mediastinal region. In 66 of these it was possible to estimate the duration of life. Others were omitted because of confusing factors such as co-

existing tuberculosis et cetera. The average duration of life in these 66 treated cases was 15 months. In a group of 48 cases in which the duration of life could be ascertained and who received no treatment other than symptomatic the average duration of life was 8.7 months. One history of particular interest was that of a patient who was admitted to the hospital in June 1935 with a history of symptoms of 2 years duration—50 pounds loss of weight, cough, dyspnea, fatigue, and substernal pain. Examination of tissue removed from the left main bronchus revealed adenocarcinoma. He received roentgen therapy in 1935, following which he regained his weight and has been practically symptom free up to the present time. It may be stated, however, that although he is symptom free except for a slight cough, the tumor has increased somewhat in size as shown by repeated roentgen ray examinations.

When the technique is perfected for lobectomy and pneumonectomy and more data are available, proper evaluation can then be placed upon these procedures. Probably the only way a complete cure can be obtained will be by one of these methods of surgery. Since so many of the cases are far advanced when seen, roentgen therapy offers a great deal to these patients in making their final days less burdensome and in many instances placing the patient in a more advantageous position socially and economically for a number of months.

SUMMARY

This report is based upon an analysis of the clinical and pathological findings presented by 164 patients having primary carcinoma of the bronchus in whom the diagnosis was established by postmortem examination (100 cases), by histological examination of tissue removed through the bronchoscope (21 cases), by other biopsy examinations (13 cases), or by clinical and roentgen ray evidence (30 cases). In each instance, the end result is known, constituting a 100 per cent follow up. This is the largest single series of cases to be reported.

There has been an increase in the incidence of primary carcinoma of the bronchus at this hospital. In 1931 the percentage of carcinomas of the bronchus as compared with all admissions made for carcinomas was 1.7, in 1936 the percentage was 6.5. It is quite possible that the increase is the result of improved methods of diagnosis rather than an actual increase in the incidence of the disease.

With regard to treatment, some surgical procedure will probably be the only means by which

a cure may be obtained. Since most of the cases generally seen are far advanced upon admission, irradiation is frequently the only choice. Irradiation therapy will cause a reduction of cough, lessening of pulmonary infections about the tumor, and general clinical improvement with prolongation of life

SKELETAL DISTRACTION OF THE TIBIA

DAVID M. BOSWORTH, M.D., F.A.C.S., New York, New York

IT SEEMS appropriate at the present time to stop and review the results of a procedure which is of foremost interest to the orthopedic profession, yet about which comparatively little has been written. On reviewing an early report of 2 cases published in 1931, the author finds his work to have been quite incomplete and the great changes that have occurred in technique of operation, construction of apparatus and methods for avoiding complications have impressed him with the necessity of a frank review. The history of leg lengthening has been described but will bear a short summation together with additional reference to the work of a French surgeon hitherto unnoted.

Codivilla in 1905 advocated skeletal traction, the first step forward in this work, but failed to note that the stress of force must not cross a joint and that it must be gradually applied over a period of time.

Beginning in 1908, Magnuson amplified previous work. Attempts to lengthen the tibia by skin traction have been tried and discarded as late as 1918. Putti in 1912 advocated direct skeletal traction on either end of the divided bone which is the principle I have called distraction, without the passage of the pins completely through the extremity. Other workers have had difficulty in preventing pins in the apparatus from slipping. Abbott of St. Louis in 1927 passed the distracting pins completely through the extremity, obviating the danger invited by Putti's method. Numerous other methods have been devised and descriptions of some of them published but all of those successfully used have embodied the principles of distraction: transfixation of pins and gradual lengthening.

Following publication of preliminary work with skeletal distraction in 1931, I received a communication from Dr. O. Lambret of Lille, France in which he referred to a presentation in 1911 before the Society of Surgery of Paris published in the *Presse Médicale* in July of that year, which embraced the principles of distraction and transfixation. Included was a two pin apparatus for use on fracture cases. In 1916 this was again published in *Grand Traité de Chirurgie* together with illustrations of the apparatus and roentgenograms of cases.

Priority for the first application of real skeletal distraction pins transfixation must therefore go to Dr. Lambret who used it in fractures only. Its development in actual lengthening of an extremity has occurred since that time.

The principles involved in successful lengthening of a bone of an extremity are (1), skeletal distraction requiring the application of positive skeletal tractive force to either end of a divided bone without the interposition of a joint, (2), complete transfixation of pins with lengthening force applied on both ends of the pins, (3), gradual lengthening over a period of time, (4), maintenance of skeletal distraction for a sufficient period of time following lengthening for solid union to occur.

Apparatus. As late as 1929, a single pin in the upper tibia and in the lower tibia was being used, together with a supporting splint or frame to maintain balance of the foot and lower fragment. Difficulty of maintaining alignment and development of a pressure sore over the os calcis on an early case forced me to the use of an additional pin through the os calcis allowing direct skeletal control of the foot and lower fragment. Even then sufficient control of alignment was not easily maintained so that in 1930, five pins in all were being used, two in the upper tibial fragment, two in the lower tibial fragment, and a free pin through the os calcis. In addition, a drill guide was devised for placing these pins accurately in alignment and in 1934 additional sleeves were made for the guide for the placement of Kirschner wires. Since that time, wire has been used in children and pins have been employed in older youths and young adults. Apparatus showing the use of both wires and pins is appended (Fig. 1). The apparatus consists of two side bars with ratchet operated by keys, a drill guide and pins or wires. When set up, the side bars are placed upon the ends of the four wires or pins extending through the extremity, and locked to them by set screws. When locked to the pins in this way, there is absolute rigidity and in the case of Kirschner wire, the same rigidity is present as soon as the spreaders have been fastened on the wires. The spreaders themselves act as a suspending apparatus whereby the extremity can be slung to a Balkan frame. When pins are used the four corners of the apparatus are connected

by wire loops to a single supporting wire for overhead suspension. The pin or wire through the os calcis provides not only for support of the foot but maintains dorsiflexion thereof. The supporting cable for the os calcis pin is kept fastened at an angle toward the head end of the Balkan frame, a padded rest being placed between the metatarsal area of the foot and the supporting cables or Kirschner spreader. The side arms are provided with holes at one-half inch intervals for a sufficient portion of their length so that they will accurately fit onto wires or pins drilled through the guide and any length of tibia can be accommodated. Lateral or anteroposterior angulation of fragments is under the complete control of the surgeon. Lateral angulation can be secured or corrected by rolling out either side arm separately (Fig. 2). Lateral displacement can be overcome by sliding either fragment sideways on the pins or wires and anteroposterior angulation can be secured or corrected in either fragment by the use of levers placed between the proximal or distal wires and drawn down and fastened to the side arms. All these corrections of displacement have been easily and safely overcome in actual cases by the means given without anesthesia and during the actual process of lengthening.

Operative procedure has changed in the last 7 years, both as regards the main procedures and as to mechanical details developed to prevent complications. If followed through carefully, though quite extensive, it progresses rapidly and smoothly. A tourniquet is always used. It is perhaps best to tabulate the procedures.

1. *Incision.* Achilles tendon lengthening is done by inverted "L" incision to maintain continuity of tendon tissue. If further dorsiflexion of the foot is needed, the deep layer of the crural fascia underneath is divided vertically. Posterior capsulotomy of the ankle itself has not been necessary.

2. *Insertion of pins.* Four pins or wires are inserted through the tibia by means of a drill guide. Inserting these pins, two should go through the upper metaphysis and two through the lower, the pins being separated 1 inch. The skin should be retracted as firmly as possible toward the center of the leg to allow for stretching required during later lengthening (Fig. 3). As the skin has been thus retracted toward the center of the leg, the drill guide is placed firmly against the skin with the templet of the guide parallel with the sagittal plane of the tibia and not with the leg. The guides themselves should be pushed through the templet until they are in contact with the skin. Pressure then applied will mark the skin at the

point of contact with the guides. Tiny stab incisions can be made through the skin at the marks left by the guides. It is well to note that the guide should be always held on the inner and not the outer side of the leg. The guide is again placed on the leg with the skin retracted toward its center, and a drill hole is placed through the lower guide. A pin placed through this guide and hole can be forced through the anterior muscle bundle of the leg and a nick in the skin is made over the end of the pin thus allowing it to emerge externally. When this pin is in place, the apparatus will be well stabilized for setting the other pins. The second of the distal pins can be placed in similar fashion. It is extremely important when placing the third pin of the series which is next to the top, that the drill guide be sprung forward one-fourth inch on the lower two pins before the hole is drilled (Fig. 4). This third hole is drilled but no pin placed through it until after the fourth pin has been drilled for, put in position, and the drill guide removed. Then the third pin can be driven into place and the fifth pin placed through the os calcis. In the use of Kirschner wire, the same procedure is followed, the wires being introduced directly without drill holes. The reason for the offset third pin is to provide for forcible maintenance of contact of the tibial fragments following osteotomy, thus preventing anterior bowing. Dressings wrung out of Dakin's solution can be placed over the ends of the pins before the next step is taken.

3. *Osteotomy of the tibia.* Through an anteromedial incision, the tibial shaft is exposed in the central area and by motor saw, its cortex is cut through near the internal border and on the lateral surface. These saw cuts are joined below by a transverse cut in front and above by means of the Gigli saw behind. This leaves a tongue above and groove below with the tibia slanted slightly on the pins so that lengthening causes increased forceful apposition of fragments. The fibula is easily reached intramuscularly through the lateral tibial periosteum and divided by osteotome. Whether single or double osteotomy was done (Fig. 7) has seemed to make no difference in the lengthening result, and the level of the osteotomy (Fig. 9) is unimportant. Through the same incision, division of the leg fascias can be done but in none of the cases subsequently reported has it been done. In view of results it seems unnecessary.

4. *Placement of side arms.* The side arms of the apparatus can now be placed on the four tibial pins and extended to tautness by the keys. By sliding the lower tibial fragment, lateral displacement can be overcome (Fig. 2d). If slight

lateral angulation is present, further extension of one side arm will overcome it (Fig 2c). Antero-posterior displacement is impossible and the fragments will be found very firmly held in apposition due to the offset third pin described. When perfect alignment has been secured, one can proceed with the closure.

5 Wound closure Wound closure should be with interrupted silk, Stewart, or submarine suture and should include merely the skin and half the fatty subcutaneous tissue. Not only is it not necessary to close the periosteal layer, but it will be found to be impossible to do so. No deep sutures should be used.

6 Dressings Dressings wrung out in Dakin's solution should be very lightly put in place, not forgetting to dress the tendo achillis incision as well as that of the osteotomy. The pin dressings have already been applied.

7 Suspension of apparatus The patient is returned to bed and the apparatus suspended from an overhead frame. At first counterbalancing weights were used but it has been found that the patients are more comfortable and the apparatus more stable with fixed suspension, all support being through wires permanently fastened to the overhead frame at a definite level without pulleys or counterweights. A sling of muslin fastened to the side arm may be placed under the calf to give a sensation of support and relieve tension on the suture line. This support should not be too great or it will cause anterior bowing of the fragments (Fig 5).

8 Suture removal Removal of sutures should be done on the seventh day, great care being taken to remove the dressing only over the suture area of the tibia and tendo achillis without disturbing the dressings covering the emergence of the pins from the leg. This is generally easy to accomplish since the dressings were placed on the pins before actual lengthening operation on the tibia was begun.

9 Lengthening process Lengthening should not be begun until 2 or 3 days after removal of sutures when all dressings are off and the actual incisions and the whole leg and foot are open to inspection except the emergence of pin holes. If any complication such as hematoma or infection develops during the course of lengthening, no further attempt to secure extension should be made until the hematoma has been evacuated and healed or other complication has been overcome. In the usual case incision healing will be present by 7 days, suture holes healed by the ninth or tenth day and lengthening can safely proceed thereafter at the rate of one tenth of an

inch every other day or slightly faster. In children, union will be occurring by the time lengthening is secured but in adolescents and adults no fear of union occurring to stop lengthening need arise. In fact, it is delayed in adolescents and fails to occur without additional bone graft in adults. Plenty of time is allowed therefore, in these latter cases for overcoming complications and still securing lengthening.

10 Fixation When the desired or maximum amount of lengthening has been secured the apparatus and limb are removed from suspension. The dressing on one side of the os calcis pin is pulled off the pin, iodine and alcohol applied at the point of passage through the skin and the pin is cut off with sterile rivet shears at a point which lies beneath the dressing and has remained sterile throughout the lengthening. The remainder of the pin can be pulled through the os calcis and iodine injected through the pinhole without anesthesia or pain to the patient. The pinholes are uniformly without sensory nerve supply. Dressings are placed over the os calcis pinholes. A plaster cast is applied inside the side arms firmly incorporating the tibial pins and their dressings in plaster. Following hardening of the cast, the pins are cut between the cast and side arms with rivet shears, and the ends of the pins remaining are covered with another layer of plaster bandage. When wires are used clips on the wire ends are included in the cast to prevent the wires from bowing. The plaster boot should extend up the thigh to give a sense of stability to the patient. The cast can be cut and wedged to get perfect alignment, and reinforced at the cut with a few layers of plaster to maintain correction. Actual contact of fragments is positively maintained by the four pins remaining in the tibia. The patient can now become ambulatory on crutches.

11 Osteoplasty Osteoplasty of the upper defect is generally required if the patient is over 12 years of age and always required if the patient is an adult. Graft of the lower defect has not proved necessary due to the large mass of shaft left there at time of operation (Fig 7). By the time lengthening is complete roentgenograms will give a definite knowledge as to whether bone graft to fill the upper defect in the tibia behind the tongue is necessary. There are several reasons for having the tongue cut above, but the most important is that it places the defect which is largest toward the upper part of the tibia where osteogenesis is best. If osteogenesis has failed to progress by the time lengthening is complete, there is no reason for delay in grafting this upper defect. It can be done within a week of the appli-

Fig 1 Lengthening apparatus as applied with three-sixteenths inch drill steel pins and Kirschner wires. Note fifth pin through the os calcis and support of padded bar under metatarsals. Tongue and groove osteotomy of the tibia shown, leaving larger portion of tibia below which regeneration is slower. Single osteotomy of fibula present. The offset position of the third pin hole causing forced apposition of fragments can be seen. Note distance of pin holes from joint surfaces and osteotomy site. Plenty of room left for dressing and exposing osteotomy wound without changing pin dressings or exposing points of pin entrance.

cation of the supporting cast through a window in the cast, bone being taken from the other tibia. Strips of bone are inserted in the defect abutting the lengthened fragment ends, thus preventing telescoping and loss of length. Following placement of the graft, the cast is closed again and remains in place without further disturbance until solid union has occurred.

APPLICATION OF PROCEDURE

Twenty-four tibial lengthenings have been completed in the past 8 years (Table I). These

Fig 2 a and b, Diagrammatic sketch to show method of correcting anterior or posterior angulation by use of levers placed between the upper and lower wires. The action of the lever in a is the same as that caused by the offset third pin at time of operation. c, Correction of lateral angulation by lengthening of one sidearm. When wires are used they go through the distal fibula. When pins are used they are placed anterior to it. d, Method of correcting lateral displacement by sliding fragments sideways on wires. e, Strips of cortex (represented as a block) have been removed from the other tibia and inserted behind the tongue in the upper defect, thus preventing loss of length and hastening osteogenesis by acting as grafts. This must be used on adults.

have been separated into three classes for study, as they vary considerably regarding the ease of lengthening and period required for the end-result secured. Six of the cases have had shortening following poliomyelitis, 13 were short normal legs, and 5 were recent fractures. By short normal legs I mean legs in which there was no pathological condition except for the shortening itself and no muscular paralysis. They include 4 cases of malunion of fracture of many months' duration, 1 due to tuberculosis of the hip, 1 due to shortening of the thigh from osteitis fibrosa cystica of the femur, 2 following early closure of the epiphyseal lines of the tibia following injury, 2 resulting from old congenital dislocation of the hip, and 3 due to dyschondroplasia. These three lengthenings for dyschondroplasia occurred in 2 patients, 1 of whose legs was lengthened and later reoperated

Fig 3 The skin is retracted toward the center of the leg to allow for the stretching it will receive as the leg is lengthened. The second pin has been drilled through to the skin and the skin is being stretched over the end of the leg before it is nicked by the scalpel for passage of the pin.

on and lengthened further. She was a chondrodystrophic dwarf with a very short femur and a total of $3\frac{1}{4}$ inches was secured by the two lengthenings. The other had a dyschondroplasia of the whole lower extremity, evenly balanced between the tibia and femur. The third classification of cases was recent fractures and of these there were 5. All were seen within 1 to 4 weeks following fracture and were easily lengthened and length maintained.

Five of the 24 cases have been done too recently to report (within the last 18 months) so that 19 remain for study. Of the cases indicated for study, the most recent was done 28 months ago and the first $8\frac{1}{2}$ years ago.

Gain in length (Table II). The greatest gain in length secured by one operation was $1\frac{1}{2}$ inches in a case of poliomyelitis (Fig 9) the least $1\frac{1}{4}$ inches. In every case, the gain secured was the

Fig 5 a The result of suspension of the leg by pins is a thinning of the scar due to pull on the tissues over the tibia by the sagging calf. b Support of the calf in a sling passed over the side arms releases the pull on the suture line resulting in quicker healing both of the skin incision and of the bony structures with a thicker pad of soft tissues over the tibia at completion of the case.

Fig 4 Above the drill guide is shown being sprung forward for the placing of the offset third pin. This will cause forcible apposition of fragments later. Pins or wires are spaced at one inch intervals. Below, all five pins are in place. Note the offset third pin from the bottom in the tibia which maintains forcible contact of tongue with groove and prevents anterior bowing.

total amount required to balance the patient. Children were measured every 3 months for 9 months to 1 year to estimate the rate of shortening.

Lengthening was then planned to care for the estimated amount of shortening at time of cessation of epiphyseal growth. No child below 8 years of age was or should be operated upon. Younger than this we could not satisfactorily estimate the rate of growth. All the adult patients were examined before operation placing a raised shoe or block under the foot and their gait and posture noted to determine accurately the amount of lengthening which would be optimal (Fig 6). Frequently a complete lengthening to match the good leg would not have given a good general correction to their posture as fixed.

TABLE I — DISTRIBUTION OF CASES

	Cases
Poliomyelitis	6
Short normal	13
Malunion fracture	4
Tuberculosis of hip	1
Osteitis fibrosa cystica femur	1
Early closure epiphysis	2
Dislocation of hip	2

Fracture	19	1½	1½	1½	2	2	5½	None

changes had already taken place in the spine and pelvis to accommodate some of the shortening present in the leg. For this reason, adult short legs were not always lengthened to match the long leg but merely enough to give them the best possible stance and gait as determined before operation. In all cases but 1, the desired amount of lengthening was secured. This case was the chondrodystrophic dwarf in whom it took two separate lengthenings, 3½ years apart, to overcome enough of the shortening to give her a fair stance and gait. In none of the cases did the lengthening secured prove too much and throw the patient out of balance. The speed of lengthening is also shown in Table II but certain points which are very important might not easily be seen. The recent fractures permitted immediate attainment of full

Fig 6 a, The block used here is not enough to compensate for full amount of shortening. Fixed spine and pelvic changes were present which made this raise of the leg comfortable and helpful. Full correction by a longer block caused the patient's trunk to shift to the left and gave her a severe posture defect. b, This patient has perfect balance resulting from full correction of shortening by a block under heel before operation, proof that fixed spine and pelvic changes do not contra-indicate full lengthening of the short extremity in this case

Fig. 6.

block and knee fusion all preceded lengthening Note angulation corrected at time of cast application Pin holes healed, single fibular osteotomy, reformed marrow cavity. Rather marked ankle eversion not appreciable clinically.

Only one other infection in the series occurred and this was due to the use of deep sutures and vaseline gauze dressing. All three healed, united, and maintained the length gained. They have shown no recurrence of infection during the past 4 years. An average speed of one-tenth of an inch a day during the complete postoperative period of lengthening is within safe limits and a greater speed is dangerous. The immediate gain in lengthening at time of operation, except in fractures, is about one-fourth of an inch, and it is not possible to secure more than three-eighths of an inch in short normal legs or poliomyelitic legs, even with very forcible extension of the apparatus (Fig 8).

Postoperative pain has been considered a reason for avoiding leg lengthening, but as can be seen from Table II, it was not persistent except in 3 cases. Two of these 3 cases were the ones in which lengthening was started immediately after operation without waiting for wound healing, and continued at too rapid a rate, namely more than one-sixth of an inch a day. The third case was a young woman who complained continuously, until after application of her cast following completion of the lengthening. The length of follow-up on all cases is included in the same table for convenience.

Numerous questions have arisen regarding the pins placed through the tibia and some of these questions can now be definitely answered. In 1 case, the pins remained in position without infection or change of dressing for 16 months. They were still tight at the end of that time. The average length of maintenance *in situ* was between 3 and 5 months. In 16 of the 19 cases the pins were still firmly in place at time of removal, and without apparent bony absorption surrounding them. In only 3 of the cases was there infection of pinholes. These 3 cases included the two which were run out too rapidly, and the one in which the wound broke down due to deep sutures. In all other cases, pinholes were dry and without discharge. All pinholes healed within 3 weeks except in 2 of the infected cases mentioned. One of these required 3 months and the other $4\frac{1}{2}$ months to heal. The holes in the tibia caused by the pins filled in completely in 8 cases, almost completely in 2 others, and partially in 1 other. In all remaining cases the hole which persisted became surrounded with cortical bone with rearrangement of the internal structure to assume new lines of force (Fig. 12). In 1 of the cases lengthening was too rapid and a sequestrum formed which was easily removed, healing took place subsequently and left a leg with full regeneration of the tibia

Fig 10 Comminuted acute fracture reduced with leg lengthening apparatus closed method and placed in immediate cast including the pins

Fig 11 Young adult 6 year result Malunion fracture of 6 months duration reduced in 1 hour with apparatus (open operation) wide stripping of the periosteum osteotomy of callus area great extensive force and manipulation of fragments and soft tissue with distractive force acting Note pin holes still not completely closed

Fig 12 Necrosis of the wound resulted in this case from the use of deep sutures and vaseline dressing One and one half inch gain maintained Healing of skin and bone defect was rapid and the same leg was lengthened another 2 inches within the past year without complication Note cortical bone formation about lower pin hole and realigned lines of force in surrounding bone

Fig 13 Following union of lengthening, this boy's tibia grew 6 inches in length in 4 years. Note that slight posterior bowing results in no defect. This is definite proof that operative lengthening does not stop epiphyseal growth.

Fig 14 Young adult, 7½ year result. Shortening due to suppurative arthritis of the knee at 1 year of age. This shows result of placing the tongue of the lengthening below. Delayed regeneration, fracture and absorption occurred. Successful relengthening to 2 inches and defect grafted.

and the original amount of length secured. Four cases required grafting following the lengthening, 3 in old malunion fractures, and 1 a young woman of 18 years with a short normal tibia (Fig 14). Growth of the legs continued in every case in which the patient was in the growing period. One

child's tibia grew 6 inches in 4 years following complete union of the lengthening (Fig. 13). No epiphyseal cartilage damage could be demonstrated in any instance. There was definite clinical evidence of damage to joint structures as follows: 6 ankles showed a loss of motion varying from

Fig 10 Comminuted acute fracture reduced with leg lengthening apparatus closed method and placed in immediate cast including the pins

TABLE III.—DISABILITY

	Total Weeks	Partial Months	Retarding Factors
Poliomyelitis			
4 uncomplicated	6-12	4-16	Age—length gained
1 complicated	12	33	Infection
Short normals			
4 uncomplicated	2-12	5-15	Age
5 complicated	6-8	4-26	Bone graft—Infection
Acute fractures			
2 simple	1	4-5	Communion
3 compound	1	4-15	Infection—Nonunion

in lengthening due to intact fascia was noted. A drain was used on one of the early cases, but it is believed better to take the risk of an occasional hematoma. The optimal dressing is one wrung out of Dakin's solution and was found to leave a cleaner incision than either dry or vaseline gauze.

The period of disability is shown in Table III. The greatest factor extending disability, appears to be the age of the patient. Children unite very fast and can be completely ambulatory in 4 to 7 months. Adults require 12 to 16 months. One infected case required 33 months. A safe average would be a year. Infection delayed the end-result in each of 3 cases tremendously.

Complications are shown in Table IV. There was infection in 3 cases, 2 following rapid lengthening and 1 from use of deep sutures and macerations by vaseline gauze dressing. I believe that they can be avoided by slow lengthening; the use of silk sutures, avoidance of locked stitch, deep sutures, and drains, and the use of a dressing wrung out in Dakin's solution. Delayed reossification occurred three times, and in each instance was directly attributable to the age of the patient, the length of the gap left in the tibia or the small size of the upper tibial tongue (Fig 8). Nonunion which required grafting occurred four times and was the result of compounding or comminution of previous fracture, failure of sufficient continuity of bone contact, or age of patient. All were grafted successfully. Anterior bowing occurred 5 times in the early cases of the series. It has not occurred since the offset third pin has been used and the cast wedged, nor has it been enough to embarrass the operator or patient. It rarely occurred during lengthening but generally afterward when skeletal traction had been removed, and the pull of the muscles bowed the soft new bone (Fig 15). Moderate eversion of the foot at the ankle occurred 6 times. In only 1 case was it of sufficient extent either to come to the patient's attention or to require correction. In

TABLE IV.—COMPLICATIONS OF LENGTHENING

Complication	Number	Causal factors
Infections	3	Too rapid lengthening, catgut sutures, locked stitch, vaseline dressing, deep sutures used
Slow re-ossification	3	Age of patient, length gained
Bone graft required	4	Age of patient, compound fracture, comminuted fracture, failure of continuity
Anterior bowing	5	Early cast removal, third pin not offset, first cast not wedged
Ankle eversion	6	Early fibular union, incomplete osteotomy fibula
Hematoma	2	Unknown

that case a later osteotomy of the tibia and fibula corrected the deformity. In 2 instances the eversion was spontaneously corrected by epiphyseal growth in less than 3 years. Hematomas have occurred twice, and in each instance have been evacuated successfully without infection and without preventing completion of lengthening. It is imperative to await complete healing of a hematoma. Reoperation is always possible at a later date, provided one has not rashly proceeded with the lengthening and lost the extremity through infection. Cavus foot and hammer toes gradually develop during lengthening, due to tautness of flexor and extensor tendons. In no case did they persist. The muscles gradually stretch after lengthening is complete and the foot and toes straighten out. A new marrow cavity developed in every case, and several times was present as early as 4 to 6 months after operation. There were no cases of footdrop, either temporary or permanent, nor evidence in any case of peroneal or tibial nerve irritation or paralysis. No extremity showed decreased blood supply due to stretching of the blood vessels.

There were 46 other operations performed on these 24 patients not including the lengthening operations and grafts of the lengthened site. Most of these other operations were on poliomyelitis patients. Their reconstruction is always more complicated than the ordinary case. In 2 cases lumbar sympathetic ganglionectomy was done so as to secure sufficient circulation for lengthening. The child who gained 6 inches in length from growth, following tibial lengthening, was not one of these, therefore his growth could not be attributed to that procedure. Other reconstructive operations on poliomyelitic cases included one osteotomy of the tibia and four osteotomies of

Fig 15 Two and one half year result in adolescent with shortening due to tuberculous hip. Slight bowing which occurred after removal of plaster due to the pull of the calf on soft bone at the site of lengthening. Note that the wires went through the distal fibula as well as tibia resulting in drawing the fibular head to a lower position than normal. No clinical embarrassment from this.

Fig 16 R O 30 year old female lengthening of 1 1/2 inches completely solid walking in 7 months. Speed of recovery due to immediate graft of upper tibial defect following lengthening. Shelf operation for congenital dislocation of hip preceded lengthening and subastragaloid arthrodesis for associated foot deformities followed immediately after lengthening to complete the case.

one tenth to one fourth. Two knees showed a loss of one eighth, and one third, the range of normal flexion respectively. No relaxation of joints could be demonstrated due to this procedure. There were no cases of shock and no

deaths. It was found that the length of time required for union was shorter when the tongue of the tibial osteotomy on the upper fragment was made fairly large. The fascia of the leg was not divided in any case. No complication or difficulty

OPERABILITY IN CANCER OF THE RECTUM

T E JONES, M D, F A C S, Cleveland, Ohio

EVIDENCE of the fact that operability is a more or less vague term is apparent when one reads the literature and finds that operability statistics in cancer of the rectum are at great variance, being quoted from 25 to 70 per cent. Many of these statistics are presented by able surgeons of equal capabilities and the only way the wide difference can be explained is that figures are arrived at by entirely different methods of analyzing groups of cases. It seems to me that a simple method of computing our statistics could be used, so that various series of cases could be compared on an equal basis. With this object in view, a critical analysis of one hundred consecutive cases of cancer of the rectum has been made, listing exactly what happened in each case. For instance, a patient is advised to have an operation and promises to go to the hospital but does not return. Such cases make up a certain percentage of everyone's total series, but the question arises: Where should this case be classified? One writer will not include the case while another will add it in his total. When such cases amount to 10 per cent of the total, it is easy to see that a wide variation in figures will result, but this would not be true if all data were summarized in the same manner. In the table below is listed exactly what happened to one hundred consecutive patients with primary untreated carcinomas of the rectum as they appeared for examination during a period ending July 1, 1937.

TABLE I

A Patients examined	100
B Radical operation advised, did not return	10
Balance	90
C Operation not advised, too far advanced.	11
Palliative procedure advised	9
D Operated upon for cure	20
E Inoperable at exploration	70
Liver involved	13
Local fixation	10
F Operation completed	3
	57

It is evident that 10 patients (B in Table I) whose condition was considered clinically operable did not return for various reasons, viz., distance away from home, objection to colostomy, or desiring another hospital or surgeon, therefore,

From the Cleveland Clinic.

operability should be computed on a basis of the figure 90. I think this is fair because, if exploration were done, it is quite likely that in at least 8 cases the operation would have been completed, judging from the number of cases with complete operation as shown in the table.

An analysis of the inoperable group of 20 cases (C in Table I) is given in Table II.

TABLE II — ANALYSIS OF INOPERABLE CASES

No operation was advised in 11 cases because	Cases
a Palpable liver metastases	3
b Extensive local invasion	1
c Bladder perforation and age	2
d Fixation in patient aged 71	1
e Age 75, condition poor	2
f Cachexia and moribund	1
	11

While I am a staunch advocate of colostomy, there are certain patients for whom it is not indicated and, in this group of 11 patients, I did not think it would add materially to their comfort.

Palliative operations were advised in 9 cases for the following reasons:

	Cases
Advanced lesions, ages over 70, condition poor	5
Fixation and pelvic metastases	4
	9

Palliative operations consisted generally in colostomy with or without radiation and, in some cases, radiation or coagulation without colostomy. The reasons for these procedures varied: (1) obstruction, (2) liver involvement, extreme age, etc.

In these two groups, then, which comprise 20 cases, the condition was considered inoperable; on a basis of 90 cases, that is 22 per cent.

There remains a group of 70 cases which we considered to be clinically operable or at least deserved exploration, even though many were borderline cases from the standpoint of fixation. Based on the figure of 90, this can be construed as an operability figure of 78 per cent. However, it will be seen that the growth in 13 of these 70 patients (D in Table I) was found at exploration to be inoperable due to liver metastases (10 cases) and local fixation (3 cases). In this group of 13 cases, 8 patients had colostomy and 5 did not, because it was estimated that death would

the femur for genu valgus, genu varus, or slight knee flexion defects, 7 subtalar arthrodeses, 1 posterior ankle block, 5 tarsal sections, 2 knee fusions, 5 transplantations of the extensor tendons to the dorsum of the foot, and 2 spine fusions for paralytic scoliosis. Besides these, the following reconstructive operations of other non poliomyelitic cases were necessary prior to lengthening of the tibia. One bone graft was done for non union fracture. Three operations for congenital dislocation of the hip had been done elsewhere on one patient and a shelf operation was done in our clinic to stabilize the extremity. A tuberculous hip had four attempts at fusion before solid union

was secured. Eight skin grafts were performed in 4 traumatic cases before lengthening, to remove adherent scar and cover the tibia. A laminectomy fusion was done in a case of chondrodystrophic dwarf with hemivertebra, angulation of the cord and bladder symptoms.

In concluding there have been no mortalities, no loss of extremities, no failure to gain or maintain length, no non union, and no unhealed or disabled cases. To take a series of such cases and carry them through successfully entails strict adherence to detail and technique, and personal attention to every step of the procedure through out the patient's operation and convalescence.

OPERABILITY IN CANCER OF THE RECTUM

T. E. JONES, M.D., F.A.C.S., Cleveland, Ohio

EVIDENCE of the fact that operability is a more or less vague term is apparent when one reads the literature and finds that operability statistics in cancer of the rectum are at great variance, being quoted from 25 to 70 per cent. Many of these statistics are presented by able surgeons of equal capabilities and the only way the wide difference can be explained is that figures are arrived at by entirely different methods of analyzing groups of cases. It seems to me that a simple method of computing our statistics could be used, so that various series of cases could be compared on an equal basis. With this object in view, a critical analysis of one hundred consecutive cases of cancer of the rectum has been made, listing exactly what happened in each case. For instance, a patient is advised to have an operation and promises to go to the hospital but does not return. Such cases make up a certain percentage of everyone's total series, but the question arises: Where should this case be classified? One writer will not include the case while another will add it in his total. When such cases amount to 10 per cent of the total, it is easy to see that a wide variation in figures will result, but this would not be true if all data were summarized in the same manner. In the table below is listed exactly what happened to one hundred consecutive patients with primary untreated carcinomas of the rectum as they appeared for examination during a period ending July 1, 1937.

TABLE I

A Patients examined	100
B Radical operation advised, did not return	10
Balance	90
C. Operation not advised, too far advanced.	11
Palliative procedure advised	9
D Operated upon for cure	20
E Inoperable at exploration	70
Liver involved	10
Local fixation	3
F Operation completed	57

It is evident that 10 patients (B in Table I) whose condition was considered clinically operable did not return for various reasons, viz., distance away from home, objection to colostomy, or desiring another hospital or surgeon, therefore,

From the Cleveland Clinic.

operability should be computed on a basis of the figure 90. I think this is fair because, if exploration were done, it is quite likely that in at least 8 cases the operation would have been completed, judging from the number of cases with complete operation as shown in the table.

An analysis of the inoperable group of 20 cases (C in Table I) is given in Table II.

TABLE II.—ANALYSIS OF INOPERABLE CASES

No operation was advised in 11 cases because.	Cases
a Palpable liver metastases	3
b Extensive local invasion	1
c Bladder perforation and age	2
d Fixation in patient aged 71	1
e Age 75, condition poor	2
f Cachexia and moribund	1
	11

While I am a staunch advocate of colostomy, there are certain patients for whom it is not indicated and, in this group of 11 patients, I did not think it would add materially to their comfort.

Palliative operations were advised in 9 cases for the following reasons:

Advanced lesions ages over 70, condition poor	Cases
Fixation and pelvic metastases	5
	4
	9

Palliative operations consisted generally in colostomy with or without radiation and, in some cases, radiation or coagulation without colostomy. The reasons for these procedures varied: (1) obstruction (2) liver involvement, extreme age, etc.

In these two groups, then, which comprise 20 cases, the condition was considered inoperable; on a basis of 90 cases, that is 22 per cent.

There remains a group of 70 cases which we considered to be clinically operable or at least deserved exploration, even though many were borderline cases from the standpoint of fixation. Based on the figure of 90, this can be construed as an operability figure of 78 per cent. However, it will be seen that the growth in 13 of these 70 patients (D in Table I) was found at exploration to be inoperable due to liver metastases (10 cases) and local fixation (3 cases). In this group of 13 cases, 8 patients had colostomy and 5 did not, because it was estimated that death would

intervene before obstruction occurred. Therefore based on the figure of 90, there were 57 completed operations, or 63 per cent, whereas computation on the basis of the 70 explored cases would give an operability figure of 80 per cent. Furthermore, it will be seen that excluding the cases in which the liver was involved, we completed the operation as far as the local lesion was concerned in 56 of 60 cases, or 93 per cent.

It is apparent then why operability figures vary. For purposes of comparison therefore, operability figures should be reported both in relation to the number of cases seen and those in which operation is advised and in relation to the cases explored. These figures bear out the fairness of eliminating the 10 patients whose condition was thought to be operable but who did not return because it is quite likely that the same ratio of 80 per cent operability would hold as it did in the group of 70 cases so that the figures would not be altered.

Of the 57 completed consecutive operations the type of operation performed is shown in Table III.

TABLE III

	Cases
Combined abdominoperineal 1 stage	54
Colostomy and posterior resection	1
Colostomy and segmental resection	1
Electrocoagulation (early lesion)	1
Total	57
Mortality in this series	4
Based on 56 major procedures	7.1%

MORTALITY

From Table III it will be seen that 80 of the 100 consecutive cases were considered operable clinically, but 10 patients did not return so that 70 entered the hospital for radical operation. Due to reasons stated previously operation was incomplete in 13 cases. 8 patients had colostomy only, and 5 did not. There were no deaths in this group. In the 57 remaining cases 56 major procedures were carried out. Fifty-four of these were combined one stage procedures, and there were 2 two-stage procedures. The additional case an early one in which electrocoagulation was done, is not counted as a major procedure and was not included in the mortality statistics.

In this group of 56 cases there were 24 females and 32 males and their ages were as follows:

TABLE IV — AGES

	Cases
25 to 30 years	1
30 to 40 years	8
40 to 50 years	10
50 to 60 years	10
60 to 65 years	11
65 to 70 years	9
70 to 80 years	7

It will be seen that more than one third of these patients were between the ages of 60 and 70 years.

In the 56 consecutive cases in which a major operation was performed, 4 deaths occurred a mortality of 7.1 per cent. Based on the 54 one stage procedures in which the deaths occurred it was 7.4 per cent.

The causes of death are shown in Table V.

TABLE V — CAUSES OF DEATH

	Cases
Peritonitis	2
Pulmonary embolus	1
Bronchopneumonia	1

One case of peritonitis and one of pulmonary embolus were proved at autopsy; the 2 others were clear cut clinical diagnoses (Table VI).

TABLE VI

No.	Sex	Age	Death after operation	Cause of death
1	M	31	12 days	Peritonitis and obstructed colon
2	F	6	70 days	Pulmonary embolus and thrombosis in a patient ready to go home (autopsy)
3	M	35	3 days	Definite peritonitis (clinical)
4	M	65	4 days	Peritonitis, at-once died in hospital. Cause of death not clear. (autopsy)

From the standpoint of operability and mortality, it is obvious then that the one stage procedure compares quite favorably with the multiple stage procedures. For purposes of analysis and comparing operability figures the simple table described previously is suggested.

TRANSVESICAL DIATHERMY IN THE TREATMENT OF CARCINOMA OF THE BLADDER

ALEXANDER RANDALL, M D, F.A.C.S., and CHARLES A. W. UHLE, M.D.,
Philadelphia, Pennsylvania

CARCINOMA of the bladder, despite the varied technical procedures devised for its management, remains a distinct problem in the field of urological surgery. Success in its treatment, commensurate with knowledge thus far attained in reference to carcinoma in general, lies in early diagnosis and prompt institution of therapy. Centralization of therapeutic data for analysis and statistical appraisal, as embodied in the Tumor Registry of the American Urological Society, will accomplish much in guiding the future therapy of this disease.

The surgical pathology of vesical neoplasia offers a distinct challenge to those who undertake its management, for the bladder must not be considered a single physiological unit but an integral part of the entire urogenital synchronization. Individualization in the selection of treatment is therefore necessary and should be guided by the characteristics of the neoplasm, its location, its size, its relationship to renal function or dysfunction, its extension into and beyond local barriers, and finally, the physical potentialities of the patient himself. Dart, recently, in reviewing 1,224 tumors of the bladder, emphasized that cellular differentiation must be supplemented by the physical characteristics of the growth if one wishes to grade carcinoma.

The multiplicity of the methods of surgical management permit a wide latitude of choice. One of these, transvesical diathermy or electrocoagulation, has received minimal consideration in the medical literature since its clinical elaboration by Corbus in 1921. Recently there have been a few articles reporting favorably on its use (4, 8). Stimulated by these observations, a survey of the case histories of patients treated by this method in the Urological Clinic of the Hospital of the University of Pennsylvania between the years 1923 and 1936 has been made.

CLASSIFICATION OF ELECTROSURGERY

The older method of destroying bladder carcinoma with the Percy cautery and glowing solder-

From the Department of Urology, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania.

Presented before The Philadelphia Urological Society, May 24, 1937.

ing iron met with moderate success. However, because of the rapid evolution of electrophysics and the introduction of refined electrosurgical equipment, these cruder methods have been displaced.

In general, electrosurgery, embodying the principles of the high frequency currents, has a three-fold clinical usage: first, the rapid, bloodless, aseptic severance of the normal tissue; second, the excision or destruction of malignant tissue; and third, the coagulation of blood vessels.

The electrosurgical domain is composed of four general groups: (1) "Acusection" refers to the cutting of tissue with the high frequency current. This term is derived from "acusector," an instrument devised by Kelly and so named by him to differentiate the electrosurgical "knife" from the scalpel. (2) "Electrodesiccation" effects destruction by dehydration, the current being of the unipolar Oudin type. (3) "Electrocoagulation" implies a thermic reaction, death of tissue being produced by heat coagulation of the tissues. This current is of the bipolar d'Arsonval type. (4) The term "diathermy" is synonymous with electrocoagulation. The dissimilarity in nomenclature represents a time factor: the longer the application of current, the more extensive the thermal effect in the tissues. Diathermy, therefore, implies a deeper penetration of heat; consequently its destructive effect is greater.

DIATHERMY

The physical limits of diathermy and its effect upon tissue depend on the amount of current generated and its length of application. Radicalism in its application to vesical carcinoma is not warranted, for extensive necrosis and sloughing lead to fistulous communication with contiguous structures—the vagina, rectum, and peritoneum. The cure, if the patient survives, then becomes worse than the disease.

Corbus used 1 ampere of current per application of electrode in his experimental work and postulated as a time limit of sufficient application a blanching and bubbling up of tissue. In 1925, Cunningham, Graves and Bovie clinically introduced the use of thermocouples in the bladder

wall to control scientifically the thermal effects of diathermy. Heat was recorded from rectum and vagina as an additional means of protection.

Our own technique consists in the setting of the high frequency apparatus so that with each application there is a delivery of 1500 to 2000 milli amperes through a flat disc electrode which measures 1 centimeter in diameter. The amount of time to produce ischemia and bubbling of tissue with the liberation of gases is taken as a criterion of sufficient length of application. This factor will be found to be directly proportional to the size of the electrode employed: the larger the electrode, the longer the period of time to obtain ischemia. A finger in the rectum or vagina is of distinct value in elevating the bladder floor, while epicritic sensation is an additional safeguard against too liberal diathermy.

Current delivered through the active electrode is concentrated in a small area and travels in a perpendicular and radiating direction therefrom. Coagulation is said to occur to a depth approximately equal to the diameter of the electrode, while the immediate peripheral zone is also affected. As the current blends out in the deeper structures coagulation is not produced but the thermal effect is sufficient to interfere with the vitality of cells. Thus there is what can be called an immediate direct and an immediate indirect reaction. Blood and lymphatic vessels are like *wire sealed* which is an additional safeguard against local growth and metastasis.

Corbus summarizes his experimental work with diathermy on dogs as follows:

The immediate effect is a slow cooking through of the underlying tissues, the effect upon the deeper structures being the same as that upon the mucosa. This is followed by an aseptic death of the submucosa and muscular. Round cell infiltron is marked only for the first 3 days. Eventually the entire area is replaced by a dense proliferation of fibrous tissue, the line of demarcation between the treated area and the surrounding normal tissue being definitely preserved.

The ureteral wall may be burned back in the dog almost to the entrance of the intramural portion. The results in 3 dogs under observation for from 3 to 5 months have shown no derangement of function in the ureteral activity or the contractility of the bladder. No obstruction to the ureteral outflow occurred in five months.

It is constantly to be borne in mind that Caulk and Harris showed that this current traveling from the active to the inactive pole followed the channels richest in electrolytes by preference. This means that the urine, the lymph, and the blood channels get the greatest current load and in these channels the coagulating effect has the greatest penetration and depth.

SELECTION OF TREATMENT

Our premises of therapy do not differ materially from those in many other clinics. Nevertheless, we feel that in attempting to achieve a so called cure, selection of treatment should be individualized and should be sufficiently radical to carry a minimal risk of operative mortality and to promise a convalescence free from excess morbidity.

The most radical procedures, such as total cystectomy, transplantation of the ureters and subtotal resection, while theoretically appealing, become less so in clinical application, because, if success is to be attained, cases must be chosen early when the growth is still small and localized (a clinical exception rather than the rule). In making a decision in this period of the growth cycle, a less radical procedure is frequently as effective and one does not always feel justified in subjecting his patient to additional hazards. Bumpus (3), in the discussion of Rathbun's presentation 'Comments on Bladder Carcinoma,' has very wisely remarked: 'If the chances of cure were equal to the risk involved in these major procedures they might be more readily justified, but when the mortality rate incident to the treatment considerably exceeds that of the possibility of cure, it seems as though more conservative measures can be justified in many cases.'

Tumors occupying the vertex of the bladder are amenable to segmental resection, but by far the greater incidence of malignant involvement is found in the base of the bladder where less enterprising measures have to be adopted. If tumors are small and accessible they warrant transurethral cystoscopic destruction, but we feel that tumors of any magnitude with a cystoscopic index of malignancy and invasiveness should be subjected to transvesical excision and diathermy. In extensive vesical carcinoma, if renal function is still maintained as revealed by urography, if urosepsis has not appeared and in the absence of local or distant metastasis, diathermy is especially applicable. Involvement of a ureteral orifice with a resultant functionless kidney is not a contraindication to the use of diathermy.

If tumors small or large are associated with concomitant pathology in the prostate, such as adenomatous hypertrophy or changes in the vesical neck, necessitating operative intervention, cauterization and diathermy of the tumor can be carried out in addition without fear of increasing surgical shock.

CLINICAL RESULTS OF DIATHERMIC TREATMENT

Counseller and Braasch in 1935 reported their results in 17 cases of carcinoma considered non

resectable from the extensive involvement of the base of the bladder. In 5 patients, the ureteral orifices could not be found since they were hidden by the growth or occluded by it. Fourteen patients were treated only with diathermy and 3 had a combination of cautery excision and diathermy. Four cases were graded 4, 5 were graded 3, 4 were graded 2, and 4 were graded 1. Fifteen of these patients, or 88 per cent, lived over 5 years and were free of recurrence. Irradiation or radium was not used as adjuncts in treatment.

Bumpus and Silver analyzed a group of 43 cases treated similarly and deducted that they obtained "approximately a 19 per cent possibility of a 3 to 5 year cure by this method."

The subject of our report is a series of 51 cases treated by transvesical diathermy between November, 1923, and July, 1936. Due to the small number of patients and insufficient time interval of follow-up in a few, they shall be considered under 3 general headings. (1) the dead; (2) the living; (3) the indeterminate.

1. There were 29 deaths in 51 cases, a mortality of 56.8 per cent. Analysis of these confirmed the oft repeated statement that the cause of death in vesical carcinoma is, in most instances, attributable to renal infection and renal failure. There were 27 cases of papillary carcinoma, 1 case of adenocarcinoma, and another case with a large growth classified as a papilloma.

Five of the 29 deaths were classified as operative deaths, a percentage of 9.8 for the entire group of 51 cases. Two of these deaths followed the second transvesical operation for extensive recurrence. The third patient died as a result of poor cardio-renal reserve after combined suprapubic prostatectomy and transvesical diathermy. The fourth and fifth patients lived 9 and 22 days, respectively, after operation, the causative factors of death in each case being marked urogenital sepsis with secondary blood stream invasion.

A sixth patient was known to have died and, despite the fact that no record of survival period or recurrence could be found, was considered in this tabulation.

The 23 remaining cases were grouped into survival periods as follows:

- 5 survived 1 to 6 months
- 11 survived 7 to 12 months
- 3 survived 13 to 18 months
- 4 survived 24, 32, 34 and 44 months, respectively.

There is insufficient follow-up data in 3 of these 23 cases as to whether or not recurrence was present at the time of death, although the period of survival in each is recorded as 8, 32, and 44 months. In the 20 remaining cases, in which the

follow-up data are accurate, recurrence was found in 17 cases and no recurrence in 3.

Further analysis of these 3 cases of non-recurrence disclosed that 1 had had a large basal growth, diagnosed papilloma. This was diathermized transvesically 24 months before a cautery-punch operation of the vesical neck was performed, from which the patient succumbed.

The second patient survived 4 months after operation. No recurrence was found in the bladder, but the chest harbored extensive metastases.

The third patient free of recurrence died 12 months after operation from pneumonia. Just prior to the patient's hospitalization for this fatal illness, cystoscopic examination disclosed the absence of recurrence, and the retraction of the right ureteral orifice into the depths of a scar. This scarring with retraction of the ureteral orifice Corbus mentions in his experimental work. No estimation of right renal function was tabulated.

2. The living group consists of those patients who have been personally contacted and studied in the preparation of this report. They number 14, or 27.4 per cent of the entire group of 51 cases. In each a diagnosis of papillary carcinoma was made. Eleven have been free of recurrences since the original operation, from 4 to 86 months.

The observation periods of these 14 living patients are grouped chronologically as follows:

- 2 patients have been observed 4 to 12 months
- 3 patients have been observed 13 to 24 months
- 2 patients have been observed 25 to 36 months
- 4 patients have been observed 37 to 48 months
- 3 patients have been observed 54, 74 and 86 months

Three patients followed 26, 40, and 44 months, respectively, were found to have had recurrences. Two of these 3 recurrences were not present at our last examination, due to control by cystoscopic fulguration. The third recurrence is extensive and is being treated with roentgen therapy.

3. This group includes a total of 8 patients whom we have been unable to trace either through letters, questionnaires, or the referring physician. There was histological corroboration of papillary carcinoma in each case.

Two patients were lost at the fourth month interval. Cystoscopy revealed at that time that each had an unhealed area covered with slough.

The third patient, age 39 years, examined 15 months after operation, had no recurrence and little scarring despite a large papillary infiltrating carcinoma.

The fourth patient, 72 years of age, with an infiltrating carcinoma, who also had a concomitant suprapubic prostatectomy, had no recurrence 20 months after operation.

wall to control scientifically the thermal effects of diathermy. Heat was recorded from rectum and vagina as an additional means of protection.

Our own technique consists in the setting of the high frequency apparatus so that with each application there is a delivery of 1500 to 2000 milli amperes through a flat disc electrode which measures 1 centimeter in diameter. The amount of time to produce ischemia and bubbling of tissue with the liberation of gases is taken as a criterion of sufficient length of application. This factor will be found to be directly proportional to the size of the electrode employed; the larger the electrode, the longer the period of time to obtain ischemia. A finger in the rectum or vagina is of distinct value in elevating the bladder floor, while epicritic sensation is an additional safeguard against too liberal diathermy.

Current delivered through the active electrode is concentrated in a small area and travels in a perpendicular and radiating direction therefrom. Coagulation is said to occur to a depth approximately equal to the diameter of the electrode, while the immediate peripheral zone is also affected. As the current blends out in the deeper structures coagulation is not produced but the thermal effect is sufficient to interfere with the vitality of cells. Thus there is what can be called an immediate direct and an immediate indirect reaction. Blood and lymphatic vessels are likewise sealed, which is an additional safeguard against local growth and metastasis.

Corbus summarizes his experimental work with diathermy on dogs as follows:

The immediate effect is a slow cooking through of the underlying tissues; the effect upon the deeper structures being the same as that upon the mucosa. This is followed by an aseptic death of the submucosa and muscularis. Round cell infiltration is marked only for the first 3 days. Eventually the entire area is replaced by a dense proliferation of fibrous tissue; the line of demarcation between the treated area and the surrounding normal tissue being definitely preserved.

The ureteral wall may be burned back in the dog almost to the entrance of the intramural portion. The results in 3 dogs under observation for from 3 to 5 months have shown no derangement of function in the ureteral activity or the contractility of the bladder. No obstruction to the ureteral outflow occurred in five months.

It is constantly to be borne in mind that Caulk and Harris showed that this current traveling from the active to the inactive pole followed the channels richest in electrolytes by preference. This means that the urine, the lymph and the blood channels get the greatest current load and in these channels the coagulating effect has the greatest penetration and depth.

SELECTION OF TREATMENT

Our premises of therapy do not differ materially from those in many other clinics. Nevertheless we feel that in attempting to achieve a so called cure, selection of treatment should be individualized and should be sufficiently radical to carry a minimal risk of operative mortality and to promote a convalescence free from excess morbidity.

The most radical procedures, such as total cystectomy, transplantation of the ureters and subtotal resection, while theoretically appealing, become less so in clinical application, because, if success is to be attained, cases must be chosen early when the growth is still small and localized (a clinical exception rather than the rule). In making a decision in this period of the growth cycle, a less radical procedure is frequently as effective, and one does not always feel justified in subjecting his patient to additional hazards. Bumpus (3) in the discussion of Rathbun's presentation, 'Comments on Bladder Carcinoma' has very wisely remarked: 'If the chances of cure were equal to the risk involved in these major procedures, they might be more readily justified, but when the mortality rate incident to the treatment considerably exceeds that of the possibility of cure, it seems as though more conservative measures can be justified in many cases.'

Tumors occupying the vertex of the bladder are amenable to segmental resection, but by far the greater incidence of malignant involvement is found in the base of the bladder where less enterprising measures have to be adopted. If tumors are small and accessible they warrant transurethral cystoscopic destruction, but we feel that tumors of any magnitude with a cystoscopic index of malignancy and invasiveness should be subjected to transvesical excision and diathermy. In extensive vesical carcinoma, if renal function is still maintained as revealed by urography, if urosepsis has not appeared and in the absence of local or distant metastasis diathermy is especially applicable. Involvement of a ureteral orifice with a resultant functionless kidney is not a contra-indication to the use of diathermy.

If tumors small or large are associated with concomitant pathology in the prostate, such as adenomatous hypertrophy or changes in the vesical neck necessitating operative intervention, cauterization and diathermy of the tumor can be carried out in addition without fear of increasing surgical shock.

CLINICAL RESULTS OF DIATHERMIC TREATMENT

Counseller and Braasch in 1935 reported their results in 17 cases of carcinoma considered non

used routinely and no definite conclusions can be drawn. In isolated instances remarkable results have been achieved, while in others, no improvement was noted. Only in its routine use can a fair appraisal be given.

We urge rather than condemn surgery combined with one of the forms of irradiation. Andrews and Uhle, in a series of unselected cases of vesical carcinoma, showed that the 5 year survival period in the group treated by combined surgery and irradiation was 22 per cent compared to 7 per cent for the group managed by surgery only.

In 10 of the 51 patients constituting this report, who were followed from 40 to 86 months, 6 were treated with combined diathermy and deep roentgen irradiation. Three of these 6 patients had recurrent growths. Of the 10 patients, 4 were managed only by transvesical diathermy. One of these 4 had a recurrence of the tumor.

COMPLICATIONS OF DIATHERMY

Clinically, Counseller and Braasch have observed that none of their 17 cases had pyelonephritis secondary to diathermy despite the fact that the ureteral ostium in some of their cases was included in the electrocoagulation. They state "Complete healing occurred in every instance, leaving a clean scar with the ureteral orifice occupying a depression in the scar."

We have likewise had occasion to observe the clean scar and lack of vesical deformity left by diathermy. In some instances in which diathermy was applied in a limited small area, the scar was almost lost to view. Nevertheless, acute pyelonephritis has been a troublesome complication in a few of our cases and to avoid this a ureteral catheter is now introduced at the conclusion of the operation if the ureteral orifice or its immediate neighborhood has been diathermized.

Bumpus and Silver state: "In the transvesical series a ureteral orifice was included 29 times in the cautery destruction, and in 10 it was considered a decided factor in an unsatisfactory convalescence if not a direct cause of the patient's death."

Chronic pyelonephritis must be taken into consideration, too, for in two exemplary cases this complication has occurred secondary to ureteral orifice contracture. One patient has a recurring pyonephrosis which spontaneously empties itself into the bladder. Nephrectomy is anticipated. The second patient had an extensive papillary carcinoma of the retrotrigonal region treated with excision and diathermy. Death followed 8 months after operation. At autopsy, the bladder and its environs were grossly free of tumor, but micro-

scopic examination revealed small nests of tumor cells in the depths of the scar tissue which was minimal considering the extensive application of diathermy. Both ureteral orifices were stenosed with resultant bilateral hydrophyonephrosis. The primary cause of death was a ruptured gangrenous gall bladder and peritonitis. We, therefore, suggest to incorporate in the follow-up treatment the dilatation of one or both ureters at periodic intervals after the immediate convalescence, in an attempt to maintain adequate renal drainage and reduce the incidence of morbidity.

Only one patient developed a fistulous communication after diathermy. A vesicovaginal fistula complicated an extensive grade 3 infiltrating basal growth 5 weeks after operation. This patient survived 9 months. The cause of death was attributable to recurrence of the growth, urosepsis, and uremia.

The immediate effect of diathermy is an aseptic necrosis. If infection supervenes, various gradations of severity from the simple to the more virulent with pelvic cellulitis, phlebitis, septicemia, and death can occur.

Later in the convalescence (1 to 4 months) sloughs denuded from the operative area may lead to dysuria and even retention of urine requiring catheterization. These pieces of tissue, in our experience, have always been spontaneously voided and have never been associated with troublesome bleeding.

Shivers has recently observed ureteral reflux as a late result of diathermy.

SUMMARY AND CONCLUSIONS

- 1 The therapy of vesical carcinoma should be selective. Transvesical diathermy is of value in the treatment of lesions involving only the basal regions of the bladder and those not amenable to bladder resection or to transurethral management. The indications and technique of diathermy have been discussed.

- 2 The safety of transvesical diathermy is shown by an operative mortality of 9.8 per cent.

- 3 The three most important complications of diathermy are the establishment of fistulous communication between bladder and rectum or vagina, acute pyelonephritis, and chronic pyelonephritis. Fistulas can be prevented by curbing the overzealous application of the high frequency current. There was only one fistula (vesicovaginal) in our series. The incidence of acute pyelonephritis can be reduced by the introduction of a ureteral catheter for drainage at the conclusion of the operation if diathermy has been applied directly over, or in close proximity to, the ureteral

The fifth patient, with a large ulcerating carcinoma was free of recurrence 22 months after operation. At this time, malignancy was discovered in his throat.

The sixth patient was free of recurrence for 32 months, when multiple papillomas appeared. These were periodically fulgurated over a period of 23 months. The patient was lost from the follow up service after a total observation of 55 months.

The seventh patient had had a mid trigonal lesion diathermized. A small papiloma was discovered 74 months later in the center of the scar. Following fulguration the patient never returned.

The eighth patient had a pedunculated carcinoma filling half the bladder cavity. Cystoscopy at an interval of 75 months disclosed no recurrence.

SUMMARY OF GROUPS 1, 2, AND 3

There were 20 deaths in 51 cases, a general mortality of 56.8 per cent. Five, 9.8 per cent were considered operative deaths. From the available statistics of 23 deaths, their survival period ranged from 1 to 44 months. Three patients lived 8, 32, and 44 months but no information could be obtained of the presence or absence of recurrence. 17 patients had recurrences at the time of death, 1 to 34 months after operation, while three patients were free of recurrence 4, 12, and 24 months, after operation.

Fourteen, or 27.4 per cent, of 51 patients were alive at the time of this study. Eleven were free of recurrence with follow up periods of 4 to 80 months, 3 had had recurrence and had been followed 26, 40, and 44 months.

Eight cases classified as indeterminate were considered separately because the final disposition of the cases was not known (5 were lost at short intervals of time). Three patients had had lengthy follow up periods of 55, 74, and 75 months, with recurrence detected in 2.

There were 24, or 47 per cent of the entire group of patients who gained vesical cure and comfort from the operative procedure. 'Cure' refers to those patients, 18 in number (35.3 per cent of 51 cases), who demonstrated no signs of local recurrence irrespective of the time limit of observation. Comfort implies the absence of distressing vesical symptoms and refers to the status of 6 of our patients who had small recurrences satisfactorily controlled by cystoscopic fulguration.

TECHNIQUE OF TRANSVESICAL DIATHERMY

The bladder is opened through the customary suprapubic extraperitoneal approach. Adequate

exposure of the region harboring the growth is imperative, for only in the adoption of this surgical principle can satisfactory electrosurgical work be accomplished.

Whenever possible the cautery loop electrode should be employed first to cut away the tumor including a 1 centimeter 'collar' of healthy tissue. The depth of severance extends to the muscular layers, care being taken not to penetrate the bladder wall. If there is any apprehension, extra peritoneal drainage should be used. In the basal regions, deep excision may lead to fistulous communication while diathermy *per se*, if applied too long, may establish false passages. The ureteral orifice, and a portion of the trigone and the vesical sphincter can, in our experience with comparative safety to the patient, be excised if infiltrated with neoplasm.

Pilcher and Cabot have drawn attention to total resection of the vesical neck combined with subtotal removal of the trigone in the female with resultant normal bladder function and normal control of urination.

Following cautery excision, the flat disc electrode is very lightly applied to the denuded area and an additional 1 centimeter of peripheral healthy tissue, until the blanching of cooking tissue and muscular contractions indicate an adequate diathermic exposure. Between 1200 and 1500 milliamperes are delivered per application. At each application the electrode is lifted the moment that bubbling appears around its periphery and it is to be accentuated that only the light contact with the tissue is to be applied and all actual sparking is to be avoided. Charring of tissue to a peculiar dirty green color commonly occurs in the area previously excised. In some instances, operators prefer the use of diathermy alone to control small or extensive growths.

At the conclusion of the operation, the bladder is carefully inspected for hemorrhage which, in our experience, has been negligible. If the ureteral orifice, or its immediate periphery, has been diathermized a ureteral catheter is introduced the end of which is brought out through the suprapubic wound and attached to a tube leading to a separate drainage bottle.

The bladder is closed about a large mushroom catheter which is not removed for a period of 2 to 4 weeks, depending upon the extensiveness of the cautery excision and diathermy. Too early removal leads to dysuria, tenesmus and bleeding.

DIATHERMY AND IRRADIATION

In this series of 51 patients, deep roentgen therapy, radium radon, or a combination was not

SOME SCANDINAVIAN CLINICS

THE Society of Clinical Surgery which makes a trip to foreign surgical clinics every five years or so, went to Scandinavia during the summer of 1937. These countries were chosen partly on account of a belated recognition of the fine scientific work which has been carried on there for many years, partly on account of the desire to see the workings of the "Middle Way," partly on account of their freedom from the threat of war, and partly, it is necessary to confess, on account of their scenic attractions. The choice proved a happy one, combining profitable professional experience with the delight of beautiful scenery.

The scientific contacts between the Scandinavian countries and our own have been rather remote until recent years. These nations traditionally looked to Germany and the British Isles in medicine as they did in commerce. Recently awards of the Nobel prize in medicine across the Atlantic have provided evidence of the attention that medi-

cal progress in this continent has been gaining there. While on our part, the work of men like Krogh in physiology, Svedberg in chemistry, and the clinical investigation in centers like the Radiumhemmet and the Finsen Institute have impressed us with the caliber of the medical sciences in Scandinavia.

In surgery this community of interest has been shown by the appearance of several of the outstanding Scandinavian surgeons such as Einar Key, Gunnar Nystrom, and Knut Giertz, as the principal guest speakers before the American Surgical Association and other important surgical meetings. Scandinavian contributions to the progress of surgery have been outstanding in many fields, particularly in the operative treatment of tuberculosis, in embolectomy, in traumatic surgery of bone, and in the practical development of radiation therapy. The recent untimely death of Professor Christian Jacobæus recalled the many contributions of this great internist in the field of pulmonary disease, including his pioneer work in devising a method of dividing intrathoracic adhesions.

Outstanding centers of surgical interest are the clinics in the three capitals, Stockholm, Copenhagen, and Oslo, the University Clinic at Uppsala and that of the Sahlgrenska Sjukhus in Göteborg. Nearly all of the hospitals are of the pavilion type in extensive grounds made beautiful in the summer time by a profusion of luxuriantly blooming flowers. However, some of the most recent additions, such as the new Pathological building at the Sabbatsberg Sjukhus, are excellent examples of the modernistic style that one sees extensively in the attractive co-operative apartment buildings. The hospital wards were neat but usually plain while the operating rooms were uniformly well

orifice Stenosis of the ureteral orifice secondary to healing fibrosis is a later manifestation of the effects produced by surgical diathermy Renal morbidity (chronic pyelonephritis) can be lessened by periodic ureteral dilatation during the period of the patient's follow up

4 Diathermy produces an aseptic necrosis If infection supervenes the progression of pathological events ranges from the simple to the fulminating type with pelvic cellulitis, pelvic phlebitis, and death

5 Cicatricial reaction following diathermy does not produce marked vesical deformity In spite of extensive diathermy, scarring is often minimal and in 47 per cent of patients vesical comfort and silence can be acquired

6 There was a general mortality of 56.8 per cent Death was ascribed in this group to recurrence of the growth with secondary renal infection and uremia Other contributory factors were distant metastases, unhealed suprapubic sinuses and septicemia Cordotomy was performed in 1 case for relief of intractable pain

7 No evidence of recurrence irrespective of the time limit of follow up, was found in 35.3 per cent Recurrent growths developed in 43.1 per cent

8 Routine cystoscopy, after operation, is of great importance in detecting early, or late recurrences In 1 instance a papillary recurrence was found 74 months after the original operation Cystoscopic fulguration is sufficient to effect control

9 The importance of an efficient follow up service cannot be overemphasized Ten patients, 19.6 per cent, were followed from 40 to 86 months Four had recurrences and 6 were free of recurrence

10 We have been unable to substantiate the figures of Counsellor and Braasch (88 per cent living over 5 years and free of recurrence) but feel that the results of diathermy in the treatment

of carcinoma of the bladder are significant and should foster a wider clinical interest in this method of treatment

Swedish people to constituted authority and in the relative stability and official recording of the place of residence of the people. And in the third place, governmental socialization assists, by making it possible to transport indigent patients from any distance to the clinic without cost to themselves.

The outstanding surgical feature in Oslo was the demonstration by Professor Holst of his method of extrapleural apicolysis combined with thoracoplasty for the obliteration of tuberculous cavities in the upper lobe. In Bergen we had visible evidence of a splendid medical victory: large institutions built for the care of hundreds of lepers today only have one or two remaining patients.

One of the most interesting features of the Scandinavian visit was the opportunity to see the impact of a plan for national socialization upon the practice of medicine. Probably no two members of the group came away with just the same impressions concerning this. But the following general conclusions seem valid. An excellent grade of surgery in general obtains today in the best Scandinavian clinics, and the medical profession occupies a position of high esteem in the community. However, there are some difficulties in medical practice already apparent that may be inherent in this type of organization or may only require certain adjustments. Most of the doctors must either seek and obtain hospital positions (on state or municipal salaries) or must support themselves by the care of a regulated number of state insurance cases at approximately \$2 25 per person a year, as the amount of private practice is almost negligible (except for a very few specialists). In either of these cases, this results in a very small cash income for the greater part of the doctor's professional life. Although with the aid of co-operative buying and the provision of quarters and food by many hospital positions, his income is usually ade-

quate for a fairly comfortable livelihood, it rarely allows for such important educational elements as visiting foreign clinics or other "brain dusting" opportunities. Another difficulty in working such a plan appears in the following situation. A separate group of physicians has had to be appointed for emergency night calls as it has become practically impossible to get a doctor after six p m for one of his state insurance cases. It was even difficult to obtain a narcotic prescription as an emergency in the evening for one of the doctors in our party. Thus the concerted action of the profession in attempting to overcome one unfortunate effect of the system has resulted in a lowering of the quality of the service rendered in another direction to the public.

There is one suggestion which should be made to those planning a trip to the Scandinavian countries including the visiting of its hospitals and clinics. Due to the many months of short days, everyone there takes the maximum possible advantage of the luxuriant summer season. Consequently, for the months of July and August the work in medical institutions is on a very restricted vacation schedule. Thus if one wishes to combine a scenic summer vacation with an opportunity of seeing Scandinavian surgery, the trip should be planned to visit the Scandinavian clinics either in the latter part of June or the early part of September.

W J MERLE SCOTT.

ETHER ANESTHESIA

ETHER anesthesia induced by the open drop method is still the best method of general anesthesia in the hands of the average person. Not infrequently it should be resorted to even by expert anesthetists when the results which they are attempting to obtain by some other method of anesthesia are unsatisfactory both from the standpoint of

equipped with excellent rustless steel instruments. Interesting clinical programs given by the speakers in English, were arranged most courteously for the Society by all of the chief surgeons of the clinics visited. In Sweden's western seaport city, Goteborg, Dr. Johansson gave an impressive demonstration of his method of treating medial fractures of the femoral neck by extra articular osteosynthesis. We were interested to see that the Finsen-institute in Copenhagen had become also a radium center where the treatment of carcinoma was receiving almost as much attention as all forms of surgical tuberculosis. The Institute represents the perpetuation, under modern conditions and with government support, of the work of a universally beloved pioneer. Finsen's achievement in establishing this Institute is all the more remarkable as he was seriously ill at the time, dying, in 1904, of pericarditis. Lupus, extremely prevalent when he did the initial work with ultra violet treatment, has now become relatively uncommon even in Denmark and ultra violet radiation no longer plays the outstanding rôle that it once did in the Institute's therapeutic program. Patients with surgical tuberculosis are still given carbon arc light baths for an hour daily for its general effect. But with the diminution in surgical tuberculosis, the Institute has enlarged its program and the treatment of all types of neoplasm is carried out.

Many interesting clinical investigations were described to us in the various clinics. Dr. Chiewitz reported the removal of a parathyroid tumor which was found in the mother because its presence had resulted in tetany in her nursing baby. Dr. Crafoord described the use of a purified heparin as an anti coagulant, given intravenously to the donor before with drawing blood for transfusion. In Dr. Berglund's medical clinic there was given an excellent demonstration of the newer methods of

studying the stomach and pancreas including gastroscopy and the response to secretion. Perhaps the most interesting innovation in diagnostic study was the method worked out by the late Professor Jacobæus with Drs. Björkman and Frenckner. This procedure called bronchospirrometry determines the respiratory function of each lung separately. It is already yielding data of great value both scientifically and also clinically in directing therapeutic measures. Thus it has been found that the functional capacity and roentgenographic appearance of the diseased lung may be significantly at variance.

The Radiumhemmet in Stockholm is probably the most famous center in the world for the irradiation of malignant disease. Like the Finsen-institute, it is a living memorial to the vision, energy, and devotion of its founders, in this case two men, one dead and one still living, Dr. Berg and Dr. Forssell. There are many fine features of the splendid work being done there, the organization of the clinics, the skill in devising apparatus and in measuring physical effects, the impartiality in judging between all alternative methods of treatment, the quantity of radium available (about 10 grams in all, of which 5 grams are in ore bomb) and the persistence with which even apparently insurmountable obstacles are attacked. But the most impressive feature of the clinic was the remarkable following of cases. Less than 10 per cent of all their thousands of cases are lost track of. And in some series including over 500 patients, the result in every case treated is known to date. This remarkable record is to be credited to several factors. In the first place the energy and devotion of the doctors following individual groups and the efficiency of the follow up system used are important. In the second place, there are significant sociological factors in the respect and obedience of the

Swedish people to constituted authority and in the relative stability and official recording of the place of residence of the people. And in the third place, governmental socialization assists, by making it possible to transport indigent patients from any distance to the clinic without cost to themselves.

The outstanding surgical feature in Oslo was the demonstration by Professor Holst of his method of extrapleural apicolysis combined with thoracoplasty for the obliteration of tuberculous cavities in the upper lobe. In Bergen we had visible evidence of a splendid medical victory: large institutions built for the care of hundreds of lepers today only have one or two remaining patients.

One of the most interesting features of the Scandinavian visit was the opportunity to see the impact of a plan for national socialization upon the practice of medicine. Probably no two members of the group came away with just the same impressions concerning this. But the following general conclusions seem valid. An excellent grade of surgery in general obtains today in the best Scandinavian clinics, and the medical profession occupies a position of high esteem in the community. However, there are some difficulties in medical practice already apparent that may be inherent in this type of organization or may only require certain adjustments. Most of the doctors must either seek and obtain hospital positions (on state or municipal salaries) or must support themselves by the care of a regulated number of state insurance cases at approximately \$2 25 per person a year, as the amount of private practice is almost negligible (except for a very few specialists). In either of these cases, this results in a very small cash income for the greater part of the doctor's professional life. Although with the aid of co-operative buying and the provision of quarters and food by many hospital positions, his income is usually ade-

quate for a fairly comfortable livelihood, it rarely allows for such important educational elements as visiting foreign clinics or other "brain dusting" opportunities. Another difficulty in working such a plan appears in the following situation: A separate group of physicians has had to be appointed for emergency night calls as it has become practically impossible to get a doctor after six p. m. for one of his state insurance cases. It was even difficult to obtain a narcotic prescription as an emergency in the evening for one of the doctors in our party. Thus the concerted action of the profession in attempting to overcome one unfortunate effect of the system has resulted in a lowering of the quality of the service rendered in another direction to the public.

There is one suggestion which should be made to those planning a trip to the Scandinavian countries including the visiting of its hospitals and clinics. Due to the many months of short days, everyone there takes the maximum possible advantage of the luxuriant summer season. Consequently, for the months of July and August the work in medical institutions is on a very restricted vacation schedule. Thus if one wishes to combine a scenic summer vacation with an opportunity of seeing Scandinavian surgery, the trip should be planned to visit the Scandinavian clinics either in the latter part of June or the early part of September.

W. J. MERLE SCOTT.

ETHER ANESTHESIA

ETHER anesthesia induced by the open drop method is still the best method of general anesthesia in the hands of the average person. Not infrequently it should be resorted to even by expert anesthetists when the results which they are attempting to obtain by some other method of anesthesia are unsatisfactory both from the standpoint of

relaxation and from that of quiet respiration. This is especially true when less potent agents than ether are being used and when a more complicated method of administration is being persisted in after the entire surgical team realizes that satisfactory anesthesia has not been accomplished.

It will also be found in a certain number of cases in which anesthesia using a gas machine does not produce relaxation and quiet breathing that this can be accomplished by administering ether by the open drop method. In many instances even fifteen to thirty minutes of anesthesia with ether by the open drop method will permit further maintenance of anesthesia with a gas.

There has been a tendency in the last few years to advocate the use, almost routinely in many cases, of new agents and methods which are incapable of producing entirely satisfactory anesthesia in all cases. As a side result of this, some anesthetists who have received their training in the last few years have not had an opportunity to become skilled in the administration of ether by the open drop method. This is without doubt a mistake that will sooner or later have to be rectified, and it seems timely now to advocate that all anesthetists, of whatever degree of skill, keep themselves well trained in the use of ether by

the open drop method. They should in turn insist that their students and all others who come under their influence also become proficient in the administration of ether.

Anesthetists should not feel chagrined in going from other methods to drop ether anesthesia if conditions are unsatisfactory and if the patient's physical condition permits. On the other hand, they should feel that they have exhibited good judgment in adapting the anesthetic to the patient rather than the patient to the anesthetic, and in thereby providing the surgeon with conditions under which he may have the best opportunity to produce maximal surgical results.

This must not be interpreted to mean, however, that administering ether by the open drop method does not have its disadvantages and that there are not numberless cases when other methods are to be preferred and when they are entirely satisfactory. For that small percentage of cases in which difficulties do arise, however, they can be eliminated by the use of ether by the open drop method. In such cases, therefore, and in the hands of the average person, anesthesia by the open drop method is a satisfactory method. Let the anesthetist turn to this method and not avoid it as one that he should be ashamed of.

JOHN S. LLOYD

AUGUST F. JONAS
1858-1934

MASTER SURGEONS OF AMERICA

AUGUST FREDERICK JONAS

ON June 12, 1858, August Frederick Jonas was born of German parentage in Columbia county, Wisconsin. His parents came to Wisconsin from Germany in the thirties of the last century, while they were still in their teens. In his infancy, the parents moved to Madison and there August Frederick was reared and educated.

As a boy in his middle teens he worked in a drug store in St. Ansgar, Iowa, and there among the mysteries of a pharmacy of pioneer days was born the desire and determination to study medicine. Guided by the idea that eclecticism meant something in advance of other systems of medical education and practice, he entered Bennett Medical College, Chicago, attended two courses of lectures and was graduated therefrom in the spring of 1877, at the age of 19 years. His first practice was at Sauk City, Wisconsin. Sauk City was settled by Germans who left Germany following the student revolution of 1848 and 1849 and their cultural influence was an inspiration to Dr. Jonas and he always felt that his five years at Sauk City profoundly influenced his subsequent life.

Medical education in the seventies was for the most part wholly unregulated by law and the prevailing system consisted of three years of study under a preceptor, including attendance at two courses of lectures at a medical college, before coming up for graduation. Becoming dissatisfied with his medical training, feeling that he had failed to get the best and most up-to-date in the medicine of that day, he went to Berlin, Vienna, and Paris for postgraduate study and to Munich in 1882, where he spent 2 years in Ludwig-Maximilian University and was graduated therefrom, *Magna cum Laude* in 1884.

Returning to Wisconsin in the fall of 1884 he located at Madison and remained there 2½ years. He desired a larger field and believed the size and importance of Madison would not satisfy his ambition to develop a worthwhile surgical practice, so he decided to take Horace Greeley's advice, "Go west."

In the spring of 1887 he located in Omaha, then as now, a growing city of much promise in the rapidly developing Middle West. Subsequent events proved his judgment sound, for here he was to carve a career the memory of which shall long endure. Here he married Dr. Metha Helfritz of St. Ansgar, Iowa, to whom, as a youth, he had revealed his ambition to study medicine and from her he received inspiration and encouragement to pursue that course. After marriage she practiced with him during the 6 years preceding her death.

Dr Jonas was one of the first to bring the message of antiseptic and aseptic surgery to Omaha. He early became interested in the then struggling Omaha Medical College, the immediate predecessor of the present Nebraska University College of Medicine and in 1892 he was made professor of clinical surgery. His active connection with the medical school as a teacher of surgery under various titles continued for 34 years. He was dean from 1898 to 1902. On retiring from the active work of the school in 1928 he was made professor emeritus and the same year the Nebraska University conferred upon him the honorary degree of LL.D.

Dr Jonas' work as a pioneer surgeon and teacher exerted a profound influence on Nebraskan and mid western surgery. As a surgeon he was conservative. As an operator speed and certainty were his gifts.

Additional hospital facilities were greatly needed in Omaha during the early residence of Dr Jonas. The matter was brought to a crisis (in 1891) when Dr Jonas made a proposition to the Methodist Church, then contemplating a new hospital, to give one half of his fortune at that time, if the Church would match it. The hospital was built. His contribution was said to have been thirty thousand dollars and his later contribution to the Methodist Hospital during his lifetime largely exceeded that amount. On opening of the hospital Dr Jonas was made chief surgeon for life.

In 1898 Dr Jonas was appointed chief surgeon of the Union Pacific railroad and held the position for 27 years until failing health caused him to resign. He almost wholly reorganized the medical department of the Union Pacific and its system of case records. "His work in this position has been outstanding as an administrator and as a surgeon with the result that the medical department under his jurisdiction is one of the best in the country." So wrote President Carl R. Gray.

Dr Jonas always took an active interest in medical organization and rarely missed a meeting. He appeared frequently on the programs and rarely missed an opportunity to take part in the discussion of surgical subjects and his contributions were always worthwhile. The Missouri Valley Medical Society, organized in 1888, was for many years the foremost medical society in all that territory tributary to the Missouri valley. Dr Jonas was a charter member and its president in 1894. He served the Western Surgical Association as president and at sometime was vice president of the American Surgical Association. In the early nineteen hundreds he was vice president of the American Medical Association and sometime chairman of the surgical section of the same body. He was a member of the Pan American Medical Association and attended the meeting held in Mexico City.

In 1905-1906 Dr Jonas was president of the Nebraska State Medical Association. He was one of the organizers of the present Omaha Douglas County Med

ical society and one of its early presidents. He was one of the organizers of the American College of Surgeons and always stood high in the councils of that organization. He was a member of the Société Internationale de Chirurgie.

During the World War, the Governor of Nebraska appointed Dr. Jonas special medical adviser to the governor with the rank of Captain. He was instrumental in the organization of Base Hospital No. 49 and in the organization of an Ambulance Corps from Nebraska.

Dr. Jonas was a tireless worker in his chosen field and for many years carried what amounted to a double load, a large private surgical practice and the chief surgeons'hip of a great railroad system, as well as instructor in surgery at the University Hospital.

He was generally considered one of the ablest surgeons of the Middle West and was well known as a surgeon all over this country and in Europe. He was a frequent contributor to medical literature. Collections of his reprints are to be found in several of the larger libraries. He wrote a chapter for Binnie's *Surgery*.

Of the opinion that a doctor should have interest aside from his profession as a relaxation, Dr. Jonas early became interested in mineralogy and geology and made a collection of minerals which ranks among the finest in the state.

In 1907 after a visit to Egypt, he became deeply interested in archeology and began to make a collection of Egyptian antiquities which contains many articles of historic interest and value. This collection has been presented by the family to the Joslyn Memorial in memory of Dr. Jonas. It will occupy a small room there.

Dr. Jonas spoke and read German and French with ease. He was a man of simple tastes and had high ideals of life. "Small talk" was not for him. He was a man of affairs and supported every movement looking to the growth and improvement of Omaha.

In 1907 Dr. Jonas and Miss Jessica Stebbins were married in Denver and the latter survives. To this union were born a daughter, recently married to Dr. Harold Gifford, Jr., son of the late prominent ophthalmologist, and two sons: one Dr. August Frederick Jonas, Jr., at present on the staff of the Johns Hopkins Hospital.

Dr. Jonas suffered a cerebral hemorrhage in 1927 resulting in an aphasia, from the effects of which he never fully recovered. He uncomplainingly accepted a life of impaired usefulness and invalidism. His greatness was most definitely expressed by the splendid way he met this challenge. He died November 1934, from a cerebral hemorrhage suffered two days before. F. A. LONG.

EARLY AMERICAN MEDICAL SCHOOLS

HISTORICAL SKETCH OF THE JEFFERSON MEDICAL COLLEGE

DAVID M. DAVIS, M.D., Philadelphia, Pennsylvania

In 1827 the entrance requirements of the first American medical school were established as a degree from a collegiate institution or evidence of enough knowledge of Latin, mathematics and natural and experimental philosophy as might be judged requisite to a medical education, and a general knowledge of pharmacy. In addition there must have been a sufficient apprenticeship to some reputable practitioner. This indicates that at the time medical education began in America medicine was seriously regarded as a learned profession. Owing to a lack of other resources it was necessary to finance these schools by means of the fees paid by the students and as enrollments grew the teaching of medicine became not only a source of honor and renown but a very lucrative occupation as well. Talented and ambitious young men were eager to take part in it and when existing schools afforded insufficient opportunities new schools were projected.

The Jefferson Medical College arose from such a project in which a remarkable young man of 29 years named George McClellan was the leading spirit. Opposed by the University already old and proud the project could not be consummated until the trustees of Jefferson College in Canonsburg, Pennsylvania had been persuaded to lend it their protection and the authority of their charter. The school opened in 1825 and was an immediate success. To McClellan belongs the credit for inventing clinical teaching and from the beginning he maintained a small dispensary—at first in a room which also served as the Dean's office—where students could observe clinical material. This room was in a reconstructed theater but in 1828 a new building for the faculty was erected by one of the trustees at Tenth and Sansom Streets where the school has remained ever since. In 1838 a separate charter was obtained and the association with Jefferson College ended.

McClellan the son of one famous soldier and the father of another was a brilliant surgical genius and

splendid teacher and a man of great energy. When representations had to be made to the Legislature he went to Harrisburg himself driving his own chaise and wearing out several horses on the journey. His able colleagues on the original faculty were John

Dr. George McClellan, Founder of the Jefferson Medical College (from a daguerrotype)

Eberle, B. Rush, Rhees, Jacob Green, Nathan R. Smith and Francis S. Beattie. His positive, emphatic and enthusiastic qualities were undoubtedly accompanied by a good deal of impatience and arrogance as in spite of theuster he lent to the school there was constant dissension in the faculty, with frequent changes. In 1831 the trustees took matters in their hands and reorganized the faculty. McClellan refused to join in the reorganization and left to found another school which drew to it a good many Jefferson students at first but finally vanished from the scene. The 1831 faculty consisted of Muetter, Pancoast, Dunglison, Huston, J. K. Mitchell, Meigs and Bache. That McClellan was a stormy petrel is further evidenced by the fact that with his departure dissension was replaced by co-operation the school prospered might

ily and no further changes occurred until 1836, when death intervened. As the famous and successful professors retired or died they were replaced by others equally competent so that the school enjoyed an uninterrupted growth in prestige and authority for more than half a century and had a reputation second to none in the world. McClellan's principles of clinical teaching and constant actual contact between student and patient were followed from the beginning and had much to do with this success. The 1828 building contained a small dispensary in which operations were all performed and in 1844 two rooms over a shop adjoining the school were rented for the reception and care of patients after they had been operated on in the clinic. These primitive hospital facilities were enlarged until they included two entire floors and their value proved to be such that in 1877 they were replaced

The first building occupied by the Jefferson Medical College in Philadelphia, 1828

The Jefferson Medical College, as it appeared in 1846

by a commodious hospital building, which was the property of the medical school and created entirely as an adjunct to the teaching of medicine. Group teaching in the dispensary was utilized at first, but as the first class numbered 109 it had to be supplemented by the clinic, in which the patient was brought to the amphitheater and exhibited to large numbers of students. At an early date, clinics were also given at the Pennsylvania and the Philadelphia Hospitals.

Jefferson's renown through this long period can be expressed in the renown of the members of its faculty. In medicine there were Robley Dunglison, J. K. Mitchell, Roberts Bartholow, and Jacob M. DaCosta. In surgery, Thomas Muetter, Joseph Pancoast, Samuel D. Gross, Samuel W. Gross, John H. Brinton, and William W. Keen. In obstetrics, Charles D. Meigs and Theophilus Parvin. Muetter collected his famous museum, now the property of the College of Physicians of Philadelphia. The incomparable Gross organized the American Surgical Association and the Philadelphia Academy of Surgery. Meigs was a prolific author, highly respected and liked in Philadelphia, but at present better known to the world at large for his luckless polemic with Oliver Wendell Holmes concerning the contagiousness of puerperal fever.

The success of the school and its constantly growing student body eliminated financial difficulties for a long time and helped to attract the eminent men who joined the faculty. On the other hand, there was a huge and growing demand for medical education, new medical schools were arising everywhere, and medical education was gradually descending toward the chaotic period of 1870-1890, when cupidity reigned and proprietary abuses were at their peak. Jefferson could not escape the effects of this trend. At the beginning, in 1825, 1 year of apprenticeship and 2 years of lectures had been required. This shows that there was already much recession from the scholarly requirements of 1767, but in 1857 there was a further relaxation to 2 years of apprenticeship and 1 year of lectures, and nothing was said in the catalog about the character of the apprenticeship. The period of lectures in each year covered only 6 months. The faculty conscientiously strove against this tendency, but economic considerations forbade them to increase the requirement for grad-

uation. Instead they established a supplementary course of lectures covering 4 additional months each year and given without extra fee. All students were urged to attend it, but it was not compulsory. In addition, a student might attend a third year of lectures without charge. In other words, a good medical education was provided for those with the will to take it, but the others could still obtain a diploma after 6 months' attendance at lectures. It must be remembered that similar conditions prevailed in all other medical schools. Jefferson led in efforts to correct this lamentable state of affairs, as in 1872, long before any general campaign for improvement had begun, students were urged in the catalog to take their entire 3 years in Jefferson and to make their studies progressive. In 1879 the regulations of the newly formed Confederation of American Medical Colleges were adopted, and 2 years in medical school again required. In 1890, simple entrance requirements were initiated, and 3 years in medical school made compulsory. Since then the elevation of standards has continued steadily, along with those of other schools, and for many years they have been second to none.

The progress of medicine was closely followed. Before 1835 a museum of normal and morbid anatomy had been begun and in 1878 a separate pathological museum was added. In 1879, a new laboratory building was opened, the finest in the country at that time. In 1886, practical instruction in obstetrics, laryngoscopy, and ophthalmoscopy was instituted. In 1895, Jefferson pioneered with a required 4 year course. In 1896, X-ray equipment was installed and with the aid of the alumni the laboratory building was enlarged and re-equipped. This rising tide of necessities made huge demands on the financial resources of the institution, and it became more and more difficult to obtain contributions from the state or from individuals in view of the custom of dividing the surplus each year among the professors. The practice, in vogue everywhere at the time, began to be vigorously attacked from within the faculty, and in 1895 it was formally abandoned, to the satisfaction of everyone concerned.

In the last years of the Nineteenth Century and the first of the Twentieth, the stature of the school is indicated by the illustrious names connected with

it, such as Hobart Amory Hare and Thomas McCrean in medicine, J. Chalmers Da Costa and Gibbon in surgery, Solis-Cohen in laryngology, deSchweinitz in ophthalmology, Stelwagon in dermatology, Dercum in neurology, and Jackson in bronchoscopy. The Medical School building was greatly enlarged in 1909, and in the same year a new hospital of 300 beds was opened. In recent years three fine modern structures have been added—a new medical school, a fourteen story addition to the hospital, and the

Curtis out patient clinic. There are also separate buildings for the departments of anatomy and of diseases of the chest.

The Jefferson of today clings to tradition in that its methods of instruction have undergone less radical changes than those of many other institutions. It is proud of its successful career in the absence of any university connection. It is strong in the belief that it will continue to have, as in the past, such success as is deserved by the men who compose its staff.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

IT IS certain that nearly every one who is interested in pulmonary tuberculosis or thoracic surgery already owns Alexander's *Collapse Therapy of Pulmonary Tuberculosis*¹ and is already aware of its excellence. Most have known that it was being prepared and have awaited its publication with curiosity and impatience—curiosity not as to its value (that was taken for granted) but as to its exposition of the present practice of the author and his evaluation of the practice of others.

A review, therefore, cannot be of value in describing and recommending it but does afford an opportunity of paying a tribute to its author and of analyzing his important position in the development of collapse therapy in pulmonary tuberculosis.

As one examines the history of the dissemination of medical ideas he is impressed with the reality of the barrier between nations and the necessity that in each country each new thing has its protagonist and popularizer. All of the measures of collapse of the lungs were developed in Europe and, with the single exception of artificial pneumothorax, had been in use there for many years before they were adopted in this country. Even pneumothorax, which was used here by Murphy and Lemke in 1898 and 1899, was soon abandoned and had to be reimported from Germany as late as 1912.

The surgical measures were only beginning to be used in America when, in 1925, Alexander's first book, *The Surgery of Pulmonary Tuberculosis* made its appearance. This afforded a necessary stimulus and immediately established its author as the leader of the advocates of this form of treatment—a position which he has since maintained. Besides contributing to the evolution of the procedures, he has made his department at the University of Michigan a proving ground for the new ideas of others. While many American surgeons were refusing to try this operation or the other, because they felt that it would not work, Alexander has tried them all and has helped to establish many as valuable. In doing this he has been meticulous in giving credit to the originators.

At the same time he has given a thorough training to a succession of young men from this country and abroad. In England and in many cities in America thoracic surgery has been stimulated and its direction influenced by men trained at Ann Arbor.

Until recently Dr. Alexander has been a full time surgeon at the medical school of the University of Michigan. One wonders to what extent the freedom from the uncertainties and the time-consuming

vexations of private practice have contributed to his work. As one looks over the list of American surgeons who are making important contributions to the science he is impressed with the fact that most of them occupy such positions. Alexander, Graham, Wangenstein, Ochsner, Whipple, Phemister, Cole, Churchill, Heuer, and Holman, are a few of an imposing list.

To return to the book under discussion, one cannot avoid making a few statements concerning the question of indications. On this subject there is, and probably always will be, a divergence of opinion, and it would be surprising if every one or, in fact, any one agreed entirely with Dr. Alexander. It would be out of place for the reviewer to express here his disagreements further than to say that the advisability of using phrenic nerve block in preference to pneumothorax, even in cases in which it is likely to prove effective, is very questionable; that the author's scant enthusiasm for the Semp apicolysis is not shared by most other surgeons and that his advice to proceed early to drainage of secondarily infected tuberculous empyemas is probably pernicious. On many of these questions the wise clinician will continue to withhold judgment and so avoid the deadening of curiosity which follows a formed opinion.

JEROME R. HEAD

THIS book, *J. B. Murphy, Stormy Petrel of Surgery*,² by Loyal Davis, is one of the most interesting contributions to surgical history that it has been my privilege to read. It tells the story of the life and work of a man who did as much to advance modern surgery as any one whom I have known, and the story is a stimulus to all who believe in the opportunity which America offers to the young man. To the older men of the disappearing generation who knew Murphy, it is a source of satisfaction that Murphy's example and achievement have been so well placed in print.

In the eighties of the Nineteenth Century, the work of Pasteur and Lister began to permeate American medicine. In the early stages there was so little understanding of the germ theory of disease that its application resulted rather in a ritual than in the use of aseptic and antiseptic methods. The carbolic acid spray appeared and disappeared, and other usages and procedures, futile or harmful, arose and vanished.

In the nineties came rapid advance in the sound application of the new knowledge to the science and art of medicine. In the spread of the new doctrine, Christian Fenger, of Chicago, a Dane, educated in

¹ THE COLLAPSE THERAPY OF PULMONARY TUBERCULOSIS. By John Alexander, B.S., M.A., M.D., F.A.C.S. Springfield, Ill., and Baltimore, Md. Charles C. Thomas, 1937.

² J. B. MURPHY, STORMY PETREL OF SURGERY. By Loyal Davis, M.D. New York: G. P. Putnam's Sons, 1938.

the Scandinavian seats of learning, demonstrated the principles of surgical pathology, and John B. Murphy became a leader in applying the new knowledge to general surgery.

During the Haymarket Riot in Chicago in 1886, newspaper comment first brought Murphy into the picture because of the daring surgery he undertook in rendering aid to the injured, and his success especially in the traumatic surgery of the abdomen was dramatic.

Murphy's scientific interest in many fields was phenomenal. In each field of work he made thorough preparation by preliminary experimentation and by careful study of surgical anatomy and pathology. His brilliant work helped lay a foundation for the great surgical advance of the succeeding years. The Murphy button, a mechanical device which started gastro intestinal surgery on its way, his work on surgery of the blood vessels and of the nervous system on the thorax, on the bones and joints, and on the endocrine system followed one after another in papers, discussions and clinical lectures.

Murphy was the greatest teacher of clinical surgery I have ever known. A kindly friendly man whom it was the good fortune of my brother Dr. Charles and myself to call friend as well as teacher, we look back to him with gratitude and loving remembrance. We would strongly urge every young man going into medicine and surgery to read Loyal Davis's life of Murphy for in it he will find courage and inspiration even when conditions appear most adverse.

W. J. Mayo

TO fill a need for a combined text and atlas of hematology Kracke and Garver have written a comprehensive volume. The first section of the book is devoted to a discussion of the principles of terminology and includes a dictionary of hematological terms. Many new terms based on Latin or Greek roots are recommended for example neutrocyte is preferred to neutrophil. Other new terms include acidoctye (eosinophil), basocyt (basophil), fragilocyte, meniscocyte, polychromatocyte, etc. Individual blood cells are then described and illustrated by colored drawings. For the most part the drawings are quite realistic and should assist greatly in identifying individual cells on blood films. The blast cells do not appear quite so realistic as they do not contain the fine chromatin structure that is usually seen in the nucleus. The colored plate of supravital stained leucocytes is good. The illustrations of blood films that accompany the clinical discussion of the various blood diseases is one of the

best features of the book. These blood films have been well chosen and represent clearly the hematological characteristics of the individual disease. They should prove of great value in a text the physician to interpret what he sees in the microscope.

The clinical and laboratory phases of the various blood diseases are discussed in detail. Very recent advances are included, and the authors frequently express their own opinions and experiences. Dr. James J. Clark has written a chapter on recent genologic treatment of the leucemic states. Dr. Francis P. Parker on blood groups and blood transfusions, Dr. Elizabeth Gambrell on malaria and Dr. R. P. Custer on bone marrow. Hematological technique is described in detail in the concluding chapter.

There are a few things that are open to criticism. Although the expression of hemoglobin in grams per 100 cubic centimeters is considered an advantage the authors use percentage hemoglobin and the grams per 100 cubic centimeters interchangeably throughout the book. It is also noted that little attention is paid to the saturation index or hemoglobin concentration of erythrocytes. In the text the terms hyperchromic, monochromic and hypochromic refer to the hemoglobin content of cells and not to the concentration. However in plate XII, red cells labeled as hyperchromic apparently have an increased hemoglobin concentration. It is not generally agreed that such cells actually occur. The etiological classification of anemias used is very similar to that of Minot and Castle. The discussion of the anemias in no way follows the classification. A large variety of anemias that are associated with a low color index are included under the term hypochromic anemia. This is confusing as it has become common to associate hypochromic anemia with iron deficiency. Following hypochromic anemia in order idiopathic hypochromic anemia, hemolytic jaundice, hypochromic anemia of lead poisoning, pernicious anemia, macrocytic anemia, aplastic anemia and sickle cell anemia are described. The reason for this arrangement is not clear. A feature of questionable value is the inclusion of a classification of anemias of childhood. These could well be discussed under the general headings of anemia. As the book is meant for reference purposes, it is lamentable that more space was not given to the anemias of bone marrow damage and dysfunction, e.g. Hant's disease and leuco erythroblastic anemia associated with metastatic carcinoma, xanthomatoses, etc.

Outside of the above criticism the book contains much to recommend it. In its scope the work is unique in this country. The book will certainly fill a useful place at the bedside in the clinical laboratory and in the student laboratory.

HOWARD L. ALST

HENRY W CAVE, *Chairman*, HOWARD A. PATTERSON, *Secretary, Committee on Arrangements*

THE 1938 CLINICAL CONGRESS IN NEW YORK AND BROOKLYN

THE surgeons of Greater New York are planning to provide a program of surgical clinics and demonstrations that will present a complete showing of their clinical activities in all departments of surgery in that great medical center during the twenty-eighth annual Clinical Congress of the American College of Surgeons, October 17-21. The Committee is assured of the hearty co-operation of the clinicians at the five medical schools and more than fifty hospitals that will participate in the clinical program. Members of the Executive Committee in charge of arrangements are:

HENRY W CAVE, *Chairman*
HOWARD A PATTERSON, *Secretary*

FRANK E ADAIR
FRANK E BERRY
ROBERT E BUCKLEY
RALPH COLP
WILLIAM DARRACH
CARL EGGERS
GEORGE J HEUER
CHARLES GORDON HEYD
ROBERT H KENNEDY
SAMUEL J KOPETSKY
JOHN A MCCREERY
DONALD E MCKENNA
JOHN J MOORHEAD

EUGENE H POOL
JAMES I RUSSELL
MORRIS K SMITH
J BENTLEY SQUIER
BYRON STOOKEY
GEORGE GRAY WARD
BENJAMIN P WATSON
CARNE WEEKS
JOHN M WHEELER
ALLEN O WHIPPLE
PHILLIP D WILSON
ARTHUR M WRIGHT

A preliminary schedule of operative clinics and demonstrations is being prepared by the Committee for publication in an early issue of *SURGERY, GYNECOLOGY AND OBSTETRICS*. Clinics will be arranged for the afternoon of Monday, October 17, and for the mornings and afternoons of each of the four following days, in which all departments of surgery will be represented.

The final program of the Congress will present an ample and carefully arranged schedule of operative clinics, demonstrating the technique of a wide variety of surgical procedures, and will include a series of demonstrations at the medical schools and the larger hospitals for the presenta-

tion of work being done in many special branches of surgery, such as fractures, cancer, traumatic surgery, neurosurgery, plastic surgery, orthopedics, etc. The program will be so arranged that the visiting surgeon may be assured of the opportunity to devote his time continuously, if he wishes, to clinics dealing with those subjects in which he is most interested.

Programs for a series of scientific sessions, symposia and conferences, to be held daily at headquarters at the Waldorf-Astoria Hotel, are being prepared by the Executive Committee of the Board of Regents. On Monday evening the retiring president, Dr. Frederic A Besley, will deliver the presidential address, and the new officers will be inaugurated: Dr. Howard C Naffziger, San Francisco, president; Dr. Vernon C David, Chicago, first vice president; Dr. Fraser B Gurd, Montreal, second vice president. The 1938 class of initiates will be received into Fellowship at this session. Eminent surgeons of the United States and Canada and a number of visiting surgeons from foreign countries will present and discuss papers dealing with surgical subjects of timely importance at these sessions. Other features of the program for the Congress include a number of conferences and symposia dealing with fractures, cancer, obstetrics and gynecology, urology, neurosurgery, traumatic surgery, thoracic surgery, etc.

In addition to an extensive schedule of operative clinics and demonstrations at the hospitals and schools prepared by the subcommittees on ophthalmological and otolaryngological surgery, programs are being prepared for evening sessions for these sections on Tuesday and Thursday evenings at the Waldorf-Astoria Hotel, at which visiting ophthalmologists and otolaryngologists will present and discuss papers of special interest to those who practice these specialties.

The annual hospital conference will open the Congress with a session in the Ball Room of the Waldorf Astoria at 10 o'clock on Monday morning, at which a complete report on the college plan for graduate training in surgery will be presented. On Monday afternoon and on Tuesday, Wednesday and Thursday, both morning and afternoon an interesting program of papers, round table conferences and practical demonstrations, dealing with many problems related to hospital efficiency is being prepared. It is planned to make this year's session of wide interest and practical character through a careful selection of subjects to be presented and discussed by surgeons and hospital executives, particular emphasis being directed toward professional standards and the vital problems related to hospital economics.

Headquarters for the Congress will be established at the Waldorf Astoria Hotel, on Park Avenue between 49th and 50th Streets, where the Grand Ball Room and large adjacent foyers, the Astor Gallery, Jade and Basilidon Rooms, all on the third floor of the hotel, have been reserved for Congress headquarters—for scientific sessions and conferences, and for the scientific and technical exhibits.

The technical exhibition, together with the registration and clinic ticket bureaus will be located in the east foyer, Astor Gallery, Jade and Basilidon Rooms, all on the third floor of the hotel. The bulletin boards, on which the daily clinical program will be posted each afternoon for the following day, will be placed in these rooms. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, pharmaceuticals and publishers

of medical books will be represented in this exhibition.

The hospitals and medical schools of Greater New York afford accommodation for a large number of visiting surgeons, but to insure against overcrowding, attendance at the Congress will be limited to a number that can be comfortably accommodated at the clinics. The limit of attendance will be based upon the result of a survey of the operating rooms and laboratories of the hospitals and medical schools, to determine their capacity for visitors. It is expected therefore that those surgeons who wish to attend the Congress will register in advance. A registration fee will be required of surgeons attending the annual Clinical Congress, such fees providing the funds with which to meet the expenses of the Congress. To each surgeon registering in advance a formal receipt will be issued which is to be exchanged for a general admission card upon his registration at headquarters during the Congress. This card is not transferable and must be presented in order to secure clinic tickets and admission to scientific sessions. The registration fee for Fellows and endorsed junior candidates is \$5.00, except that no fee will be required of local Fellows participating in the program and inmates of the class of 1938. For all others, invited as guests of the Clinical Congress, the fee will be \$10.00.

Admittance to the clinics and demonstrations will be controlled by means of special clinic tickets, such plan providing an efficient means for the distribution of the visiting surgeons among the several clinics and insuring against overcrowding the number of tickets issued for any one clinic being limited to the capacity of the room in which the clinic is given.

INDUCED SPREADING PERITONITIS COMPLICATING ACUTE PERFORATIVE APPENDICITIS

JOHN O BOWER, M D, F.A.C.S., JOHN C BURNS, M.D., and HAROLD A MENGLE, M D,
Philadelphia, Pennsylvania

PERITONITIS causes 92 per cent of the deaths of patients admitted to hospitals with a diagnosis of acute appendicitis. Of these deaths, according to the surgeons who operated or the physicians who wrote the gross findings, ¹ 81.7 per cent were due to spreading peritonitis, 10.4 per cent to local peritonitis, and 7.9 per cent to other causes. Deaths under the caption "Due to Other Causes" will not be discussed—the number is practically constant from year to year and includes catastrophes, deaths due to anesthetics, hemorrhage, cardiac dilatation, embolism, atelectasis, pneumonia, etc.

Deaths under the caption "Local Peritonitis," however, will be discussed in detail. Of each 100 patients admitted to hospitals with a diagnosis of acute appendicitis, between 15 and 20 have a localized abscess. These patients are usually operated upon within 24 hours, following operation, however, a number far in excess of what the average surgeon would consider moderate, develop hyperpyrexia or tachycardia and some of them die. A careful study of the clinical rec-

ords of these patients shows that those who recovered had a stormy and protracted convalescence. The cause of death written by the interne was, with very few exceptions, local peritonitis, the diagnosis on admission. We call this Group I—Operative-Induced Spreading Peritonitis.

A second group of patients, approximately 89 per cent of those admitted to the hospital with spreading peritonitis complicating acute

Plate I. A, Normal peritoneal cavity, living dog. Note large left lobe of liver; robin's egg blue of gall bladder; visceral peritoneum, light pinkish gray; parietal peritoneum, ileum, pinkish gray, omentum uniformly distributed covering large and small intestine. B, Twenty-four hour local peritonitis, no laxative. Appendix and mesentery ligated. Demonstrates omental quarantine of distended gangrenous appendix. Visceral peritoneum slightly injected, parietal peritoneum, unprotected loops of ileum, show dark pink injection. C, Twenty-four hour spreading peritonitis, no laxative. Appendix and mesentery ligated, visceral peritoneum hyperemic; parietal peritoneum, ileum, injected, vessels prominent, slightly distended. Stomach vessels injected, slightly distended. Liver displaced upward; omentum uniformly distributed over viscera. Exudate seropurulent. D, Twenty-four hour peritonitis, laxative induced. Appendix and mesentery ligated and 30 cubic centimeters of castor oil given immediately after operation. Parietal peritoneum intensely injected, visceral peritoneum, ileum, compare with lower left, loops distended in upper abdomen, stomach injected, marked increase in size of gastro-epiploic vessels. Omentum attempting to localize process, it extends from left lower to upper right between coils of ileum, exudate purulent.

¹From the analysis of 18,687 cases admitted to 28 hospitals in Philadelphia over a period of 6 years.

perforative appendicitis, had received one or more than one laxative. The mortality of this group of patients was 115 per cent higher than that of the group that had not received laxatives. This is Group II—Laxative Induced Spreading Peritonitis.

Deaths in a third group of patients occurred because of a reactivation of the infectious process induced through errors in judgment in the management following operation. This is Group III—Postoperative Induced Spreading Peritonitis.

GROUP I—OPERATIVE INDUCED SPREADING PERITONITIS

Factors mainly responsible for its induction are

- 1 Failure to diagnose before operation the localizing process,
- 2 Failure to recognize the localizing process at operation,
- 3 Radical surgery.

1 Failure to diagnose before operation the localizing process. A clinical pathological classification of acute appendicitis and peritonitis based on correlation of symptoms and signs, gross findings at operation and what happens to the patient after operation will be reported elsewhere. The important addition to the generally accepted pathological classification—acute appendicitis, spreading peritonitis, and local abscess—is the localizing process, the potential or retrogressive spreading process.

Perforations of the appendix are either acute or subacute. The stage of transition between an intact serosa and perforation with spreading peritonitis in the acute fulminating type of appendicitis is minimal in point of time. The symptoms and signs however are usually consistently progressive, only occasionally because an excessive amount of antigen escapes through the perforation into the peritoneal cavity, do the symptoms and signs of perforation alone dominate the clinical picture. In subacute perforations, however, the symptoms and signs associated with rupture of the serous coat are minimal because the local tissue changes preceding and following it are designed by nature to limit the dose of antigen to an amount commensurate with the reactive

capacity of the patient. Before perforation the deposition of fibrin upon the serous coat swelling of the endothelial cells and the serous mobilization of neutrophils tend to thicken and strengthen the wall of the appendix. These changes are accompanied by an increase of intra appendiceal pressure which continues as long as the serous coat remains viable. When the cells composing this membrane die, the serous coat becomes separated from the gangrenous tissue beneath and intra appendiceal tension is diminished. At this point symptoms and signs previously present may disappear—it is the "lucid interval" (1). Absorption of antigen during this period is minimal. When perforation occurs because of liquefaction necrosis and increased intra appendiceal tension the spread of the process may be prevented by plastic exudate or by the parietal or visceral peritoneum or omentum. This is the localizing process (Fig. 1). The amount of antigen absorbed during this stage is also minimal. An analysis of this large number of clinical records shows that the average physician and surgeon invariably diagnose acute appendicitis and its chief complication, spreading peritonitis when the process is fulminant or moderately active, the same is true of the local abscess. The surgeon and his associates however frequently fail not only to diagnose the localizing process but certain lesions which frequently precede its formation as well—partial or complete gangrene of the appendix which, as we have previously stated, is responsible for the lucid interval. Every death that occurred from appendicitis and its complications on my service in 3 hospitals during the past 4 years was due to failure of the operator to diagnose these lesions before operation. The diagnosis of the localizing process before operation is dependent to a great extent upon a complete account, written in detail, of what happens to the patient before he is admitted to the hospital. This must include not only questioning the patient but the physician who first sees him as well which is especially important if the patient has had hypodermic injections. It should be emphasized that the physician who first sees a patient with an acute lesion of the abdomen whether immediately or potentially surgical

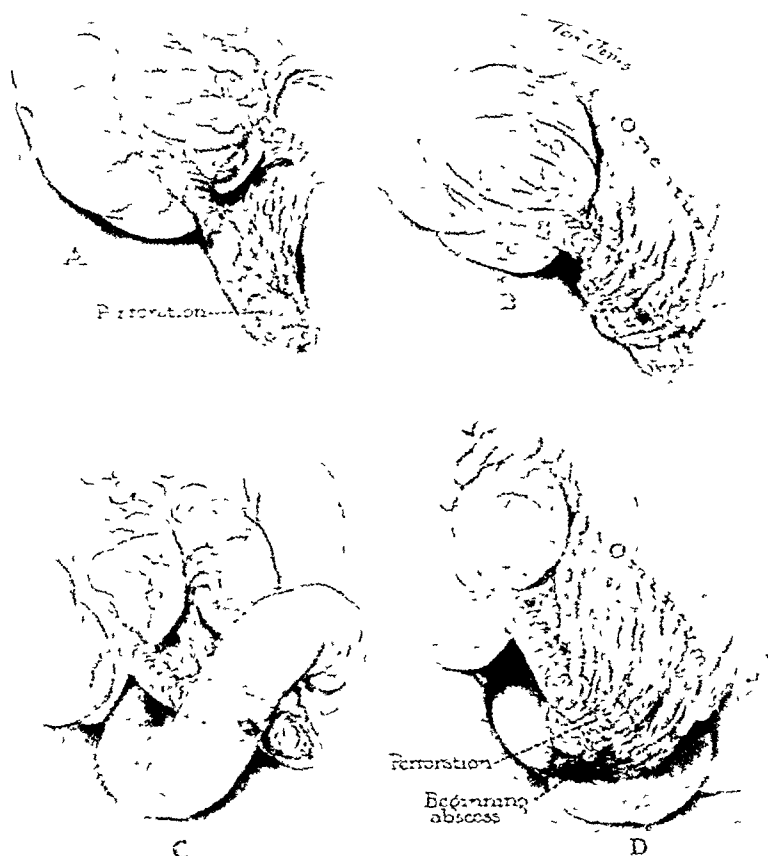

Fig 1

has the best opportunity to interpret correctly the tissue changes which have occurred intraperitoneally

Pre-operative diagnosis is also dependent upon a careful clinical study and repeated physical examinations after the patient is admitted to the hospital. The process usually begins in the mucosa, progressing to a partial or extensive gangrene or an acute suppurative process followed by necrosis, which accounts for the fact that early symptoms and signs are usually typical of an appendiceal colic of moderate degree. General colic-like pains which later localize to the right lower quadrant, nausea and one or two attempts at vomiting are the usual symptoms. The presence or ab-

sence of tenderness and tenseness or rigidity of the abdominal muscles depends on the situation of the appendix. During the first 24 hours the temperature is usually not higher than 101 degrees, pulse between 90 and 100, leucocyte count around 12,000 with a preponderance of neutrophils.

If perforation has been preceded by gangrene, the lucid interval which accompanies it may be confused with resolution by the attending physician, the relief of pain and the absence of tenderness and rigidity accompanying perforation are due to diminished intraperitoneal pressure; accompanying resolution, to the absorption of the products of inflammation in an intact appendix. A localiz-

Graph 1. Mortality of spreading peritonitis. 2,573 cases—24 hour groups 1925-1933

ing process in a resistant patient, when adequately Ochsnerized may be at times completely absorbed. It is not uncommon for a surgeon to remove an appendix while operating for another lesion, that shows definite evidence of a previous perforation. Ochsnerization instituted in the home is usually incomplete, enforced only to the point of cessation of acute symptoms. Frequently tenderness is present when fluids are given by mouth. The physician may send the patient to the hospital at this time but on admission signs of an acute process may have disappeared. Whether at home or in the hospital the prognosis is dependent upon whether a clinical pathologist is called in or whether something is given by mouth to stimulate peristalsis. If the clinical pathologist is consulted a catastrophe may be prevented if a laxative is given a frank spreading peritonitis invariably develop.

The diagnosis of a localizing process which is progressing to abscess formation is usually not difficult if the physician or surgeon is thinking of the possibility of its existence. A vaginal or rectal examination should be made in addition to the abdominal examination and the results of each recorded. A word of caution regarding repeated abdominal examinations

should be interpolated at this point. My associates and I have had the unpleasant experience of observing a rather obese female die following the conversion of a localized abscess into a spreading peritonitis by forceful manipulation. The safety of the patient is dependent in part upon repeated abdominal examinations but they should be done deliberately and carefully, the patient should be requested to co-operate, the physician explaining that the opening of the mouth and the bending of the knees facilitates relaxation. The entire hand of the examiner should be placed gently on the abdomen pressure being exerted only with the tips of the fingers.

2. *Failure to recognize the localizing process at operation.* Because of the gradual development of the localizing process, gross tissue changes are not marked, at least those visible through the average abdominal incision. The preperitoneal tissues are edematous and if the incision has been made over or near the lesion the parietal peritoneum will be injected—the degree of hyperemia of the visceral peritoneum will depend upon the time that has elapsed between perforation and operation. Free fluid, if present, is usually moderate in amount, cloudy, seropurulent, and slightly odorous. A smear may show micro-organisms, cultures frequently do. If rupture occurs in an appendix which has previously been involved in an infectious process, the accompanying appendiceal fibrosis and periappendiceal adhesions diminish absorption, and hyperemia of the peritoneum and transudation of fluids will be comparatively less. If the process is in close proximity to the incision it can be visualized and recognized without difficulty. Coils of distended small intestine cecum or thickened omentum however, may make visibility difficult. Perhaps the most important pathological finding which may lead one to suspect a concealed perforation is the marked thickening of the omentum caused by the increased vascularity edema neutrophilic and clasmatic infiltration. The foregoing is all that can be seen through a transverse or muscle splitting incision.

3. *Radical surgery.* A surgeon's mortality percentage is dependent to a great extent not only upon the number of cases he has managed

but on whether he has profited by the mistakes he has made as well. Without exception, there is no lesion of the abdomen requiring surgery in which errors of commission influence mortality so markedly as in spreading peritonitis complicating acute perforative appendicitis. Errors of omission are not so death dealing—if the patient with a localized abscess is left alone, he may absorb it—50 per cent of the dogs with appendiceal abscess following induced gangrene do. The old controversy as to whether immediate operation should be done or watchful waiting instituted has been definitely settled, in my opinion. Individuals recover or die from spreading peritonitis just as they do from a pneumonia or a spreading cellulitis because they do or do not develop a general and local tissue immunity. Doses of antigen, clasmatoctytic response, and antitoxin formation are as important in one as the other.

Graph 1 shows the mortality of 2,573 patients operated upon for spreading peritonitis following a perforated appendix. They have been divided into 24 hour groups—the vertical column shows mortality percentage; the horizontal line shows the day of the disease. You will observe that the mortality increases with each 24 hours up to the fifth day—there is a slight decrease on the sixth and a marked drop on the seventh day because general and local tissue immunity approach their maximum at that time. We have not found antitoxin in the blood of patients before the sixth day following perforation.

The important point in this discussion is the character of the reaction and the outcome of patients who are operated upon during the localizing stage. While the McBurney or muscle-splitting incision is made in less than 50 per cent of the acute cases, we will suppose that the operator suspects the possibility of rupture and that he selects this type of incision for obvious reasons. The peritoneal cavity reveals in part the gross findings described, but loops of intestine obstruct the surgeon's view. A small gauze pack is inserted and he attempts to quarantine the suspected process which he finally accomplishes but his vision is limited because of the small incision; after enlarging it, visibility is still only about

Fig. 2.

70 per cent. He is not sure whether the tip of the appendix adherent to the parietal peritoneum near the brim of the pelvis and surrounded by a loop of ileum is or is not perforated. Finally he separates the adherent tip from the peritoneum and purulent material exudes. The peritoneum has been well prepared for rapid absorption of antigen. Loops of ileum have been separated, fibrinous plaques have been brushed off, endothelial cells have been destroyed, exposing capillaries and lymph vessels. If at this point a drain is inserted, the gauze strips gently removed, a normal saline dressing applied and Ochsnerization instituted, 9 out of 10 patients will successfully combat the dose of antigen. But now that the operator has started he wants to finish the job and he removes the appendix. In a large number of instances death follows.

Perhaps the surgeon has not followed the procedure described; perhaps he has done something worse—not being able to visualize the process he may have placed an index finger into the wound and attempted to hook up the appendix—Figure 2 shows definitely what happens. One-twenty-millionth gram of crys-

Fig 3

talline egg albumen is sufficient to stimulate antibody formation. How much antigen escapes into the peritoneal cavity from the average ruptured appendix? How much is absorbed from this gauze abraded area? This cannot be estimated at operation but the immediate postoperative response of the patient will tell—perhaps he will respond satisfactorily—80 per cent of them do but 20 per cent of them do not.

While the mortality of the localizing process is high, when the appendix is removed in the presence of a spreading process the mortality is still higher. Table I shows what occurred in 12 of the 18 hospitals in Philadelphia where radical surgery was practiced. The average time between onset of symptoms and operation was 56 hours; the mortality 37.4 per cent; the appendix was removed in 93.7 per cent of instances.

THE PREVENTION OF OPERATIVE INDUCED SPREADING PERITONITIS

Anesthesia. When the patient is a good spinal anesthesia risk, and the anesthesiologist has had experience in the technique of induction

TABLE I

H. P.	Spread of peritonitis			Appendix removed per cent	Average hours onset of symptoms and operation	
	Cases	Deaths	Mortality per cent		Recovery %	Deaths
1	1	4	40	77.7	64	11.7
10	4	1	25	100	37.6	14
12	21	5	23.8	100	50.4	23.7
15	12	8	66.6	90	61	66
7	3	2	100	100	9	97
19	39	11	28.1	100	60.9	9
21	25	4	16.0	100	59.6	51.2
2	21	7	33.3	95	61.5	5
24	7	2	28.5	100	45.7	14
2	17	8	46.5	80	71.9	97
10	20	10	50	63	4.9	54.7
28	8	3	37.5	100	35	75
	171	64	37.4	93.7	57 hrs	35.4 hrs

and the management of patients who have had spinal anesthesia, it is ideal for opening an appendiceal abscess. The surgeon or anesthesiologist endeavoring to develop a spinal technique should not include patients with spreading peritonitis. If the diffusion of the anesthetic is too high and artificial respiration is resorted to, or carbon dioxide with oxygen is given under pressure, the excursions of the diaphragm and the passive movements of the accessory muscles of respiration will diffuse the process and increase absorption.

Advantages of spinal anesthesia are

1. The accessory muscles of respiration and the transverse abdominal muscles are relaxed thus permitting a maximum of visualization of the peritoneal cavity in addition absorption is diminished because of the minimal excursions of the diaphragm and anterior abdominal wall.

2. The abscess can be outlined accurately by palpation and at times can be seen protruding above the normal contour of the abdomen.

3. The relaxed and more quiet abdomen permits a better preperitoneal palpation of the intraperitoneal abscess (see technique, Fig 3B).

Spinal anesthesia increases peristalsis. In early spreading peritonitis adherent loops of

intestine may be separated, which we have shown by cinema, taking place in the peritoneal cavity of dogs. The greater ease of accessibility diminishes the likelihood of rupturing the abscess wall which, in my opinion, more than offsets the effect of the toxemia induced by the increase in peristalsis produced by the spinal anesthesia.

Abdominal incision and preperitoneal palpation. The location and type of incision are determined by the situation of the abscess. In all instances an attempt is made to open the abscess from the roof. The advantage is twofold—drainage is simple and absorption is minimal, a single rubber tube only being required (Fig. 3C).

Figure 3 shows the method employed when the transverse incision is used. Following separation of the fibers of the internal oblique and transversalis muscles, the index finger palpates the mass beneath, no attempt being made to aspirate (Fig. 3B). If it is tense and resistant to the touch, the peritoneum is opened and a drainage tube is inserted into the abscess (Fig. 3C). Two small cigarette drains may be inserted, one on either side of the tube, to control oozing and permit the gradual withdrawing of the tube, thus reducing absorption to a minimum. The wound is not sutured, a safety pin is pierced through the tube and gauze is placed above and below so as to insure its being securely anchored by the retentive bandage.

When preperitoneal palpation with the index finger discloses a non-resisting mass (Fig. 4A), intestinal coils are undoubtedly present beneath, and another attempt should be made to locate that portion of the abdominal wall which the operator considers a more direct route to the roof of the abscess. Another incision is made and preperitoneal palpation again carried out. If it is located the first incision is closed and a tube inserted through the roof (Fig. 4B). If the surgeon discovers intestinal coils instead of an abscess, after the peritoneal cavity is opened, he should carefully insert his index finger and locate the wall, another incision should then be made over the roof after the first incision is closed, if the abscess cannot be definitely located by this method, the patient should be returned

Fig. 4

to the ward for further observation and Ochsnerization continued—frequently this type of abscess will be absorbed and appendectomy can be carried out at the end of 8 weeks.

Removal of appendix. The appendix is not removed in the presence of a localized abscess, or when an unsuspected localizing or spreading process is found at operation. The only exception to this is in spreading peritonitis when there is no evidence of localization and the perforated appendix is accessible, it is removed and a catheter is placed in the cecum.

The following abstract with graphic illustration (Graph 2) shows how a spreading peritonitis *should not* be managed.

Female, aged 21 years, had symptoms and signs of an acute surgical abdomen. "Results" (laxative) given 5 hours after onset of pain. Patient was admitted to the hospital and operated upon 30 hours after onset of symptoms, anesthetic spinal novocaine and local novocain. A right rectus incision was used. The appendix was retrocecal, and perforation was not recognized immediately. The appendix was removed and multiple drains were inserted. Eighty cubic centimeters of perfringens antitoxin in divided doses was given intramuscularly, glucose metabolic balance instituted; death in 5 days.

Fig 3

talline egg albumen is sufficient to stimulate antibody formation. How much antigen escapes into the peritoneal cavity from the average ruptured appendix? How much is absorbed from this gauze abraded area? This cannot be estimated at operation but the immediate postoperative response of the patient will tell—perhaps he will respond satisfactorily—80 per cent of them do but 20 per cent of them do not.

While the mortality of the localizing process is high, when the appendix is removed in the presence of a spreading process the mortality is still higher. Table I shows what occurred in 12 of the 28 hospitals in Philadelphia where radical surgery was practiced. The average time between onset of symptoms and operation was 58 hours, the mortality 37.4 per cent; the appendix was removed in 93.7 per cent of instances.

 (See legends on opposite page)

A spreading process was suspected but was not definitely diagnosed before operation. Spinal anesthesia was unsatisfactory. Death was due to two large doses of antigen, laxative before operation and search for and removal of appendix. Too radical surgery.

The following abstract with graphic illustration (Graph 3) shows how a *localizing process*—a laxative induced retrogressing process—should be managed.

Female aged 17 years had symptoms and signs typical of spreading peritonitis. Citrate of magnesia was given 24 hours after the onset of symptoms. Patient was admitted to the hospital 72 hours after the onset of pain. She was given 100 cubic centimeters of perfringens antitoxin intramuscularly in 3 doses and continuous hypodermic of normal saline. Patient held 5 days before operation. Spinal anesthesia neocaine was used. Through a transverse incision the *localizing process* was recognized but not disturbed. A cigarette drain was inserted down to, but not into the abscess cavity. Drain was removed on fifth postoperative day. Subsequent operation on nineteenth day after onset of symptoms—14 days after first operation—showed complete absorption of the appendix.

Glucose should have been given with the normal saline solution. A gauze drain would not have been necessary. Good judgment was shown in not disturbing a localizing process. One dose of antigen.

The following abstract with graphic illustration (Graph 4) shows the results of the failure to diagnose before operation the localizing process, and the disastrous results induced by simple drainage.

Male aged 22 years had symptoms and signs typical of acute appendicitis. An Ex lax tablet was given immediately after the onset of pain. Patient was admitted to the hospital 48 hours after onset of symptoms and was operated upon immediately. Spinal anesthesia neocaine was given. A transverse incision was made. The localizing process was not recognized until the pus exuded retroceally. The appendix was not removed. Rubber tube and cigarette

drains were inserted—gauze quarantine drain was removed. Thirty cubic centimeters of perfringens antitoxin was given immediately and again in 24 hours intramuscularly. An attempt was made to maintain the glucose metabolic balance. Symptoms and signs of spreading peritonitis diminished but patient developed pneumonia and died on twelfth postoperative day. Postmortem showed localized peritonitis.

This patient received two doses of antigen laxative before operation plus search for and opening of abscess. He should have been held until a localized abscess had developed.

GROUP II—LAXATIVE INDUCED SPREADING PERITONITIS

Of the 2,578 patients admitted to hospitals in Philadelphia with spreading peritonitis complicating acute perforative appendicitis, 1,406 gave definite statements regarding laxative administration, 89.14 per cent had received laxatives. In this same group 153 had not received laxatives and 16, or 10.43 per cent, died, 1,119 received one laxative and 250, or 22.34 per cent, died, 136 received more than one laxative and 33, or 28.67 per cent, died.

These observations are not new, surgeons have known for many years that laxatives increase the incidence of spreading peritonitis and interfere with the possibility of localization, not only in perforation of the appendix but in acute lesions involving other abdominal viscera. Heretofore there has been no definite evidence, however, to show that a laxative induced spreading peritonitis differs pathologically from a spreading peritonitis when laxatives have not been given. An inspection of the colored photographs (Plates I and II) will show more than any number of words can describe, the difference between spreading peritonitis that has and has not been induced

Plate II. A. Forty-eight hour spreading peritonitis no laxative. Appendix and mesenteryligated parietal peritoneum upper left normal color. Visceral peritoneum ileum blood vessels more prominent loops nearest focus of infection brilliant red stomach normal color omentum lower right localized over perforated appendix exudate serous slightly cloudy. B. Forty-eight hour laxative induced spreading peritonitis. Thirty cubic centimeters of castor oil given immediately after ligation of appendix and mesentery parietal peritoneum light to dark mahogany visceral peritoneum, compare with upper left omentum not localized lighter area in center crossed by large mesenteric veins left to right exudate hemorrhagic purulent. C. Seventy

two hour spreading peritonitis no laxative. Appendix and mesentery ligated, parietal peritoneum more injected than upper right visceral peritoneum ileum injected loops adherent, slightly distended stomach not visible omentum mobilized around the perforated appendix in left midabdomen exudate hemorrhagic. D. Seventy-two hour laxative induced spreading peritonitis. Thirty cubic centimeters of castor oil given immediately after ligation of appendix and mesentery parietal peritoneum dark red due to venous congestion visceral peritoneum, ileum lusterless no serbation of normal intestine loop in hypergastric region cyanotic. Omentum disintegrated beginning necrosis exudate dark purulent.

Graph 2 Pulse and temperature charts in case of F. S. showing how a spreading peritonitis should not be handled

by laxatives. These photographs of the dog's peritoneal cavity were made before death of the animal: clinical investigations as well as our experimental work show that if man is treated similarly to these dogs he has 3 chances in 8 of dying in the same fashion

EXPERIMENTAL WORK

A summary of the experimental work conducted by Drs J. C. Burns, H. A. Mengle and myself in the Department of Surgical Research, Temple University, is appended

We ligated the base and mesentery of the appendix in a group of dogs. Fifty per cent of them developed a localized abscess and recovered and 50 per cent died of spreading peritonitis. In a second group of 54, the base of the appendix and the mesentery were ligated, 30 cubic centimeters of castor oil was given 24 hours after ligation and 68 per cent died of spreading peritonitis. To a fourth group of 12, 54 cubic centimeters of castor oil was given immediately after operation and 91 per cent died of spread-

ing peritonitis. In a fifth group the appendix and its mesentery were ligated; laxatives administered. The animals were re-operated upon at varying periods of time and the peritoneal exudate studied bacteriologically. These findings, and the results of a study of the bacterial flora obtained from patients operated upon for spreading peritonitis complicating acute perforative appendicitis, together with a review of the literature have been reported (2). Our investigations showed that the aerobic bacterial flora in man and dog differed in that the colon bacillus was found only in 14 per cent in the dog as compared with 68 per cent in man. A study of the anaerobic flora showed that the *Clostridium welchii* was present in 60 per cent of instances in man and 63 per cent in the dog. These figures are practically the same as those of Weinberg.

We then treated dogs that had an induced spreading peritonitis with perfringens antitoxin (*Clostridium welchii*). The mortality of the control group—89 dogs—was 74 per cent; of the treated group, 38 per cent. A second group was given horse serum—the mortality was 60 per cent, in a third group perfringens antitoxin combined with whole blood was given, mortality 33 per cent, in a fourth perfringens antitoxin combined with *Bacillus coli* serum, mor-

Graph 3. Pulse and temperature charts in case showing how localizing process should be managed

Graph 4. Results of failure to diagnose the localizing process and of the use of drainage

Graph 5 Effect of too early removal of drains

tality 33 per cent, in a fifth, perfringens antitoxin combined with immune serum, mortality 33½ per cent, and finally lyophilized convalescent serum (serum removed from dogs that had recovered from a laxative-induced spreading peritonitis) was injected, in this group we obtained the lowest mortality—25 per cent (to be reported in detail elsewhere, 3). Following this animal experimentation, two groups of patients, over 90 per cent of whom had received laxatives and had had a frank spreading peritonitis due to a perforated appendix, were studied. They had been treated with perfringens antitoxin. The first group is made up of 31 patients who had been operated upon directly after admission, average 61 hours, and given perfringens antitoxin and glucose intravenously—with a mortality of 19.35 per cent. A second group, 35 patients, had been held and given perfringens antitoxin and glucose intravenously, localized abscess opened on seventh day—the mortality was 57.1 per cent.

Up to this point, we have shown that—

1 The incidence as well as the mortality of spreading peritonitis in both man and dog

were increased by the administration of laxatives;

2 The time of administration and the dose of laxative influenced the mortality;

3 The *Clostridium welchii* was present in 60 per cent of instances in the flora of spreading peritonitis in man and dog;

4 The administration of perfringens antitoxin reduced the mortality of spreading peritonitis 122.52 per cent in man and 94.74 per cent in the dog;

5 Convalescent serum, lyophilized, was a factor in the low mortality of spreading peritonitis in both man (to be reported) and dog.

There remained but one discovery necessary to establish the proof and that was to find the antitoxin of the *Clostridium welchii* in the blood of patients who had recovered from spreading peritonitis due to a perforated appendix. This has been reported (4).

Graph 6 Effect of meddlesome postoperative management

Using the technique required by the National Institute of Health pigeons weighing 350 grams were injected with a lethal dose of *Clostridium welchii* toxin—0.013 gram and 1 cubic centimeter of perfringens antitoxin, all of the control pigeons died. One cubic centimeter of serum obtained from individuals in a normal state of health was then injected with the *Clostridium welchii* toxin antitoxin mixture into 28 pigeons, they all died. In another group 1 cubic centimeter of serum obtained from patients who had recovered from simple appendicitis was injected with the *Clostridium welchii* toxin antitoxin mixture 23 died and 2 lived. In another group serum obtained from patients suffering with peritonitis due to a pelvic infection was injected into 33 pigeons 25 died and 8 lived. Finally 63 pigeons were injected with the lethal dose of *Clostridium welchii* toxin antitoxin mixture and serum obtained from patients who had recovered from spreading peritonitis due to a perforated appendix, 46 per cent of them lived and 54 per cent died. Antitoxin of the *Clostridium welchii* was present in 75 per cent of the patient serum—18 of 24. In addition to these tests convalescent lyophilized serums that had been removed from man and dogs and had been standing at room temperature for 465

days were injected into pigeons and found to contain antitoxin of the *Clostridium welchii*.

GROUP III—POSTOPERATIVE INDUCED SPREADING PERITONITIS

In another communication the senior author has emphasized the importance of 'Management of Spreading Peritonitis Due to a Perforated Appendix' (6). A disease with a recognized mortality of from 27 to 45 per cent can be successfully treated only by those who have previously managed similar cases. From the time of admission until the patient has successfully overcome the usual maximum dose of toxins conferences should be held between surgeon in chief, associates, and surgical residents. Had this been done routinely, on the services on which the following patients were treated catastrophes would not have occurred. The following abstract with graphic illustration (Graph 5) shows what may happen when drains are removed too early.

Graph 7 Effect of use of peristaltic stimulants after operation

Male, aged 15 years, had symptoms and signs of spreading peritonitis following a perforated appendix. Castor oil was given immediately after onset of symptoms. Nitrous oxide-ether anesthesia was used. Through a transverse incision, the appendix was removed, and saline and glucose were given after operation. No perfringens antitoxin was given. Drains were removed at the end of 24 and 48 hours, respectively.

Four doses of antigen were given as well as a laxative before operation. Appendix was removed at operation, the drains were removed 24 hours and 48 hours after operation.

Meddlesome postoperative management is shown in this abstract and Graph 6.

Female, aged 21 years, had symptoms and signs typical of spreading peritonitis complicating acute perforative appendicitis. Physician prescribed laxative immediately after onset of pain. Operation was performed 45 hours after the onset of symptoms. Spinal anesthesia, neocaine, was used. A transverse incision was made, and the appendix removed. Twelve hours after operation 1 cubic centimeter

bacteriophage and 100 cubic centimeters of normal saline were introduced through drainage tube into the peritoneal cavity.

Three doses of antigen, a laxative before operation, then removal of appendix at operation, and injection of bacteriophage and saline, after operation, are the factors in this case.

The postoperative use of peristaltic stimulants is shown in this abstract with Graph 7.

Female, aged 61 years, had symptoms and signs typical of a spreading peritonitis complicating acute appendicitis. Epsom salts were given immediately after onset of symptoms. The physician gave morphine before diagnosis was made. Operation was performed 92 hours after onset of symptoms. The anesthetic, neocaine, spinal. A transverse incision was used and the appendix removed. Immediately after operation patient was given fluids by mouth and 3 doses of pitressin.

In this case, 4 doses of antigen were given, a laxative given before operation, then the appendix was removed, and water and pitressin were given after operation. This death cannot be attributed to pitressin alone, but it is difficult to grasp the logic

Graph 8 Effect of enema after operation

of stimulating peristalsis thereby increasing absorption when nature is attempting to prevent absorption by diminishing peristalsis in every possible manner

Enemas and postoperative management are noteworthy in this case (Graph 8)

Male aged 25 years was admitted to the hospital with a diagnosis of acute fulminating appendicitis. Epsom salts were given 30 hours after the onset of pain. Operation was done 54 hours after onset of symptoms anesthetic neocaine spinal. A right rectus incision was used and a perforated appendix with spreading peritonitis was encountered. The appendix was not removed drainage instituted. Patient was given glucose intravenously and 80 cubic centimeters of perfringens antitoxin. Inspection of Graph 8 shows a favorable reaction until the nurse, by mistake gave him a 2 quart enema—the recurring spreading peritonitis caused his death 96 hours after operation. At autopsy the odor of acetone was still present in the peritoneal cavity.

Ten years after this patient's operation and death we were informed by an associate of what actually caused the death. The enema was ordered by the

resident physician for a patient in an adjoining bed. The associate then a resident in the hospital performed the autopsy.

SUMMARY

1 Of any 100 patients who die from acute appendicitis and its complications according to the cause of death on the patient's clinical records 81 per cent die of spreading peritonitis over 10 per cent of local peritonitis and 7.9 per cent of other causes.

2 An accurate analysis of the group 'local peritonitis' shows that a number larger than would be considered moderate by the average surgeon dies not from local peritonitis but from an operative induced spreading peritonitis. The cause of death in this group is the failure to diagnose the 'localizing process' before and to recognize it at operation. Notes on its recognition before and at operation, of the value of spinal anesthesia

and the advantages of preperitoneal palpation are appended.

3 Laxative-induced spreading peritonitis is described; colored photographs of the peritoneal cavity of living dogs contrasting the gross changes accompanying non-laxative and laxative induced spreading peritonitis are shown

4 The part radical surgery plays in the high mortality, especially the search for and the removal of the appendix in the presence of a spreading or a localizing process before local and general immunity have developed, is emphasized.

5 Brief abstracts of case histories showing how localizing or localized processes in post-operative induced spreading peritonitis were converted into spreading processes with fatal

terminations because of errors in management committed during the immediate postoperative period, are reported.

ACUTE APPENDICITIS IN CHILDREN

J M DEEVER, M D F A C S and A G MARTIN, M D, Philadelphia, Pennsylvania

ALTHOUGH the diagnosis and treatment of acute appendicitis have been standardized to a degree, further improvement in the handling of cases must be attained if the mortality is to be still further reduced. Whether or not the mortality of acute appendicitis has been rising during the past decade, papers by Walker, Fitz, Bower, and others clearly show that the treatment of this disease has not been perfected. Certainly no one is justified in assuming a smug attitude of contentment in view of present mortality figures.

The most important factor in acute appendicitis in children is the rapidity with which the disease progresses. It is not uncommon to find a perforated appendix in a child who has been ill less than 12 hours. Advanced disease is encountered early most frequently in the two extremes of life. In a series of 100 cases in adults over 40 years of age reported by Maes, Boyce, and McFetridge, 77 per cent had gangrene, perforation, abscess formation, peritonitis or a combination of these complications. The mortality for the series was 21 per cent. The same authors report a series of 250 children with similar complications in 73 per cent, the mortality of this series was 7.6 per cent. Hudson, quoting the State of Massachusetts vital statistics, reports that appendicitis ranks eighth in importance among all causes of death for children between the ages of 1 and 9. In children the appendiceal structures are delicate and contain a large amount of lymphoid tissue. Also the great omentum is less developed, shorter, smaller and hence less efficient as a localizing and protective agent than it is in adults. In our own cases the omentum seldom aided in localizing the infection, and then only in a few patients over 10 years of age.

In this paper we are reporting a study of 235 consecutive cases of acute appendicitis in children 14 years of age and under. The cri-

terion used in the final diagnosis in these cases was the composite picture made by the history, physical examination, blood count, operative findings, and the pathological report. All borderline cases were listed as chronic and excluded from the series. All patients were operated upon.

The fact that procrastination on the part of parents and physicians, as well as the giving of cathartics, raises the incidence of perforation and the mortality of this disease is well proved and ably discussed by other writers. We feel no need of going over this well known ground. Rather we wish to present this series from the viewpoint of what is to be done for a child with acute appendicitis when the patient enters a hospital. The series is presented also for the purpose of comparing procedures and results with those of other clinics in the hope that by joining forces a general advance may be made against the disease.

Stone states that the general picture of appendicitis in children is similar to that in adults except that the mortality in children with peritonitis is higher—34 per cent as compared with 16 per cent in adults in his series. We agree that a similarity exists and we believe that the same criteria in history and physical examination should be used. Difficulties in diagnosis are three fold and are found most often in the young children, from whom it is difficult to obtain a history, in whom examination must often be made without the patient's co-operation, and in whom the laboratory findings may be misleading. White cells in the urine do not rule out acute appendicitis, in fact they frequently accompany an inflamed pelvic or retrocolic appendix. Moreover a greater number of atypical cases are found in children than in adults.

There are some definite aids to diagnosis, however, which should always be employed. The rectal examination is even more valuable in children than in adults because of the relatively greater distance the finger can reach. No examination is complete in the child un-

less a rectal examination has been done. Acute appendicitis is often seen in nearly an epidemic form. Evans showed that after an epidemic of acute upper respiratory infection a wave of appendicitis will follow, the average interval in a given case being 16 days, the extremes being 1 to 60 days. Stone finds his greatest frequency of acute appendicitis in children when gastro-intestinal upsets are most frequent. Our experience corroborates that of both these authors. It is our belief that appendicitis which follows a gastro-enteritis is not only difficult to diagnose, but it is often of the rapidly progressive fulminating type.

OPERATIVE PROCEDURES

In practically every paper on appendicitis the mortality in unruptured cases is very satisfactory. The patients with perforations are the ones likely to die; therefore the skillful care of such patients is one very fruitful method of lowering the mortality of appendicitis in children. Table I is a comparison of the mortality of perforation cases in the first 3 and the last 4 years of this series. The reason for this division is that the two periods offer a contrast in operative technique, fluid administration, and postoperative care, which we believe accounts for the difference in mortality rates. In the entire series the mortality in perforation cases was reduced from 16.3 to 6.5 per cent, while the percentage of perforation cases remained unchanged. In children under 6 the mortality fell from 33.3 to 17.6 per cent. This mortality figure of 17.6 per cent was obtained in the face of a greatly increased number of perforations: 85 per cent, as compared with 46.2 per cent for the first period.

The increasing use of the McBurney incision is one of the reasons, we believe, for this lowering of mortality.

Chart 1 Showing increasing use of the McBurney incision in this series, from 5 per cent in 1930 to 87 per cent in 1936

Chart 1 shows the relative frequency of McBurney and right rectus incisions from year to year. There are four distinct advantages of the McBurney incision over the right rectus. It permits easy, direct access to the site of disease, minimizing any soiling of uninvolved peritoneum. Drains, when necessary, can be placed laterally. A McBurney incision can be closed loosely without great risk of postoperative hernia, and such closure is very important in the peritonitis cases. In drainage cases when the McBurney incision is employed only the peritoneum need be sutured. Postoperative wound complications, such as sloughing, infection or cellulitis of

TABLE I—MORTALITY IN PERFORATION CASES

Period	Entire series				Ages 1-5 inclusive			
	No cases	% Perforation	Deaths	% Mortality	No cases	% Perforations	Deaths	% Mortality
1930-1932	43	38.7	7	16.3	6	46.2	2	33.3
1933-1936	46	37.1	3	6.5	17	85.0	3	17.6
1930-1936	89	37.9	10	11.2	23	69.6	5	21.7

The figures in the percentage columns show the proportion of perforation cases in the series during the various time periods.

the abdominal wall are rarely seen. Lastly, when a secondary operation for obstruction is necessary, it can be easily performed by the right rectus route through uncontaminated structures if the primary operation was performed by the McBurney approach. For these reasons the McBurney incision is used almost exclusively.

The appendix should always be removed. The only cases in which this rule is not followed are those in the localized abscess group. Merely to drain in cases of appendiceal peritonitis is not logical, for what will prevent the continued pouring out of septic and fecal material from the diseased organ into the free peritoneal cavity? There is only one case in this series in which the appendix was not removed in the presence of peritonitis; this patient died, as is usually the case.

Drainage is used only when gross septic or fecal soiling is present or when exudate exists on the cecum, terminal ileum, or parietal peritoneum. The presence of fluid, even cloudy fluid, is no indication for drainage. When drains are used, they are used freely. A soft rubber tube is placed in the pelvis. One or two cigarette drains are placed below or lateral to the cecum. We believe that drains placed medially to the cecum increase the possibility of obstruction. Postoperative obstruction may occur in spite of placing the drains laterally, but then it is probably due to the terminal ileum falling against and adhering to the appendiceal bed. This complication can be minimized by placing a rubber sheet in the form of a cofferdam between the terminal ileum and the raw appendiceal bed. Usually it is necessary to pack a little gauze loosely in the cofferdam, care being taken to avoid contact between the gauze and the serosal surfaces. The cofferdam may be dispensed with in those cases in which all raw surfaces can be satisfactorily covered by omentum. On about the fourth postoperative day the drains should be loosened by twisting them. Depending upon the amount of drainage, cigarette drains may be removed by the fifth or sixth day. When three have been used, it is best not to remove more than one or two on a given day. When the cofferdam technique is used, the gauze packing is removed on the sixth or seventh

day. The rubber dam is not removed before the ninth or tenth day. The rubber tube is the most important drain of all and is removed last. This is done by shortening it a few centimeters on consecutive days, starting at about the sixth day. It usually comes out between the ninth and twelfth days. We cannot agree with Shipley's statement that drainage can be dispensed with in early peritonitis. When drainage is used, the wound is closed loosely about the drains. In some of the severer cases no sutures at all were placed in muscles, fascia or skin. The McBurney incision makes this possible.

When the base of the appendix and the cecum are involved, i. e., when the appendiceocecal junction is indurated or friable, cecostomy as an auxiliary procedure is of great benefit. This procedure is also indicated in peritonitis when the bowel is greatly distended, and it is far more effective than late enterostomy. The tube is placed directly through the appendiceal stump and when possible through the ileocecal valve, extending into the terminal ileum. In this series it was used in 4 cases: in 2 because the cecum was involved and closure would have been difficult, and in 2 because of peritonitis with great distention of the large bowel. In these 4 cases the catheter was removed at about the eleventh day, and all the wounds healed promptly.

Although a few operations were performed under local and spinal anesthesia, nitrous oxide induction followed by ether was the method generally used. We look forward to appraising the effect of the newer gaseous anesthetics on mortality and morbidity.

Most of the patients were operated upon immediately after admission. In a few cases operation was delayed. These children were all extremely ill. They showed generalized abdominal tenderness, moderate general rigidity, marked distention and peristaltic sounds could not be heard. All had the typical faces of peritonitis. In these cases the Ochsner-Deaver treatment was instituted. If improvement was noted in 12 hours, the treatment was continued; if not, operation was performed. By postponing operation in these cases we feel sure that a few were saved who would not have survived immediate operation. It must be

emphasized, however, that the cases in which delayed operation is indicated in children are relatively few. Certainly Sir James Berry, who in his address "The Fallen Idols" pleads categorically and without qualification for delayed operation in acute appendicitis, has injured the reputation of a useful plan of therapy by advocating its application beyond its limitations.

LOCALIZED ABSCESES

In the localized abscess group there is no need for urgency; most patients respond better if treated for a day or two by the delayed method. When the abscess is palpable and the mass is lateral, the extraperitoneal approach is ideal, the incision being carried to the outer side of the mass, the aponeurosis of the external oblique being divided and the internal oblique and the transversalis being cut across in the line of the incision. The transversalis fascia and preperitoneal fat, which frequently are infected, are separated from the peritoneum. The peritoneum is then opened and, if the abscess is well to the outer side, one opens directly into the abscess without encroaching upon the free peritoneal cavity. The appendix should not be removed unless it is accessible and appendectomy can be accomplished without danger of contaminating the uninvolved peritoneal cavity. When the mass is not lateral or when for one reason or another it is not feasible to use the extraperitoneal approach, the incision should be made over the presenting mass. When arranging the drainage it is a help to place a cofferdam or Penrose drains in the appendiceal bed in such a manner as to keep the terminal ileum from contacting this area. This we believe will help to prevent post-operative obstruction.

POSTOPERATIVE TREATMENT AND FLUID THERAPY

The vitality of cells depends largely upon the integrity of their surrounding medium. The preservation or restoration of normal cellular environment is the sole purpose of fluid administration and represents the basic principle of fluid therapy.

The fluids we are interested in are the extracellular fluids, namely the blood plasma and the interstitial fluid. The latter, which con-

stitutes about 20 to 27 per cent of adult body weight, is the great reservoir of the body which bathes all tissue cells. Across it food is brought to the cells and wastes are carried away. Interstitial fluid and blood plasma may be regarded as media composed of three interdependent units: water, sodium, and chloride. Sodium and chloride are known as the major extracellular ions. When waste changes affect the extracellular fluids, sodium and chloride ions are simultaneously retained or lost, but not necessarily in equal amounts.

At present, clinical tests frequently used are the plasma chloride concentration and the carbon dioxide combining power of the plasma. They measure the concentration of chloride and alkali reserve in plasma, and reflect the concentration of these substances in interstitial fluid.

The safety mechanisms of the body which insure stability of cellular fluid environment depend largely upon kidney function. The kidneys excrete excess water with dissolved waste products. When the fluid intake is low, the kidneys excrete a smaller more concentrated quantity of urine. The interstitial fluid reservoir can shrink or expand in accordance with body needs. The hydrogen-ion concentration of the extracellular fluids is stabilized because they are buffered solutions, and their osmotic pressure remains practically constant due to the interdependence of solvents and solute.

However, there are limits beyond which the stabilizing mechanisms cannot go, and in children with appendicitis, especially the late perforation cases, those limits have frequently been passed. One of the first symptoms of a sick child is its refusal to take solid food. Soon liquids too are refused. The small fluid volume intake results in dehydration. The small caloric intake makes the child dependent upon its own tissue stores of glycogen (body carbohydrate), fat, and protein for maintenance of metabolism. Children, because of their higher metabolic rates, exert a greater demand on such stores than adults, and consequently the complications of depletion occur earlier in childhood. Fats are dependent upon carbohydrates for complete oxidation. In periods of starvation, glycogen is depleted before fat, and the fat must then be oxidized alone. Such

Chart 2 The double column on the left represents plasma concentration of base and acid ions in a normal individual. The second double column represents the case of a child who was vomiting because of upper intestinal obstruction. The situation is qualitatively analogous to the sequence of events in severe acute appendicitis. (Case 2 of this section.)

oxidation is incomplete leaving the so called ketone bodies (acetone, diacetic acid, and beta hydroxy butyric acid) as useless end products which cannot be oxidized alone and must be excreted in the urine. Worse still ketone bodies can be excreted only in the presence of base. This leads to acidosis of starvation.

Transposing the processes into a clinical picture, we see a child who has been too ill to eat or drink for 12 or more hours. The skin and tongue reflect dehydration. The urine contains acetone. When the blood count is taken, the hemoglobin and red cells are increased again indicating dehydration which is further corroborated by decreased urinary volume of high specific gravity. At this stage an infusion of normal salt solution with glucose will re-establish equilibrium. Glucose must be given in order to oxidize fat and ketone bodies, thus clearing the urine of acetone. Part of the salt solution replenishes the depleted body fluid reservoir. The kidneys conserve base by retaining the sodium component until the base which was lost in the excretion of ketones is replenished.

The next step in the breakdown of body balances comes with the symptom of vomiting. Since vomitus contains so much gastric juice, chlorides as well as fluid are lost to the body. Ketosis and acidosis of starvation are present. Continued vomiting brings about great chloride depletion. The continued loss of chlorides changes the picture from acidosis dehydration and ketosis to *alkalosis*, dehydration and ketosis. Gamble calls this condition *alkalosis and ketosis*. It is also called *hypochloremia*. Clinically the outstanding consideration is the presence of acetone in the urine of a dehydrated patient who is not diabetic, not in acidosis, but really in alkalosis.

Chart 2 will make these relationships clear. It is taken from Gamble and illustrates the changes discussed.

We wish to state that in this discussion we are not necessarily charting a type case of appendicitis. Rather the symptoms are taken up in an order which facilitates explanation of fluid-electrolyte changes.

Once the underlying physiology is understood, estimation of the type and quantity of

fluids to be given may be discussed. In balancing the daily intake and output, fluid losses as perspiration, hemorrhage, vomitus, and drainage must be replaced by salt solution. Blood loss is obviously best replaced by blood. Fluid loss in the urine and by vaporization (exhaled air and insensible perspiration) should be replaced by distilled water. The work of Collier and Maddock in fluid balance well illustrates this. They estimate the average fluid loss by vaporization in an adult as 2,000 cubic centimeters per 24 hours. They believe an adult should excrete from 1,000 to 1,500 cubic centimeters of urine per day, preferably the latter amount, and never less than 600 cubic centimeters. The minimum daily intake for an adult is therefore 3,500 cubic centimeters and to it they add additional quantities to cover amounts lost by vomiting, drainage, hemorrhage, etc. In children the problem is more difficult. A child's surface area is larger in proportion to its weight than an adult's and for this reason children lose proportionately more fluid by vaporization. Twenty-four hour urine specimens are difficult and often impossible to collect from children. The drawing of blood for blood chemistry determinations cannot be done frequently in infants. Moreover, a child can easily be overwhelmed—drowned—by well meant but too zealous administration of parenteral fluids.

A calculation of fluid requirements for each case must first be made. In older children this must be deduced from adult requirements. In infants, formula techniques can sometimes be used. The situation is admittedly unsatisfactory and it will remain so until values for children can be established. Careful clinical observations combined with simple laboratory tests frequently repeated must check the use of fluids throughout their administration. Optimally, the tongue should be moist and skin turgor should be preserved. The optimum urine specific gravity is in the neighborhood of 1.015; acetone and sugar should not appear. A suppression of urine frequently indicates chloride edema. In such a situation glucose and distilled water are needed to preserve kidney flow. Salt solution is not diuretic and tends to be retained if excess water is not given to facilitate the selective excretion of super-

Chart 3. Case illustrating rapid development of chloride edema. This chart represents successive days in the hospital. The amounts and types of fluid are indicated. A temperature chart is superimposed.

fluorous ions. Blood chemistry determinations in children must be regarded as occasionally used procedures, very valuable, but hardly feasible as a daily routine.

Case illustrations will make these points clearer. Chart 3 illustrates the case of a well nourished 5½ year old girl who weighed 44 pounds.

She had been ill 11 hours, but had not vomited. Clinically there were no signs of dehydration. The urine specific gravity was 1.026, but no acetone was present. A diagnosis of acute appendicitis with perforation was made, and at operation a gangrenous perforated appendix was removed. The chart shows the amount and type of fluids given. On the second day edema and suppression of urine occurred. Blood chemistry determinations revealed a blood chloride of 890 milligrams per 100 cubic centimeters and a carbon dioxide combining power of 59 volumes per cent. Obviously the edema was caused by the administration of too much salt solution. When the infusion fluid was changed to 5 per cent glucose in

fluids to be given may be discussed. In balancing the daily intake and output, fluid losses as perspiration, hemorrhage, vomitus, and drainage must be replaced by salt solution. Blood loss is obviously best replaced by blood. Fluid loss in the urine and by vaporization (exhaled air and insensible perspiration) should be replaced by distilled water. The work of Collier and Maddock in fluid balance well illustrates this. They estimate the average fluid loss by vaporization in an adult as 2,000 cubic centimeters per 24 hours. They believe an adult should excrete from 1,000 to 1,500 cubic centimeters of urine per day, preferably the latter amount; and never less than 600 cubic centimeters. The minimum daily intake for an adult is therefore 3,500 cubic centimeters and to it they add additional quantities to cover amounts lost by vomiting, drainage, hemorrhage, etc. In children the problem is more difficult. A child's surface area is larger in proportion to its weight than an adult's and for this reason children lose proportionately more fluid by vaporization. Twenty-four hour urine specimens are difficult and often impossible to collect from children. The drawing of blood for blood chemistry determinations cannot be done frequently in infants. Moreover, a child can easily be overwhelmed—drowned—by well meant but too zealous administration of parenteral fluids.

A calculation of fluid requirements for each case must first be made. In older children this must be deduced from adult requirements. In infants, formula techniques can sometimes be used. The situation is admittedly unsatisfactory and it will remain so until values for children can be established. Careful clinical observations combined with simple laboratory tests frequently repeated must check the use of fluids throughout their administration. Optimally, the tongue should be moist and skin turgor should be preserved. The optimum urine specific gravity is in the neighborhood of 1.015, acetone and sugar should not appear. A suppression of urine frequently indicates chloride edema. In such a situation glucose and distilled water are needed to preserve kidney flow. Salt solution is not diuretic and tends to be retained if excess water is not given to facilitate the selective excretion of super-

Chart 3. Case illustrating rapid development of chloride edema. This chart represents successive days in the hospital. The amounts and types of fluid are indicated. A temperature chart is superimposed.

fluorous ions. Blood chemistry determinations in children must be regarded as occasionally used procedures, very valuable, but hardly feasible as a daily routine.

Case illustrations will make these points clearer. Chart 3 illustrates the case of a well nourished 5½ year old girl who weighed 44 pounds.

She had been ill 11 hours, but had not vomited. Clinically there were no signs of dehydration. The urine specific gravity was 1.026, but no acetone was present. A diagnosis of acute appendicitis with perforation was made, and at operation a gangrenous perforated appendix was removed. The chart shows the amount and type of fluids given. On the second day edema and suppression of urine occurred. Blood chemistry determinations revealed a blood chloride of 890 milligrams per 100 cubic centimeters and a carbon dioxide combining power of 59 volumes per cent. Obviously the edema was caused by the administration of too much salt solution. When the infusion fluid was changed to 5 per cent glucose in

TABLE II — ESTIMATED REQUIREMENTS

Age	20 months	weight	24 pounds	height	28 inches
Fluids	600 cc	per lb	per 24 hrs	— 1 400 cc	per 24 hrs
Energy	25 calories	per lb	per 24 hrs	— 600 calories	per 24 hrs
Salt	Probable average minimum 0.4-0.6 gm per day				
	Average intake 1.5-2.5 gm per day				
	Maximum amount tolerated greatly above average intake				
	Determined by excretory ability of kidneys				

distilled water urine output was re established and edema disappeared. The 5 per cent glucose in water solution is practically isotonic and is the proper solution for use when water is needed and electrolytes are not depleted.

This case illustrates the effect of overzealous administration of salt solution to a child who, though slightly dehydrated, was not in electrolytic imbalance.

Another instructive case is that of a child 20 months old.

A 36 hour history revealed principally listlessness, refusal of food, purgation, vomiting and abdominal swelling. The salient point on physical examination was a huge symmetrically distended tender and rigid abdomen. The tongue was dry, the skin was wrinkled. Pulse respirations and temperature were all elevated. The specific gravity of the urine was 1.019 and acetone was present. Clearly this was a typical case of dehydration, letosis and hypochloremia. A hemoglobin of 40 indicated marked anemia. The intra abdominal complaint was first diagnosed as intestinal obstruction and operation was decided upon with the intention of exposing the cecum, possibly doing a cecostomy, and at any event examining the appendix. At operation under local anesthesia through a McBurney incision a perforated appendix with peritonitis and paralytic ileus was found. The appendix was removed and drainage instituted. The drainage consisted of a rubber tube in the pelvis, a cigarette drain at the appendiceal site and a cigarette drain in the lateral paracolic groove. The problem of postoperative treatment then arose. The requirements of the child who weighed 24 pounds were calculated on a formula basis and are expressed in Table II.

The progress of the case is shown in Chart 4. The first column represents fluids given on the day of operation as well as on the first postoperative day. The urine analyses are instructive, acetone vanished indicating that the administered glucose was effective, no sugar appeared showing that administered glucose was being utilized, the reaction changed from acid to alkaline, probably indicating that base had been replenished within the body and the kidneys were excreting the administered sodium but retaining chloride. On the third postoperative day sugar appeared in the urine and therefore the glucose

content of the infusion solution was changed from 10 per cent to 5 per cent. Thereafter the urine was sugar free. Slight puffiness of the face and decreased urine output occurred toward the end of the fourth day. Therefore the infusion solution was changed to 5 per cent glucose in water. Puffiness did not progress and the extremely low urine specific gravity of 1.002 indicated that the volume of body fluids had been more than restored. On this day too water was first given by mouth and tolerated. Parenteral fluids were therefore discontinued. Undoubtedly chloride edema was imminent on the fourth day, but this could not be determined chemically because the child's only available vein carried the infusion cannula.

The case serves as an illustration of the amount of water and salt a depleted organism may require. It also illustrates how simple observations can reveal internal changes and how therapy can, if necessary, be guided in the absence of complete laboratory data.

The edema which occurred in the first patient and was incipient in the second is the so called chloride edema. The mechanism seems to be a piling up of water, chloride and sodium (pre renal deviation) in the interstitial tissues when superfluous amounts of salt solution are administered parenterally. If plasma proteins are depleted by blood loss, wound drainage, or previous undernutrition, chloride edema will occur more readily. Profuse drainage undoubtedly plays an important rôle in depleting plasma proteins in these cases.

Patients with peritonitis are routinely given a small transfusion every other day until parenteral fluids are discontinued. In the second case 80 to 100 cubic centimeters were given each time. In larger children 150 to 300 cubic centimeters are given. The value of transfusions lies, we believe, in the support they give to the blood proteins and the immune bodies as well as to the red cells.

Distention as a complication in the post operative course deserves special mention. Not only does a distended abdomen splint the diaphragms and increase the risk of pulmonary complications, but Herrin and Meek have conclusively shown that when the bowel is distended, fluid is actually secreted into the lumen. Such fluid is lost to the body until relief of distention permits reabsorption. Heat applied intermittently to the abdomen, glycerine and water enemas and the rectal tube are

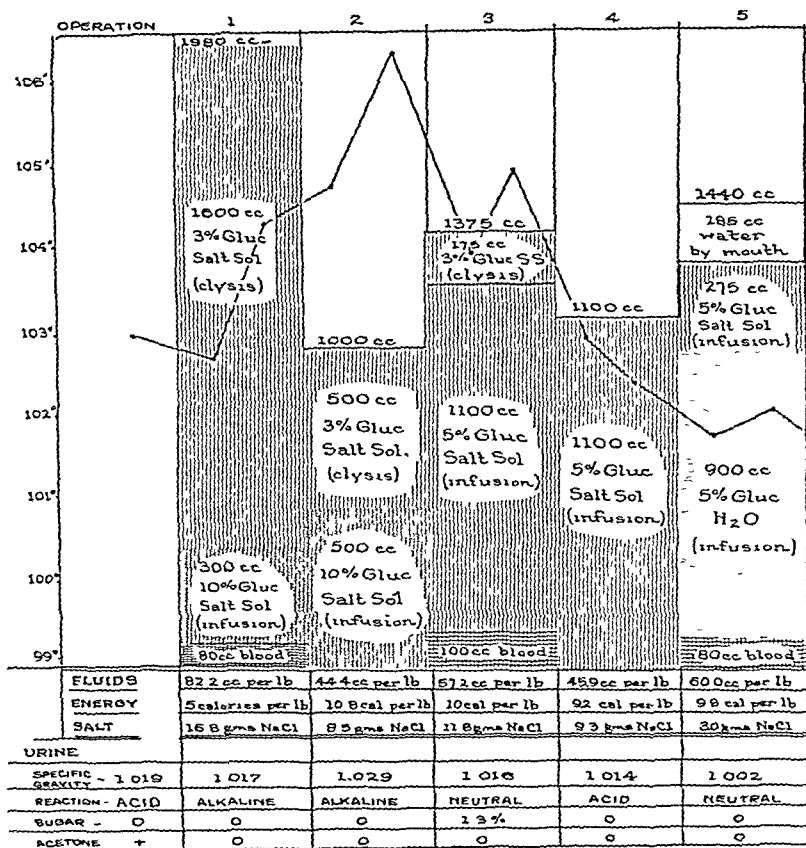

Chart 4 This chart represents successive days in the hospital. The amounts and types of fluid are indicated. A temperature chart is superimposed.

sometimes sufficient to control distention. When they are not adequate, the Wangensteen suction apparatus and repeated small doses of pitressin practically always bring relief. We believe that the relief of distention far outweighs the possibility of spreading a peritonitis by stimulation of bowel contractions.

In the suppurative and peritonitis cases the presence of nausea, vomiting, and distention calls for the use of gastric lavage, preferably by means of the Wangensteen suction apparatus. In the peritonitis cases this procedure is used routinely, both before and after operation. Fluid requirements are estimated. When the daily intake and output are balanced, fluid losses by perspiration, vomitus, Wangensteen drainage, and other drainage must be replaced by salt solution. Blood loss is obviously best replaced by blood. Fluid loss in

urine and by vaporization should be replaced by distilled water. Fluids are given subcutaneously or intravenously. Normal salt solution is used subcutaneously. Intravenously, 5 per cent glucose in normal salt solution is alternated with 5 per cent glucose in distilled water as calculations indicate. Half normal saline solution with $2\frac{1}{2}$ per cent glucose may be used.

The preservation or restoration of normal cellular environment is the sole purpose of fluid administration. Critical clinical observation with frequent blood counts and daily urinalyses must sometimes serve as the only guides. When determinations of plasma chloride concentration and carbon dioxide combining power, together with blood urea and blood sugar values can be obtained, additional information is secured.

TABLE III — POSTOPERATIVE COMPLICATIONS

Complication	Cases
Intestinal obstruction	4
Fecal fistula	1
Transient fecal fistula	3
Secondary abscess	2
Wound infection	6
Pneumonia	3
Bronchitis	2
Otitis media bilateral	1
Acute tonsillitis	1
Abscess of thigh following hypodermoclysis	1

POSTOPERATIVE COMPLICATIONS

The postoperative complications in this series are shown in Table III. They are the conditions which increased morbidity and, in some cases, threatened to increase mortality. Concurrent illnesses present on admission, such as diabetes or pyelitis, are not listed. Complications which caused death are discussed in the section on mortality. Those listed here resulted in complete recovery.

Intestinal obstruction was by far the most serious postoperative complication. It occurred in 4 cases. All were of the perforated group

CASE 1. Patient developed intestinal obstruction on the twentieth day. Obstruction was found at the terminal ileum. Ileocolostomy and an ileostomy above the anastomosis were performed. The child left the hospital 26 days after the second operation.

CASE 2. Patient developed obstruction on the twenty-ninth day. Obstruction was found at the terminal ileum, adhesions were divided and the obstruction was relieved. The child was discharged 23 days after the second operation.

CASE 3. Patient developed obstruction on the nineteenth day, failed to respond to conservative treatment and was operated upon the twentieth day. A loop of ileum was bound down in the pelvis, kinked and obstructed. The loop was freed thus relieving obstruction but due to torn serosa and exudate in this part of the ileum an ileo-ileostomy was performed. Patient was discharged 20 days later.

CASE 4. Patient developed obstruction on the nineteenth postoperative day. The obstruction was found due to the matting together of loops of small intestine about an abscess. The abscess was drained. Ileostomy was performed above the involved ileum. Patient was discharged 27 days after the second operation.

It is of interest to note that the primary operation in these 4 cases was performed through a McBurney incision. This, we feel, made the secondary operations less complicated by using a right rectus incision the obstruction was

approached through an uncontaminated field free of adhesions.

Fecal fistula. Four patients developed fecal fistulas. All of these at primary operation had a ruptured appendix and required drainage.

CASE 1. Fecal drainage started on the third day after operation and ceased on the eleventh day. The entire stay in the hospital was 24 days.

CASE 2. At the primary operation the appendiceal junction was gangrenous. A fecal fistula developed 16 days after operation following the removal of drainage. Free drainage ceased in 14 days. Intermittent drainage continued for 2 more weeks. The entire stay in the hospital was 59 days.

CASE 3. A fecal fistula developed 12 days after operation and drained for 8 days. The child was in the hospital 32 days.

CASE 4. This is the only case in the fecal fistula group which did not heal spontaneously. At primary operation the appendix was not removed. Abscesses under the liver in the pelvis and at the ileocecal junction were drained. A fistula appeared on the eighth day. The child had a very stormy convalescence. The fecal fistula failed to heal spontaneously. A second operation several months later revealed multiple fistulas to the cecum and terminal ileum necessitating a resection of the cecum and terminal ileum followed by an ileocolostomy.

Secondary abscesses. In two cases secondary abscesses developed.

CASE 1. At the primary operation a perforated appendix was removed. One cigarette drain was placed down to the appendiceal site and one rubber tube in the pelvis. The child pulled out the drains on the sixth day. A secondary pelvic abscess formed which necessitated operation and drainage on the fifteenth day.

CASE 2. At primary operation a gangrenous appendix covered with exudate was removed. The wound was closed without drainage. Patient had a stormy postoperative period. Finally on the thirty-fourth day after operation a huge pelvic abscess was drained by the abdominal route. The abscess extended from the pelvis up the left paracolic groove.

Wound infection. Six cases occurred. One of the 6 was a drained case in which the spread of infection necessitated the laying open of the entire wound. No other drained cases are included. Of the 5 remaining wound infections, 2 occurred after secondary operations for intestinal obstruction. Only one McBurney incision became infected.

Pneumonia. The 3 cases were all the bronchial type. One occurred on the twenty-third day following an acute tonsillitis which first

TABLE IV.—DIVISION OF CASES IN THREE GROUPS

	Number	Percentage	Deaths	Mortality %
1 Non-perforated cases	146	62.2	0	0
2 Perforated with localized abscess	14	5.9	1	7.1
3 Perforated with peritonitis	75	31.9	9	12.0
Total	235	100.0	10	4.26

TABLE V.—CHILDREN 5 YEARS OF AGE AND UNDER

	Number	Percentage	Deaths	Mortality %
Non-perforated cases	10	30.3	0	0
Perforated with peritonitis	23	69.7	5	21.7
Perforated with localized abscess	0	0	0	0
Total	33	100.0	5	15.15

appeared on the eighteenth day. The second case was further complicated by bilateral otitis media. The patient, who was 18 months of age, and whose appendix was perforated, had a head cold when he was admitted to the hospital.

A single case of abscess following hyperdermoclysis casts no reflection on a procedure which is very valuable in children.

MORTALITY

Of the 235 cases in this series 10 patients died, setting the mortality at 4.26 per cent. Eighty-nine, or 31.0 per cent of the cases, were perforated and all the deaths occurred in this group, thus giving a mortality of 11.2 per cent for all the ruptured cases. Fourteen of the latter were cases of localized abscess. One of these patients died, making the mortality for the localized abscess group 7.1 per cent. The perforated cases are not divided into subgroups of local or spreading peritonitis. It is often difficult to tell the extent of peritonitis at the operating table, this is especially true when the McBurney incision, the incision of choice at this clinic, is used. Moreover, different operators will not agree on the extent of a peritonitis. Bancroft, in a recent article, is also of this opinion. We divide our cases into 3 groups: non-perforated, perforated with localized abscess, and perforated with peritonitis (Table IV).

McLanahan	27	—	22.2
Heyl	90	—	12.2
This series	33	69.6	15.15

*These cases are 9 per cent of 250

Thirty-three of the cases were 5 years of age or younger. This group is 13.6 per cent of the entire series (Table V). The general mortality of the group is 15.15 per cent. Twenty-three, or 69.6 per cent, were perforated and 5 of these cases died, a mortality of 21.7 per cent for ruptured cases in the younger age group. No cases of localized abscess occurred in this group.

These figures are compared with mortality rates from other clinics (Tables VI and VII).

A summary of the histories of the 10 patients who died follows and our decision as to the cause of death is noted for each (Table VIII):

CASE 1. P. S., aged 11 years. Patient had been sick 3 days and had been purged. Child was operated on 8 hours after admission, following an infusion of saline and glucose. The appendix was perforated, peritonitis was present. Operation consisted merely of drainage, the appendix not removed. The child died 48 hours after operation, cause of death, peritonitis.

CASE 2. R. H., aged 8 years. Child came to the hospital and a diagnosis of subacute appendicitis, bronchitis, and pharyngitis was made. She was operated on 10 days after admission. A diagnosis of chronic or subsiding appendicitis was then made.

TABLE III—CAUSES OF DEATH

	Number
Peritonitis	5
Secondary abscess followed by peritonitis	1
Intestinal obstruction	2
Intestinal obstruction and peritonitis	1
Pneumonia	1

At operation a retrocecal appendix was found with localized abscess at the tip. The appendix was removed and drainage was instituted. Child died of peritonitis 14 days after operation. A fecal fistula having developed.

CASE 3 J W aged 5 years. Patient had been ill 48 hours. Entered hospital with temperature of 104 degrees, pulse, 130 respirations, 40. Child was operated on immediately, and a ruptured appendix with peritonitis was found. Appendectomy and drainage were done. The child died 2 days following operation of peritonitis, due to the streptococcus.

CASE 4 L D aged 2 years. Child had been ill 6 days with persistent vomiting. Was in hospital 10 hours before operation. Before operation patient was given an infusion. At operation a perforated appendix with peritonitis was found. Appendectomy and drainage. Child died 60 hours after operation cause of death peritonitis.

CASE 5 J K, aged 2½ years had been ill 48 hours. At operation a ruptured appendix with peritonitis was found. There was also a pedunculated Meckel's diverticulum which was evidently not involved. The child died 24 hours after operation, from peritonitis. Cultures showed the colon bacillus.

CASE 6 L W aged 4 years had been ill 4 days. Persistent vomiting had been present for 24 hours before admission. At operation a ruptured appendix was found with peritonitis. A link in the terminal ileum produced complete obstruction. Operation consisted of appendectomy and drainage and the freeing of obstruction. Child died 1 hour after operation. The cause of death was intestinal obstruction and peritonitis.

CASE 7 W K aged 7 years. At primary operation a ruptured appendix with peritonitis was found. Appendectomy with drainage was done. Convalescence was normal for 10 days then intestinal obstruction developed. A second operation was done revealing obstruction in the terminal ileum due to adhesions to the abdominal wall. The terminal ileum was beefy and dark in color. Ileocolostomy was performed. Patient died 24 hours following last operation—cause of death intestinal obstruction.

CASE 8 A C aged 7 years. Child had been ill 48 hours. At operation a perforated appendix with peritonitis was found. Appendectomy and drainage were done. Convalescence was normal for 7 days then child developed symptoms of intestinal obstruction. Patient was carried along for another 24 hours, and was then operated again. The terminal ileum was obstructed due to adhesions at the appendiceal site. The adhesions were separated and the obstruction was released. The child died 4 days

following this operation—cause of death intestinal obstruction.

CASE 9 M B aged 3 years. Child had been ill 4 days before operation. At operation a ruptured appendix with peritonitis was found. Child had a normal convalescence for 16 days after operation then developed temperature and cough and then bronchial pneumonia. The chest was tapped and thin pus was obtained. Culture of which showed the streptococcus. The cause of death was bronchopneumonia complicated by empyema.

CASE 10 J M aged 4 years had been ill 2 days. At operation a ruptured appendix with peritonitis was found. Appendectomy and drainage were done. Convalescence was normal until the fourteenth day, when child developed fever and distention. Three days later the child was again operated upon. A localized collection of pus was found in the pelvis. There was pelvic peritonitis but no obstruction. The pelvic abscess was drained. Child died 7 days following last operation—cause of death, peritonitis.

In the first 5 cases we believe that the primary cause of death was peritonitis. Case 1 is the only one in the series in which the appendix was not removed in the presence of peritonitis. In Case 2 there was an appendiceal abscess and the appendix was removed with difficulty, which we feel was an error in operative judgment, for following the operation the child developed a typical peritonitis. In Case 5 a Meckel's diverticulum, which was not diseased, was removed. Such procedures we feel are not wise in the presence of an acute appendiceal infection.

In Case 6 there was a linked terminal ileum with obstruction in addition to the appendiceal lesion. The child's preoperative condition was critical and operation was finally decided upon with hesitancy. The child died 1 hour after operation. In this case nothing could have been lost by delaying operation decompressing the intestinal tract, and administering fluids.

In Cases 7 and 8 deaths are clearly due to postoperative intestinal obstruction. The cases were operated upon a second time on the seventh and tenth days respectively, and the obstruction was found at the terminal ileum. In Case 7 an ileocolostomy was performed. In Case 8 the adhesions were simply freed.

In Case 9 convalescence was normal for 16 days when a bronchopneumonia developed. We feel warranted in listing this as a pulmonary death.

In Case 10 a secondary pelvic abscess developed requiring a second operation and drainage. The child died of a pelvic peritonitis.

In reviewing the operative technique in these 10 fatal cases, the authors feel it is very significant that the McBurney incision was employed in only one of the cases, the right rectus being used in the others.

SUMMARY AND CONCLUSIONS

A series of 235 cases of acute appendicitis in children is presented. The series is studied from the viewpoint of what can be done for a child with acute appendicitis when patient enters a hospital. The details of pre-operative preparation, operative procedure, and post-operative care are discussed. The use of parenteral fluids is stressed as the most important part of postoperative care.

Although acute appendicitis is a common disease and its treatment is standardized to some extent, the mortality from this illness is still too high. The mortality of appendicitis is particularly high at the extremes of life.

The series of cases presented covers 7 years. The general mortality is 4.26 per cent and the mortality for children 5 years of age and younger is 15.15 per cent. The first 3 and the last 4 years of the study show clear-cut differences in operative procedures, postoperative treatment, and mortality. In the second of these two periods the mortality of acute appendicitis with perforation and peritonitis was strikingly lowered. In the entire series it fell from 16.3 per cent to 6.5 per cent. In the children under 6 years of age it fell from 33.3 per cent to 17.6 per cent.

A decrease in the use of the right rectus incision and an increase in the use of the McBurney incision paralleled the fall in mortality.

During the first 3 years of the study, fluid administration was poorly understood; but in the last 4 years, with increasing knowledge of underlying physiology, the use of parenteral fluids and their importance as an integral part of postoperative treatment was definitely established.

We believe that by continued emphasis of three cardinal points, namely, careful pre-

operative preparation, individualized operative technique, and skillful postoperative care, a further reduction in the mortality of acute appendicitis in children can be attained.

TABLE VIII—CAUSES OF DEATH

	Number
Penttonitis	5
Secondary abscess followed by penttonitis	1
Intestinal obstruction	2
Intestinal obstruction and penttonitis	1
Pneumonia	1

At operation a retrocecal appendix was found with localized abscess at the tip. The appendix was removed and drainage was instituted. Child died of peritonitis 14 days after operation. A fecal fistula having developed.

CASE 3 J W aged 5 years. Patient had been ill 48 hours entered hospital with temperature of 104 degrees, pulse, 130 respirations 40. Child was operated on immediately and a ruptured appendix with peritonitis was found. Appendectomy and drainage were done. The child died 2 days following operation of peritonitis due to the streptococcus.

CASE 4 L D aged 2 years. Child had been ill 6 days with persistent vomiting. Was in hospital 10 hours before operation. Before operation patient was given an infusion. At operation a perforated appendix with peritonitis was found. Appendectomy and drainage. Child died 60 hours after operation cause of death peritonitis.

CASE 5 J H, aged 255 years had been ill 48 hours. At operation a ruptured appendix with peritonitis was found. There was also a pedunculated Meckel's diverticulum which was evidently not involved. The child died 24 hours after operation, from peritonitis. Cultures showed the colon bacillus.

CASE 6 L W aged 4 years had been ill 4 days. Persistent vomiting had been present for 24 hours before admission. At operation a ruptured appendix was found with peritonitis. A kink in the terminal ileum produced complete obstruction. Operation consisted of appendectomy and drainage and the freeing of obstruction. Child died 1 hour after operation. The cause of death was intestinal obstruction and peritonitis.

CASE 7 W K aged 7 years. At primary operation a ruptured appendix with peritonitis was found. Appendectomy with drainage was done. Convalescence was normal for 10 days then intestinal obstruction developed. A second operation was done revealing obstruction in the terminal ileum due to adhesions to the abdominal wall. The terminal ileum was beefy and dark in color. Ileocolostomy was performed. Patient died 24 hours following last operation—cause of death intestinal obstruction.

CASE 8 A C aged 7 years. Child had been ill 48 hours. At operation a perforated appendix with peritonitis was found. Appendectomy and drainage were done. Convalescence was normal for 7 days then child developed symptoms of intestinal obstruction. Patient was carried along for another 14 hours and was then operated again. The terminal ileum was obstructed due to adhesions at the appendiceal site. The adhesions were separated and the obstruction was released. The child died 4 days

following the operation—cause of death intestinal obstruction.

CASE 9 M B aged 3 years. Child had been ill 4 days before operation. At operation a ruptured appendix with peritonitis was found. Child had a normal convalescence for 16 days after operation then developed temperature and cough, and then bronchial pneumonia. The chest was tapped and thin pus was obtained culture of which showed the streptococcus. The cause of death was bronchopneumonia complicated by empyema.

CASE 10 J M, aged 4 years had been ill 2 days. At operation, a ruptured appendix with peritonitis was found. Appendectomy and drainage were done. Convalescence was normal until the fourteenth day, when child developed fever and distention. Three days later the child was again operated upon. A localized collection of pus was found in the pelvis. There was pelvic peritonitis but no obstruction. The pelvic abscess was drained. Child died 2 days following last operation—cause of death peritonitis.

In the first 5 cases we believe that the primary cause of death was peritonitis. Case 1 is the only one in the series in which the appendix was not removed in the presence of peritonitis. In Case 2 there was an appendiceal abscess and the appendix was removed with difficulty, which we feel was an error in operative judgment for following the operation the child developed a typical peritonitis. In Case 5 a Meckel's diverticulum, which was not diseased, was removed. Such procedures we feel are not wise in the presence of an acute appendiceal infection.

In Case 6 there was a kinked terminal ileum with obstruction in addition to the appendiceal lesion. The child's pre-operative condition was critical and operation was finally decided upon with hesitancy. The child died 1 hour after operation. In this case nothing could have been lost by delaying operation decompressing the intestinal tract, and administering fluids.

In Cases 7 and 8 deaths are clearly due to postoperative intestinal obstruction. The cases were operated upon a second time on the seventh and tenth days respectively, and the obstruction was found at the terminal ileum. In Case 7 an ileocolostomy was performed, in Case 8 the adhesions were simply freed.

In Case 9 convalescence was normal for 16 days when a bronchopneumonia developed. We feel warranted in listing this as a pulmonary death.

INTRAVENOUS CALCIUM CHLORIDE AND ITS USE FOR THE RELIEF OF VISCERAL COLIC

A Clinical and Experimental Study

R S LAMPSON, M D, Hartford, Connecticut, and F. A. SIMEONE, M D, Boston, Massachusetts

SINCE Aub and his associates first observed that calcium chloride given by vein to patients with lead colic produced immediate relief, little has been done to emphasize the importance of this drug as an agent for the relief of spasmodic visceral pain. A search of the literature reveals that its use as an analgesic has been limited. Bauer, Salter, and Aub reported favorable results from its administration in various colics. The cramps of bile duct and ureteral obstruction and those of tuberculous enteritis and lead colic have been readily relieved by its use. The pain in these cases was thought to result from smooth muscle spasm, and the relief was attributed to smooth muscle relaxation. Calcium chloride, therefore, was credited with the property of relaxing smooth muscle. With these facts in mind it seemed worth while to investigate further its usefulness in the relief of colic-like pain and in bladder spasm. This report is a presentation of clinical observations on the effects of intravenous calcium chloride and of experimental studies dealing with its mode of action.

PROCEDURE

The clinical value of intravenous calcium chloride was tested by administering the drug to patients suffering from severe visceral pain on the surgical and urological services of the Massachusetts General Hospital. Each patient received one or more 10 cubic centimeter doses of a sterile aqueous solution of 10 per cent calcium chloride at a rate of 1.5 to 2 cubic centimeters per minute. Since calcium chloride is irritating in extravascular tissues, care was taken to avoid subcutaneous injection. The drug produced, in all cases, a warm sensation in the mouth and often over the entire

body. The intensity of this reaction was used as a guide to the rate of injection. Occasionally, if given too rapidly, nausea was experienced and rarely vomiting followed. There was no demonstrable effect upon the heart rate. The drug is contra-indicated in patients receiving digitalis. Calcium chloride in large doses in animals produces bradycardia and finally cessation of the heart beat in systole (6, 8). This action apparently is intensified in digitalized subjects. Two fatalities have recently been reported following the intravenous administration of calcium salts in patients who were receiving digitalis (4).

Calcium chloride was given to 16 patients suffering from various kinds of spasmodic pain. Nine were completely relieved, 3 partially relieved, and 4 were not benefited. The 16 patients may be classified in 4 groups, according to the type of colic: (1) 8 patients suffering from renal colic; (2) 5 patients suffering from severe bladder spasm secondary to urethral or trigone irritation; (3) 2 patients suffering from excruciating gall-stone colic; (4) 1 patient complaining of postoperative gas pains.

EXPERIMENTAL OBSERVATIONS

In order to obtain information on the mode of action of calcium chloride, cystometric studies were made in 9 patients. Six of these had abnormal bladders from prostatic obstruction, and 3 had normal bladders. The human urinary bladder was chosen for study because it is easily adaptable to cystometry; because it is composed chiefly of smooth muscle controlled by the autonomic nervous system; and because an important part of the clinical material presented bladder symptoms. A simple water manometer connected to a fluid reservoir served as a very accurate cystometer. A standard rubber urethral catheter was used to connect the apparatus with the

derived. The experimental findings are illustrated by Figures 1 and 2. The observations fall in groups as follows

Group 1. Renal colic. Five of the 8 patients with renal colic were relieved of their pain for 10 to 45 minutes; 2 were relieved for 12 hours or more, and 1 received no benefit. This last case was unusual in that the pain was secondary to the congenital anomaly of double pelvis and ureter. No evidence of obstruction or inflammation was found in this patient at the time of operation.

Group 2. Bladder spasm. After intravenous calcium chloride, 3 of the 5 patients suffering from severe bladder spasm were relieved of pain for 5 to 18 hours. Repetition of the drug in each favorable case was followed by a similar beneficial effect. Two patients received no benefit. Both of these were suffering from spasm secondary to such extensive disease that relief was obtained only by repeated large doses of morphine.

Group 3. Gall-bladder colic. Two patients suffering from severe gall-stone colic were completely relieved for $\frac{1}{2}$ and 10 hours, respectively, after the administration of calcium chloride. Both patients were operated upon and each was found to have common duct stones.

Group 4. Postoperative gas pains. One patient suffering from gas pains 4 days after appendectomy was given the drug without relief.

Group 5. Cystometric observations. The cystometrograms of normal and pathological bladders have been discussed in another paper (9). After the administration of calcium chloride, in no case was there any change in the

Fig 1 Normal cystometrogram of a 50 year old man. Ten cubic centimeters of 10 per cent calcium chloride were given intravenously as indicated, with no effect upon the shape of the curve.

shape of the cystometrogram or in the tone of the bladder. The sensations of urgency experienced as the bladder became distended were not relieved, nor were the marked rhythmic contractions observed at this point altered by the drug (Figs 1 and 2).

Fig 2 A kymographic record of the same experiment showing that there is no change upon the bladder tone.

TABLE I—CASES IN WHICH CALCIUM CHLORIDE WAS EFFECTIVE

Patient	Disease	Type of pain	Effect of CaCl	Remarks
F M 5 F 342-903	Left ureteral lithiasis	Renal colic	Immediate relief of pain	Patient awakened at 2 a.m. with severe renal colic in spine. Following ureteral catheter After CaCl ₂ had immediate relief of pain and slept again. Pain did not recur.
E M 18 F 343-610	Left hydro-nephrosis from obstructed vessel	Renal colic	Immediate relief of pain	Colic completely relieved until operation 2 days later but after 3 hrs patient had a return of dull ache in left C.V. which did not require medication. At operation hydronephrosis and obstructed vessel found.
M F 31 M E.W. 44 n	Ureteral lithiasis	Renal colic	Immediate relief of pain	Patient was given 1 gr of mephine with part 1 of CaCl ₂ before CaCl ₂ . Followed complete relief for 45 min. A second dose of 1 gr later was effective for 10 min. Vomiting produced each time.
W B 30 M E.W. 4 n	Polycystic kidneys	Renal colic	Immediate relief of pain	Complete relief of the colic after 12 hrs but dull left flank pain remains. Retrograde pyelogram showed bilateral polycystic kidneys.
N O 40 M E.W. 415	Right nephrolithiasis	Renal colic	Immediate relief of pain	Had been having constant severe colic until CaCl ₂ was given. Pain to some extent was produced for 10 min. The colic was relieved but a dull ache remained. Colic then returned and was partially relieved by morphine 1 gr.
F H 64 F 343-447	Right renopelvic lithiasis	Renal colic	Immediate relief of pain	Awakened with severe colic. CaCl ₂ produced relief of colic for 30 min. Dull ache remained. Right renopelvic lithiasis was demonstrated by x-ray and confirmed at operation.
G M 33 M 343-259	Left ureterolithiasis	Renal colic	Immediate relief of pain	Entered having severe renal colic from a renal pelvic stone. CaCl ₂ produced immediate relief of the colic but a dull ache remained. The colic did not recur during the 4 days after operation before operation. Retrograde pyelogram showed stone and hydronephrosis of left kidney confirmed at operation.
F S 65 M 342-344	Ruptured urethra	Bladder spasm	Immediate relief of complete	Patient on constant drainage to ruptured urethra. Developed severe bladder spasm around the catheter. Given CaCl ₂ three times in 3 days with complete relief for 12 to 18 hrs each time.
E I 23 F 342-204	Constant drainage of bladder	Bladder spasm	Immediate relief of complete	Patient on constant drainage but having severe bladder spasm. Given CaCl ₂ three times in 10 days with relief for 18 to 24 hrs each time. Had previous history of bladder spasm after 1/2 hr. Complete relief on several occasions.
A B 70 M 342-057	Benign prostatic hypertrophy	Bladder spasm	Immediate relief of complete	Perineal prostatectomy, placing catheter. Spasms at 15 min intervals relieved by CaCl ₂ 4 hrs. Second dose 15 hrs later had a similar effect.
A O 41 M 342-033	Cholelithiasis	Biliary colic	Immediate relief	Very frequent attacks relieved for 4 hrs permitting sleep after each of two doses on separate days. Common duct not removed. Peristalsis.
N R 44 F 342-044	Cholelithiasis	Biliary colic	Immediate relief	Awakened by severe colic. Given CaCl ₂ with complete relief for 10 hrs. Common duct not removed. Peristalsis.

TABLE II—CASES IN WHICH CALCIUM CHLORIDE WAS NOT EFFECTIVE

Patient	Disease	Type of pain	Effect of CaCl	Remarks
S M 8 F 342-628	Double right ureter and pelvis	Renal colic	relief	Patient had attacks typical renal colic. Pyelogram showed double right ureter and pelvis with obstruction in either. At operation there was no evidence of lithiasis or infection.
S T 64 M 342-307	Benign prostatic hypertrophy marked cystitis	Bladder spasm	No relief	May have bladder spasms around only catheter. Given two doses of CaCl ₂ without relief of either cystitis or spasm. Patient had a very severe cystitis.
C T 74 M 342-357	Constant drainage of bladder	Bladder spasm	No relief	Patient with severe bladder spasm. Suprapubic tube placed but no relief of spasm. The dose was too low and there was marked cystitis. The dose of CaCl ₂ was ineffective.
H G 10 M 343-534	Acute appendicitis postoperative	Gas pain	No relief	Patient having other marked gas pain in second postoperative day. Given CaCl ₂ with no relief.

bladder. A Brodie bellows which recorded on a smoked drum kymograph was attached to the open top of the manometer when permanent records were desired (9). Ten cubic centimeters of 10 per cent calcium chloride was given intravenously to each of these patients at different points along the cystometric curve.

RESULTS

In the group of cases in which calcium chloride was given therapeutically the results were extremely gratifying and in some cases dramatic. Table I gives a summary of each case which responded favorably to the drug and Table II lists the cases in which no benefit was

THE RELATION OF SPASM OF THE SECOND PORTION OF THE DUODENUM TO BILIARY COLIC

JOHN M. MCGOWAN, M D, Quincy, Massachusetts

PAUL A. KNEPPER, M.D., Gilman, Colorado,

WALTMAN WALTERS, M D, F.A.C.S., and ALBERT M. SNELL, M D, Rochester, Minnesota

PREVIOUS papers by three of us (2, 3, 4, 7) and Butsch were concerned with reports showing that, in certain individuals, attacks of biliary colic following cholecystectomy were associated with contraction of the sphincter of the common bile duct which temporarily prevented bile from entering the duodenum and which resulted in elevations of pressure within the biliary system. It was shown that morphine could produce this spasm, and that in cases in which patients were suffering from the syndrome of postcholecystectomy colic its administration would result in a definite and severe attack of biliary colic.

The question that presented itself to us at that time was whether or not the spasm associated with postcholecystectomy biliary pain involved only the separate sphincter of the common duct, the existence of which was recently demonstrated embryologically by Boyden, or whether the duodenal musculature was also involved. That disturbed gastrointestinal motility is in some way involved in biliary colic has been shown by the studies of Westphal who demonstrated delayed emptying of the stomach during attacks of biliary pain. The findings to be reported here are in partial accord with Westphal's observation, and they support the theory that contraction of the duodenal musculature may play a rôle in the production of certain symptoms associated with biliary colic.

METHODS OF STUDY

Both patients suffering from repeated attacks of postcholecystectomy biliary colic and a series of normal individuals were studied

From the Divisions of Surgery and of Medicine, The Mayo Clinic

In each case a Sawyer tube was passed into the stomach. The patient was directed to lie on his right side, and the stomach was repeatedly lavaged with warm water in order to free it of all mucus and secretion. The tube was then allowed to pass into the duodenum, its location was verified by a free flow of clear bile, by a characteristic tugging sensation transmitted to the piston of the syringe when the tube was aspirated, and by roentgenograms. The duodenal tube was then connected to a straight, glass tube manometer containing a float for recording changes in pressure on a smoked drum (Fig. 1). The system was filled from a reservoir bottle with warm physiologic saline solution. When the reservoir was clamped off from the rest of the system, there remained a continuous column of water extending from the duodenum to the manometer. The readings of pressure thus obtained were recorded in millimeters of water.

In a few cases a rubber balloon was tied over the lower end of the duodenal tube; this was passed into the duodenum and a small amount of water was injected into it through the duodenal tube. Care was taken not to overdistend either the rubber bag or the duodenum. The end of the closed tube was then attached to the manometer for measuring changes in pressure within the duodenum. The closed system gave results identical to those obtained when the open system was used.

On several occasions in one case, two duodenal tubes were passed simultaneously. To one was attached a rubber bag, whereas the other opened freely into the duodenum. By switching the manometer from one tube to the other, without allowing the escape of fluid and therefore not altering the volume of fluid

EVALUATION OF STUDY

The use of calcium chloride for the relief of colic like visceral pain is empirical in that no satisfactory explanation for its action has been advanced. Several interesting observations, however, can be assembled and speculations offered. It was suggested and discarded by Aub and his associates that calcium chloride produced relief by relaxing smooth muscle. Their observations on the activity of obstructed intestinal loops in dogs showed that no change was produced by intravenous calcium chloride when given in twice the human dosage (5). Rozen and Perusse were unable to demonstrate definite effects on gastric contractions in dogs by oral or intravenous administration of calcium chloride or lactate. Bigg and Rosenblueth have shown that in the cat calcium chloride does not relax smooth muscle in the nictitating membrane or the non pregnant uterus. In fact, the drug was shown to produce contraction of these structures. In the experimental observations reported herein, the discomfort induced by distention and contraction of the bladder was not relieved, nor was the tone of the bladder musculature relaxed. From this evidence it appears that calcium chloride does not bring relief of pain by producing relaxation of the smooth muscle.

The clinical cases reported here in which calcium chloride was used for the relief of pain fell into two main groups: 14 cases in which there was an irritative background and 2 with no irritative element. In the first group symptomatic relief was produced in all but 2 cases, in both of which the disease was so extensive that only large doses of morphine afforded relief. In the second group calcium chloride produced no relief. It appears that calcium chloride is effective in the patients with spasmodic pain resulting from a localized irritative state. Since calcium chloride does not produce relaxation of smooth muscle it is reasonable to assume that it acts by exerting an analgesic effect upon the nervous system. Whether it

interrupts afferent impulses or exerts its effect centrally is problematical.

Whatever its mode of action may be calcium chloride is a valuable drug for the relief of spasmodic pain. It acts promptly. It is a diagnostic aid in that when the pain is relieved, the marked voluntary muscular spasm which accompanied the pain is relaxed. This permits more careful examination of the patient without the generalized sensory depression which is brought about by morphine or its derivatives.

SUMMARY

1. The effectiveness of calcium chloride in the relief of colic like visceral pain has been demonstrated.

2. Calcium chloride is contra indicated in digitalized patients.

3. Calcium chloride was found to have no effect on the tone or contractions of the human bladder.

4. A suggestion for its mode of action has been offered.

THE RELATION OF SPASM OF THE SECOND PORTION OF THE DUODENUM TO BILIARY COLIC

JOHN M. MCGOWAN, M.D., Quincy, Massachusetts

PAUL A. KNEPPER, M.D., Gilman, Colorado,

WALTMAN WALTERS, M.D., F.A.C.S., and ALBERT M. SNELL, M.D., Rochester, Minnesota

PREVIOUS papers by three of us (2, 3, 4, 7) and Butsch were concerned with reports showing that, in certain individuals, attacks of biliary colic following cholecystectomy were associated with contraction of the sphincter of the common bile duct which temporarily prevented bile from entering the duodenum and which resulted in elevations of pressure within the biliary system. It was shown that morphine could produce this spasm, and that in cases in which patients were suffering from the syndrome of postcholecystectomy colic its administration would result in a definite and severe attack of biliary colic.

The question that presented itself to us at that time was whether or not the spasm associated with postcholecystectomy biliary pain involved only the separate sphincter of the common duct, the existence of which was recently demonstrated embryologically by Boyden, or whether the duodenal musculature was also involved. That disturbed gastrointestinal motility is in some way involved in biliary colic has been shown by the studies of Westphal who demonstrated delayed emptying of the stomach during attacks of biliary pain. The findings to be reported here are in partial accord with Westphal's observation, and they support the theory that contraction of the duodenal musculature may play a rôle in the production of certain symptoms associated with biliary colic.

METHODS OF STUDY

Both patients suffering from repeated attacks of postcholecystectomy biliary colic and a series of normal individuals were studied

In each case a Sawyer tube was passed into the stomach. The patient was directed to lie on his right side, and the stomach was repeatedly lavaged with warm water in order to free it of all mucus and secretion. The tube was then allowed to pass into the duodenum; its location was verified by a free flow of clear bile, by a characteristic tugging sensation transmitted to the piston of the syringe when the tube was aspirated, and by roentgenograms. The duodenal tube was then connected to a straight, glass tube manometer containing a float for recording changes in pressure on a smoked drum (Fig. 1). The system was filled from a reservoir bottle with warm physiologic saline solution. When the reservoir was clamped off from the rest of the system, there remained a continuous column of water extending from the duodenum to the manometer. The readings of pressure thus obtained were recorded in millimeters of water.

In a few cases a rubber balloon was tied over the lower end of the duodenal tube; this was passed into the duodenum and a small amount of water was injected into it through the duodenal tube. Care was taken not to overdistend either the rubber bag or the duodenum. The end of the closed tube was then attached to the manometer for measuring changes in pressure within the duodenum. The closed system gave results identical to those obtained when the open system was used.

On several occasions in one case, two duodenal tubes were passed simultaneously. To one was attached a rubber bag, whereas the other opened freely into the duodenum. By switching the manometer from one tube to the other, without allowing the escape of fluid and therefore not altering the volume of fluid

Fig. 1. An apparatus for measuring changes in intraduodenal pressure

within the duodenum, we were able to demonstrate clearly that the results obtained using the open tube, were identical to those obtained when using the balloon (Fig. 2)

In some cases roentgenological studies were made by injecting a suspension of barium into the duodenum through the duodenal tube. When resistance to injection was noted, a roentgenogram was taken when no resistance to the injection was experienced, as is usually the case with normal subjects. 40 cubic centimeters of the barium suspension were injected. Duodenal motility was observed fluoroscopically in a few cases. In other cases, patients who had had a T tube inserted in the common duct for prolonged biliary drainage kindly consented to serve as subjects for simultaneous studies on the behavior of the sphincter and the duodenum.

RESULTS

Studies were made in three groups of cases, and 25 determinations of intraduodenal pressure were made on 17 subjects. Group 1 consisted of 6 normal individuals who served as controls. Group 2 consisted of 5 patients who

had suffered from repeated attacks of postcholecystectomy biliary colic unaccompanied by jaundice, chills or fever, in these cases attacks of pain could be induced by the subcutaneous administration of $1/6$ grain (0.01 gm) of morphine sulphate, and these attacks could then be completely and consistently relieved by the sublingual administration of $1/100$ grain (0.0006 gm) of glyceryl trinitrate. Group 3 consisted of 6 patients who had suffered unusually severe and frequent attacks of postcholecystectomy pain which had been relieved by the administration of glyceryl trinitrate only occasionally, partially or not at all.

Group 1 (normal persons) The intraduodenal pressure of normal persons ranged from minus 30 millimeters of water to zero, zero being designated as the point of the manometer on a level with the xiphoid process when the patient was in the recumbent position. Tracings of the duodenal movements in such cases showed two types of wave. One type consisted of short, small waves about 1 millimeter in height corresponding in time to respiratory movements; the second was made

Fig 2 Tracing showing reduction of intraduodenal pressure on bending the head acutely forward. In this case two tubes were inserted into the duodenum, one open and one with a rubber bag on the end. The pressure tracing from each is essentially the same.

up of longer waves independent of respiratory excursions. These last mentioned waves corresponded to a 5 millimeter increase in pressure and lasted from a half to two minutes. An increase in intra-abdominal pressure produced coughing or straining but increased the intraduodenal pressure to only a relatively small degree (10 mm of water or less).

Group 2 (patients with biliary dyskinesia). The 5 patients in this group had suffered repeated attacks of postcholecystectomy colic, this was described as pain in the right upper quadrant of the abdomen that was projected around the right subcostal margin and into the right scapular region. As has been said, pain could be induced in these cases by morphine sulphate and relieved by nitrites. Three of these patients were studied after their common bile ducts had been drained surgically by means of T-tubes. Perfusing the common bile duct at pressures of from 50 to 200 millimeters of water produced pain described by the patient as being of the same nature as that ordinarily suffered during spontaneous colics, whereas opening the T-tube, even during the attacks of spontaneous pain, gave relief. The intraduodenal pressure in these 3 cases varied from minus 50 millimeters of water to zero (zero being at xiphoid level), the average pressure was minus 35 millimeters. In other words, the resting values for intraduodenal pressure

did not differ materially from those of patients in the normal group.

These studies of intraduodenal pressure were made only during periods of freedom from pain; it seems probable that if they had been determined during attacks of pain, higher pressures would have been found. The results of studies made after the administration of morphine to a third group of patients bore out this contention.

Group 3 (patients with intractable biliary dyskinesia) This group comprised 6 patients who, following cholecystectomy, complained of pain confined to a point in the epigastrium just to the right of the midline; this pain was not projected, although occasionally it ran straight through to the back. Amyl nitrite did not relieve the pain in these cases. Three of these patients were studied while a T-tube was present in the common bile duct. Perfusing the common bile duct with saline solution at pressures up to 500 millimeters of water did not produce pain, although a feeling of fullness and distress was noted. The resting values for intraduodenal pressure in these cases were higher than those for either of the 2 other groups, and they ranged from 20 to 100 millimeters above the xiphoid level (that is, plus 20 to plus 100 millimeters of water, or an average of plus 58 millimeters). In 2 of these 3 cases attacks of pain developed while

Fig 1 An apparatus for measuring changes in intraduodenal pressure

within the duodenum, we were able to demonstrate clearly that the results obtained, using the open tube were identical to those obtained when using the balloon (Fig 2)

In some cases roentgenological studies were made by injecting a suspension of barium into the duodenum through the duodenal tube. When resistance to injection was noted, a roentgenogram was taken, when no resistance to the injection was experienced, as is usually the case with normal subjects, 40 cubic centimeters of the barium suspension were injected. Duodenal motility was observed fluoroscopically in a few cases. In other cases, patients who had had a T tube inserted in the common duct for prolonged biliary drainage kindly consented to serve as subjects for simultaneous studies on the behavior of the sphincter and the duodenum.

RESULTS

Studies were made in three groups of cases and 25 determinations of intraduodenal pressure were made on 17 subjects. Group 1 consisted of 6 normal individuals who served as controls. Group 2 consisted of 5 patients who

had suffered from repeated attacks of postcholecystectomy biliary colic unaccompanied by jaundice, chills, or fever, in these cases attacks of pain could be induced by the subcutaneous administration of $1/6$ grain (0.01 gm) of morphine sulphate, and these attacks could then be completely and consistently relieved by the sublingual administration of $1/100$ grain (0.006 gm) of glyceryl trinitrate. Group 3 consisted of 6 patients who had suffered unusually severe and frequent attacks of postcholecystectomy pain which had been relieved by the administration of glyceryl trinitrate only occasionally partially, or not at all.

Group 1 (normal persons) The intraduodenal pressure of normal persons ranged from minus 30 millimeters of water to zero zero being designated as the point of the manometer on a level with the xiphoid process when the patient was in the recumbent position. Tracings of the duodenal movements in such cases showed two types of wave. One type consisted of short small waves about 1 millimeter in height corresponding in time to respiratory movements, the second was made

Fig 4 Duodenum of a patient with a persistently high intraduodenal pressure: a, Resting state showing obstruction in third portion and some spasm in second portion, closing it partially, b, same patient 10 minutes after administration of morphine sulphate, the second portion of

the duodenum having been closed completely by more spasm, and c, same patient following inhalation of amyl nitrite, the duodenum is again relaxed but there is a persistent narrowing in the second portion and a persistence of obstruction at the duodenojejunal junction

phine, on the other hand, affects the duodenum of these patients, a point which will be discussed subsequently in this paper.

Patients with the severe and intractable forms of biliary dyskinesia have been shown to have a high resting value for intraduodenal pressure which is greatly increased during attacks of pain. In 1 case (Fig 4) there was not only a high intraduodenal pressure, but a resting intrabiliary pressure in the common duct of 150 millimeters of water (the normal value being 0 to +10 mm of water). Amyl nitrite had only a slight effect on this pressure, and an unusually large dose was required to produce even a moderate effect.

The elevated resting value for intrabiliary pressure in such cases of intractable biliary dyskinesia may be explained partly on the basis of associated duodenal spasm and partly on the basis of associated fibrosis, inflammation, or edema of the wall of the duct and of the sphincter itself. The fact that glyceryl trinitrate has given relief from pain in some cases and not in others may eventually be explained on the basis of some underlying organic change in the wall of the duct, in the sphincter, or in the duodenum in the intractable case. In 3 such cases patients have been completely relieved by placing a T-tube in the common bile duct and instituting prolonged biliary drainage. One other patient acciden-

tally pulled out the T-tube after 5 weeks' drainage and, a few weeks later, the pain returned; at first it was mild, and then it gradually became more severe. Operation was subsequently performed, replacing the tube and complete relief was again obtained.

A duct which is dilated and thin-walled probably withstands increased pressure poorly, T-tube drainage allows a dilated common bile duct to return to its normal size. This fact was borne out in a series of studies on intrabiliary pressure made at varying periods after the insertion of a T-tube into the common bile duct. Three weeks following operation, perfusion of the common bile duct with physiologic saline solution at a pressure of 150 millimeters of water produced pain, whereas 2 months later, the patient's common duct was able to withstand pressures of 500 millimeters of water without distress. Roentgenograms made by injecting the common bile duct with brominol, according to the method of Walters and Thiessen, showed the presence of a dilated common bile duct on the earlier date and a normal sized duct 2 months later. The persistently high, resting value for intraduodenal pressure in these cases of intractable biliary dyskinesia argues for a local source of irritation which induces spasm of the duodenal musculature; this may also influence intrabiliary pressure, as will be shown later.

Fig 3. Tracing obtained in a case in which the patient had a high resting value for intraduodenal pressure showing a further increase in pressure during an attack of pain.

studies of duodenal pressure were being made in each case the intraduodenal pressure rose above an average value of 90 millimeters to a level of 350 millimeters of water (Fig 3). In the third case perfusing the common duct at a pressure of 150 millimeters of water produced pain, whereas perfusing the duodenum at a pressure of 500 millimeters or more of water did not produce discomfort. In still a fourth case without a T tube in the common duct perfusing the duodenum produced only head ache.

Röntgenograms of the duodenum of 2 of these patients with abnormally high intra duodenal pressures showed the presence of some form of resistance to the flow of barium from the duodenum into the jejunum (Fig 4 a) the barium in the third portion of the duodenum seeming to stop short at a point opposite the vertebral column. Figure 4 b also shows narrowing of the second portion of the duodenum suggesting a moderate degree of local muscle spasm. Figure 4 c shows that this spasm can be partially relaxed by the inhala-

tion of amyl nitrite. In this case however, there was some evidence of constriction of the second and third portions of the duodenum even after the administration of amyl nitrite.

THE NATURE OF POSTCHOLECYSTECTOMY COLIC

The nature of postcholecystectomy colic, or if one prefers 'biliary dyskinesia' may now be considered in light of these findings. It appears that in the ordinary case in which the condition is characterized by occasional colics there is moderate sensitivity to morphine and relief from nitrites but there is a constant change in the behavior of the duodenum the site of the difficulty presumably being an irritable and hyperactive sphincter of Oddi. That duodenal contractions accompany prolonged spasm of the sphincter can hardly be disputed especially in view of Westphal's observations we had however no opportunity to study a patient during an attack of spontaneous pain. The important thing is that the duodenal spasm does not persist in such cases. Mor-

Fig 6 Serial roentgenograms after simultaneous injection of the common bile duct with brominol through a T-tube and of the duodenum with barium. a, at rest, b, 10 minutes after administration of morphine sulphate, showing

spasm of duodenum and reflux of medium into the finer radicles of the biliary tree, and c, after inhalation of amyl nitrite, showing relaxation of duodenal spasm and decrease in amount of medium in the bile ducts

METHODS OF REDUCING INTRADUODENAL PRESSURE

Two methods of reducing intraduodenal pressure were found (1) pressure applied to the neck in the region of the carotid sinus, and (2) moderate sized doses of insulin

Stimulating the endings of the vagus nerve in the neck by such procedures as bending the head acutely forward, by pressure over the carotid sinuses, or by electric stimulation over the left carotid sinus, produced a marked reduction in intraduodenal pressure on 15 occasions in 5 individuals; such stimulation produced a fall of from plus 148 to plus 30 millimeters of water in 1 case. Insulin in doses of 20 to 30 units was used on 3 occasions in 1 case and on 2 occasions in another, its administration reduced an elevated intraduodenal pressure from around plus 65 to plus 10 millimeters of water. This effect began 15 minutes after the insulin was given and progressed for from 35 to 45 minutes thereafter. Pressure rose in each case following the intravenous administrations of glucose. What the significance of these findings is we do not know. Such procedures produce no result on the intraduodenal pressure of normal individuals for the obvious reason that there is no resistance to the flow of fluid at the lower end of the duodenum and the pressure is already low.

APPLICATION OF METHODS

The methods described for lowering intraduodenal pressure, namely, administering insulin and applying pressure over the carotid sinus or vagus nerve in the neck, will require further investigation to determine whether the decrease in duodenal pressure is due to relaxation of the pylorus or of the distal part of the duodenum. Schmidt and one of us (McGowan) has demonstrated a similar relaxation of the normal human cardia by means of these methods.

The duodenum of a young girl with a roentgenologically normal gall bladder was studied fluoroscopically during an attack of biliary colic. Through a Sawyer tube a suspension of barium was injected slowly into the duodenum while it was observed under the fluoroscope. Marked spasm was present in the second portion of the duodenum, similar to that represented in Figure 4, b. At intervals, a small bolus of barium, representing 3 to 5 cubic centimeters measured on the injecting syringe, would pass down through the spastic second portion of the duodenum. When it reached the point where the duodenum joined the jejunum, it would encounter an antiperistaltic wave which forced it back into the stomach. Following the inhalation of amyl nitrite this situation was entirely changed, the

Fig 5 Tracing of intraduodenal pressure in a normal person showing effects of administration of morphine sulphate

THE ACTION OF MORPHINE ON THE DUODENUM

Following the subcutaneous injection of 1/6 grain (0.01 gm) of morphine sulphate to a mixed group of normal subjects and patients with postcholecystectomy colic the intraduodenal pressure rose in 10 cases from an average of minus 17 to plus 41 millimeters of water after a period of from 3 to 15 minutes (Fig 5).

In patients with postcholecystectomy colic, roentgenological studies made 10 minutes after the injection of morphine showed spasm of the second portion of the duodenum. The outline of the first portion as well as that of the pyloric sphincter remained unchanged (Fig 4, b). A series of roentgenograms made after simultaneously injecting the common bile duct and duodenum in one of our "intractable cases" showed that when the duodenum contracted following an injection of morphine the lower end of the common bile duct was sharply obstructed and the opaque medium was forced up into the radicles of the biliary tree (Fig 6). Here the closed lower end of the common bile duct and the duodenal musculature are so intimately associated that the sphincter of the common bile duct can hardly be differentiated from that constriction produced by contraction of the muscle of the duodenal wall. The possibility that morphine acts on the duodenum and on the sphincter of Oddi simultaneously must of course be admitted. The reaction of the duodenum to morphine so far as roentgenological and pres-

sure changes are concerned, was essentially identical in normal subjects and in patients with occasional colic but the reaction to morphine seemed most pronounced in patients with intractable biliary dyskinesia.

METHODS OF REDUCING DUODENAL PRESSURE

In order for an elevated pressure to exist within the duodenum, some form of resistance to the free flow of fluid in either direction must be postulated. Roentgenograms taken in cases with normal resting values for intraduodenal pressure showed that the barium tended to run freely down the bowel and up to the pyloric sphincter but that it rarely ran into the stomach, hence the resistance offered by pyloric tonus is greater than that encountered in the lower portion of the duodenum.

In other cases with high resting values for intraduodenal pressure there was roentgenological evidence which indicated some form of resistance to the flow of barium from the duodenum to the jejunum (Fig 4, a and b).

In such cases a rapid reduction in pressure could be due either to relaxation of the duodenal musculature or to relaxation of the pylorus. The present studies do not furnish evidence which would allow for definite differentiation. We have not been able to determine whether the decreased pressure is due to relaxation of the pylorus or to a decrease in the resistance offered to the flow of fluid from the duodenum to the jejunum.

In other cases with high resting values for intraduodenal pressure there was roentgenological evidence which indicated some form of resistance to the flow of barium from the duodenum to the jejunum (Fig 4 a and b).

In such cases a rapid reduction in pressure could be due either to relaxation of the duodenal musculature or to relaxation of the pylorus. The present studies do not furnish evidence which would allow for definite differentiation. We have not been able to determine whether the decreased pressure is due to relaxation of the pylorus or to a decrease in the resistance offered to the flow of fluid from the duodenum to the jejunum.

denal pressure were between plus 30 and plus 100 millimeters of water. In patients with abnormally high intraduodenal pressures, stimulation of the carotid sinus or moderate doses of insulin produced a moderate reduction in pressure, this was of a temporary nature, however, and did not give any constant relief from pain.

The evidence presented indicates the importance of studying duodenal motility in cases of intractable biliary colic and the desirability in such cases of searching for some organic change in the common duct, sphincter, or in the duodenal wall itself.

A NOTE ON THE RESPIRATION-LIKE MOVEMENTS OF THE HUMAN FETUS

W. F. WINDLE, Ph D, C. A. DRAGSTEDT, Ph D, M D, D. E. MURRAY, M.B., and R. R. GREENE, M D., Chicago, Illinois

IT is well known that the breathing mechanism is developed before birth and that premature interruption of a pregnancy does not necessarily lead to death of the fetus for want of functional lungs. Furthermore, the fetus occasionally executes rhythmic respiratory movements spontaneously *in utero* shortly before birth. Ahlfeld (1905) published very convincing graphic records of such activities and Snyder and Rosenfeld (1937) have demonstrated them cinematographically.

Although incidental mention of respiratory-like movements of the human fetus at artificial abortion, hysterectomy, or hysterotomy has been made by a number of investigators, very few reports concern the fetus in the first

half of gestation. The youngest specimens have been described by Erbkam (1837) and Minkowski (1922). The former saw a fetus of about 4 months (170 mm crown-heel length) open its mouth as though to breathe. The latter reported deep inspiratory movements of the thorax with the mouth opening and the elevation of the arms in one of 180 millimeters crown-heel length. Strassmann (1903) expressed the opinion that the first human fetal movement is an elevation of the arms as in taking a breath but he cited no evidence for his belief. Hooker (1936) stated that respiration was about the only specific activity not represented in at least an imperfect stage at 14 weeks (121 mm crown-heel length).

Because so little is known about early prenatal respiratory activity and because the subject is receiving attention in several experi-

whole of the duodenum filling evenly with barium. At intervals a constricting band would appear at the junction of the first and second portions of the duodenum and pass leisurely downward, pushing in front of it a generous quantity of barium over into the jejunum. Similar studies were made later on another patient, during periods of freedom from pain. There was then no evidence of spasm in the duodenum and the barium passed readily into the jejunum.

Two other patients were also studied roentgenologically. They had had persistent postcholecystectomy biliary colic, associated with repeated attacks of vomiting existing respectively, for 8 and 10 years. Glyceryl trinitrate relieved the pain only partially. Marked narrowing of the duodenum was found in each case. One of these patients was subsequently operated on and a tube was placed in the common bile duct for prolonged drainage. Her pain was promptly relieved but the vomiting continued for 2 weeks subsiding only completely one month after operation. At this time roentgenograms were taken following the injection of the common bile duct with brominol and the duodenum with barium. These showed narrowing of the second portion of the duodenum. The common bile duct was dilated, and narrowed at the lower end where it joined the duodenum.

The foregoing observations while by no means complete and therefore insufficient to warrant any sweeping conclusions do appear to incriminate the duodenal musculature as a factor in the production of some of the symptoms of biliary colic. While the pain itself may not necessarily depend upon such a state of duodenal contraction, it is probable that the nausea, vomiting, fullness and epigastric distress may be related to the irritable or spastic state of the duodenum. The nausea and vomiting which so often follow the administration of morphine are probably due to vigorous contractions of an already spastic musculature. Furthermore evidence is offered to show that, in intractable biliary dyskinesia the duodenal motility is altered sufficiently to produce of itself certain symptoms. In such cases there is some interference with normal duodenal emptying due to an apparent con-

tracting ring at the duodenojejunal junction. One would not be justified in assuming on the basis of the evidence presented that altered duodenal motility is a pathognomonic sign of intractable biliary dyskinesia, but it does appear that duodenal hyperirritability plays a definite role in the persistence of symptoms in such cases. In other words the behavior of the duodenum deserves further study in these intractable cases, since its continued spastic state argues for a possible reflex or local cause of organic nature. In distinction to these cases one may cite cases of transient and easily relieved colics of simple biliary dyskinesia in which intraduodenal pressures are normal.

SUMMARY AND CONCLUSIONS

A method for studying the activities of the duodenum has been presented which consists of measuring changes in pressure in the duodenum by means of an ordinary open Sawyer duodenal tube and a water manometer. After injecting a mixture of barium and water directly into the duodenum through the tube roentgenograms were taken of the duodenum under various phases of changes in pressure. Morphine produced an increase in intraduodenal pressure, apparently due to spasm of its second portion. Amyl nitrite relaxed this spasm. Roentgenograms taken by simultaneously injecting brominol into the common bile duct through a previously inserted T tube and by injecting barium into the duodenum through a Sawyer tube showed that the spasm of the duodenum produced by morphine seems also to involve the lower end of the common bile duct.

Resting values for intraduodenal pressure were determined in 3 groups of cases. Patients suffering from repeated attacks of postcholecystectomy biliary colic capable of relief by nitrites were found to have intraduodenal pressures of from minus 35 to minus 50 millimeters of water. In normal subjects pressures of minus 30 to 0 millimeters of water were encountered. In individuals with intractable postcholecystectomy colic not relieved by nitrites and presenting roentgenological evidence of obstruction of the third portion of the duodenum the resting values for intradu-

denal pressure were between plus 30 and plus 100 millimeters of water. In patients with abnormally high intraduodenal pressures, stimulation of the carotid sinus or moderate doses of insulin produced a moderate reduction in pressure; this was of a temporary nature, however, and did not give any constant relief from pain.

The evidence presented indicates the importance of studying duodenal motility in cases of intractable biliary colic and the desirability in such cases of searching for some organic change in the common duct, sphincter, or in the duodenal wall itself

A NOTE ON THE RESPIRATION-LIKE MOVEMENTS OF THE HUMAN FETUS

W. F. WINDLE, Ph.D., C. A. DRAGSTEDT, Ph.D., M.D., D. E. MURRAY, M.B., and R. R. GREENE, M.D., Chicago, Illinois

IT is well known that the breathing mechanism is developed before birth and that premature interruption of a pregnancy does not necessarily lead to death of the fetus for want of functional lungs. Furthermore, the fetus occasionally executes rhythmic respiratory movements spontaneously *in utero* shortly before birth. Ahlfeld (1905) published very convincing graphic records of such activities and Snyder and Rosenfeld (1937) have demonstrated them cinematographically.

Although incidental mention of respiratory-like movements of the human fetus at artificial abortion, hysterectomy, or hysterotomy has been made by a number of investigators, very few reports concern the fetus in the first

half of gestation. The youngest specimens have been described by Erbkam (1837) and Minkowski (1922). The former saw a fetus of about 4 months (170 mm crown-heel length) open its mouth as though to breathe. The latter reported deep inspiratory movements of the thorax with the mouth opening and the elevation of the arms in one of 180 millimeters crown-heel length. Strassmann (1903) expressed the opinion that the first human fetal movement is an elevation of the arms as in taking a breath but he cited no evidence for his belief. Hooker (1936) stated that respiration was about the only specific activity not represented in at least an imperfect stage at 14 weeks (121 mm crown-heel length).

Because so little is known about early prenatal respiratory activity and because the subject is receiving attention in several experi-

mental laboratories at the present time, it seems desirable to report observations in three new specimens smaller than any that have been described previously.

Several years ago one of us (C A D) had the opportunity to observe the behavior of a 4 month old fetus of about 140 or 150 millimeters crown heel length. Pregnancy was terminated for therapeutic reasons by dilating the cervix, the specimen with its placenta was delivered promptly. It was soon seen to be executing rhythmic movements of the head and trunk which involved contractions of the diaphragm and chest muscles. These inspiration like activities were strong and resembled rhythmic gasping. They continued for many minutes, becoming slower after they were first noticed.

On another occasion (observed by D E M and R R G) a gravid uterus was obtained,¹ taken to a room adjoining the operating theater and opened approximately 3 minutes after the blood vessels had been clamped. The fetus was freed from its membranes and the umbilical cord was severed. At this time rhythmic movements of thoracic and abdominal muscles resembling rapid breathing were seen. They occurred periodically for about 3 minutes. Occasionally the fetus threw back its head as though to gasp and with this movement the costal margin was elevated. The specimen measured 70 millimeters crown rump

length, 85 millimeters crown heel length. Eighty four days had elapsed since the last menstruation.

Again more recently a fetus of 62 millimeters crown rump length and 85 millimeters crown heel length was obtained (by R R G) at hysterectomy. The last menstruation had begun 84 days previously. Three distinct respiratory movements were seen in the first 3 minutes of observation. Contralateral arm reflexes followed tapping the arm but no responses were obtained from the legs.

It is evident from these observations that the human fetus can execute rhythmic respiratory like movements in the third and fourth months. That they do so normally *in utero* is not implied, because in every instance a state of anoxemia with carbon dioxide accumulation had been set up in the fetus by removal from the uterus. Observations in other forms of mammals and in birds (W F W, unpublished) indicate that such activities do not appear until late in fetal life unless the oxygen exchange mechanism is disturbed.

THE EFFECT OF LIGHT ON BENZOPYRENE CANCER IN MICE

JOSEPH TAUSSIG, M D, ZOLA K. COOPER, Ph.D, and M G. SEELIG, M D., St. Louis, Missouri

ALTHOUGH it has long been assumed that light is a factor in the production of skin cancer in man, until recent years little experimental evidence has been adduced to support or deny this conclusion. The study of the rôle of light in the production of carcinoma has of late received increasing attention and the problem has been approached from many angles. Some workers have merely subjected experimental animals to light from various portions of the spectrum. For example, Finlay exposed mice to the rays of a quartz mercury-vapor lamp and found that after 8 months papillomas and malignant epitheliomas appeared. Tarred animals exposed to ultraviolet light developed carcinoma in a shorter time than when either tar or violet ray exposure was used alone. Herlitz, Jundell and Wahlgren, using mice, and Putschar and Holtz, using rats, were able to produce more carcinomas in the animals exposed to ultraviolet light than in unexposed controls. On the contrary, Rathman and Bernhardt, using rabbits, were unable to produce carcinoma after repeated exposure to ultraviolet rays, and Kohn-Speyer could not produce tar tumors in mice more quickly by the additional use of ultraviolet light. Thus, this line of approach has given quite contradictory results.

Other workers have attempted an opposite approach to the problem in that they subjected experimental animals to a complete absence of light. Dodds, Bang, Lipschuetz, Schorr and Ssobolewa, Vlès, de Coulon and Ugo, and Seelig and Cooper, are among the workers who have attempted experimental studies on the effect of total darkness on the production of carcinoma. The conclusions from these studies have also been contradictory.

A third line of approach has been the study of the effect of certain so-called light sensi-

tizing agents on experimental carcinogenesis. Various agents have been used in an attempt to produce light sensitivity in animals, the most important of which in connection with our studies are cholesterol and hematoporphyrin. Roffo and his co-workers believe that a relationship exists between the photoactivity of cholesterol and cell function, that sunlight serves to fix the cholesterol in the tissues and that cholesterol then becomes an organic accumulator of light. The cholesterol which he believes becomes photoactive as a result of oxidation by light is thought to play an important rôle in the production of carcinoma. Hausmann has perhaps done the greatest amount of work upon the use of hematoporphyrin as a light sensitizing agent. It has been found that mice injected subcutaneously with hematoporphyrin and kept in the dark show no peculiar effects of the drug; however, when these animals are exposed to light their ears, noses, and paws become markedly hyperemic and after sufficient exposures a marginal necrosis of the ears may develop. The drug also apparently produces an intense itching of the skin, for the mice scratch almost constantly during the period of exposure to light. Rothmund has also made extensive studies upon the physiological effects of hematoporphyrin and other light sensitizing substances, such as certain derivatives of chlorophyll. However, not much work has been done on the use of these chemicals with relation to carcinogenesis. Buengeler has studied the effect of the injection of various light sensitizing agents, such as eosin, anthrasol, and hematoporphyrin on the production of tar cancer in mice, and has found that these substances which increase the light sensitivity of the experimental animals seem also to increase their susceptibility to tar cancer. However, work upon this phase of the problem of the rôle of light in the production of carcinoma is still in its infancy and the results are as yet not clear cut.

Since so much confusion exists concerning the relationship between light and carcinogenesis the present experiments were undertaken to determine (1) the effect of repeated exposures to light from a definite source upon the production of benzpyrene carcinoma in mice, and (2) the effect of this light upon the development of benzpyrene carcinoma in mice

previously made light sensitive by repeated injections of small doses of hematoporphyrin

MATERIALS AND METHODS

One hundred and fifty female mice were used in these experiments. The animals were obtained from the Rockland Farms, New York City, and belonged to the Rockland all purpose strain, which has been inbred for 35 generations. At the beginning of the experiment all of the animals were 3 to 4 months old. The mice were divided into three groups of 50 each. All of the groups were housed in standard metal cages which except during the experimental procedures were kept in a compartment darkened with black paper. One drop of a 0.5 per cent solution of benzpyrene (Union Chimique Belge) in benzol was applied twice weekly to the skin on the back of the necks of all the mice for a period of 6 months. In addition, the animals in one group of 50 mice were injected subcutaneously on the rump 6 times (at 4-day intervals) with 0.3 cubic centimeter of a solution of hematoporphyrin prepared by dissolving 0.1 gram of hematoporphyrin in 2.5 cubic centimeters of tenth normal sodium hydroxide and diluting the mixture to 100 cubic centimeters with distilled water. After six injections this procedure was discontinued, because of the high mortality due to the toxicity of the hematoporphyrin. This group and a second group of 50 mice, which were simply painted with benzpyrene were exposed for 1 hour daily for 6 months to the light from a General Electric Type S1 sun lamp 600 glass bulb. This lamp transmits a band of rays between 2894 and 5500 Angstrom units (thus including rays from the ultraviolet and from the visible spectrum). This lamp according to the General Electric Company's supplies approximately 10,000 "E vitamins" and takes about 7 minutes at a distance of 30 inches from the lamp to produce an immediate slight reddening of the skin in humans. The mice were exposed to the lamp in a cage measuring 20 inches in length by 20 inches in width and 6 inches in height, made of 1/2 inch mesh wire screen. The cage was divided by similar

We are deeply indebted to the General Electric Company for their fine co-operation in this research.

screening into 25 compartments, each measuring 4 by 4 inches. Not more than 2 mice were placed in each compartment during the period of exposure. The cage was placed upon a white enameled metal base to insure a maximum reflection of light. The center of this base was always placed 36 inches below the bulb of the lamp.

The third group of 50 mice, which were used as controls, were kept constantly in the darkened compartment.

During the 6-month experimental period, the necks of all of the mice were carefully examined once a week for gross evidence of carcinoma at the site of benzpyrene application. The thickness and hardness of the lesion, the depth and width of the infiltration, and the shape of the pearly border were noted. When the border was approximately 3 millimeters thick, when the induration was woody hard and extended over an area at least 1 centimeter in diameter, and involved the subcutaneous tissue, and when the edge of the lesion had a typical pearly appearance, a diagnosis of carcinoma was made.

The control mice, which died during the course of the experiment, were subjected to autopsies and the areas on the backs of the necks which had been treated with benzpyrene were removed for sectioning and microscopic study. Thus, a rigid control was maintained against the purely tentative clinical diagnoses of carcinoma. At the end of 6 months all the mice remaining alive were killed with ether and likewise subjected to autopsies. Microscopic sections of the lesions on their necks produced by the application of benzpyrene were also made. Sections were stained routinely with hematoxylin and eosin, and with Van Gieson's stain for connective tissue.

DISCUSSION

The first definite clinical or gross evidence of carcinoma was observed in both the experimental and the control mice at the beginning of the seventeenth week of the experiment. At that time, basing our conclusions on the gross factors of thickness and hardness of the lesion, degree of infiltration, and appearance of the border, 14 per cent of the animals painted with benzpyrene and exposed

Graph 1—Showing the percentage of mice developing carcinoma after the 17th week of the experiment
 Group of mice kept in the dark and painted with benzpyrene
 Group of mice exposed to light and painted with benzpyrene

daily to the sun lamp and 16 per cent of the controls which were painted with benzpyrene and kept in the dark, showed evidence of carcinoma. From that time until the end of the experiment the percentage of malignancy rose about equally in both groups until the twenty-third week, at which time 50 per cent of the experimental animals and 45 per cent of the controls had apparently developed carcinoma. A curve showing the increasing percentage of mice developing carcinoma in the two groups during the latter part of the experimental period is shown in Graph 1.

The mortality during the course of the experiment was rather high in all groups of mice. Graph 2 presents a mortality curve for all of the animals used in the experiment. Of the group of animals which were painted with benzpyrene and exposed daily to the sun lamp, 22 died before the end of the experiment. Of these 10 animals were found to have developed carcinoma (proved by microscopic section). Among the controls, which were painted with benzpyrene, but kept in the

Graph 2—Showing the mortality rate in the three groups of mice used in the experiment
 —●— Group exposed to light and painted with benzpyrene
 —×— Group exposed to light injected with hematoporphyrin and painted with benzpyrene
 —○— Group kept in the dark and painted with benzpyrene

dark, 26 animals died during the course of the experiment and of these 13 developed carcinoma. Thus 45.4 per cent of the experimental animals and 50 per cent of the control animals, dying during the course of the experiment developed carcinoma. The difference in the incidence of carcinoma in the two groups is quite insignificant.

Of the group exposed daily to the sun lamp 28 were still alive at the end of 6 months and of the controls 23 were living at the end of the same period. These animals were killed at autopsies were performed, and microscopic sections prepared of the areas on the neck. Twenty-three, or 82.1 per cent of the experimental animals and 17, or 73.9 per cent, of the controls were found to have carcinoma. Table I presents an analysis of the autopsy findings in these two groups of mice. Because of the relatively small number of animals in the two groups this difference is suggestive rather than significant.

The group of 50 mice which were given injections of hematoporphyrin, furnished very little reliable data concerning the relation of light sensitivity to the development of benzpyrene carcinoma. The hematoporphyrin proved to be highly toxic and after 6 injections the use of the drug was discontinued. The mortality in this group was very high.

Twenty-one of these mice died during the first month of the experiment, the period during which hematoporphyrin was being given. The mortality rate of this group as compared with the controls is given in Graph 2. Only 4 of the mice that died during the course of the experiment developed carcinoma. At the end of 6 months when the animals remaining alive in all groups were killed and examined, only 7 of this group were still alive. Upon microscopic examination of the lesions on the necks of these animals, all but one of them were found to have carcinoma. Because of the high mortality in this group occasioned by the toxicity of the hematoporphyrin these results are only suggestive. This study of the effect of light sensitizing substances upon benzpyrene cancer in mice is to be continued.

SUMMARY

The incidence of skin cancer in mice treated with benzpyrene was studied in a group of 50 mice exposed to a sun lamp and contrasted with the incidence in a similar group kept in the dark.

The difference in the incidence of skin cancer in the two groups was found in our judgment, not to be sufficiently marked to warrant drawing dogmatic conclusions.

THE CONCENTRATION OF SERUM SULPHATE AND BLOOD UREA IN PROSTATIC HYPERTROPHY ASSOCIATED WITH URINARY OBSTRUCTION

HAROLD C HABEIN, M D, GERSHOM J THOMPSON, M D, and
E G WAKEFIELD, M D, Rochester, Minnesota

ORDINARY tests of renal function at times may be of limited value in the estimation of renal function in cases in which retention of urine is associated with prostatic hypertrophy. There are several reasons for this regrettable fact. A patient afflicted with an enlarged prostate gland may have kidneys which have inadequate functional ability as the result of changes secondary to a renal arteriosclerosis which existed prior to the onset of urinary obstruction, while another patient may have had sound kidneys prior to the onset of urinary obstruction but renal insufficiency may develop as a consequence of the obstruction of the urinary stream. Obviously, all possible gradations and variations between these two extremes will be found in practice. It is a well known fact that the excretion of phenolsulphonphthalein may be normal or at most slightly decreased at the onset of acute renal insufficiency which developed from urinary obstruction in a case in which a patient had sound kidneys prior to the obstruction. In another case in which renal function was impaired as a result of renal arteriosclerosis and urinary obstruction occurs secondarily as the result of a hypertrophied prostate gland, the excretion of phenolsulphonphthalein may indicate the degree of renal insufficiency produced by these combined factors. Undoubtedly, some degree of impaired renal function which is the result of arteriosclerosis exists in cases of prostatic hypertrophy. It is the arteriosclerosis and not the recent urinary obstruction that accounts for the decreased excretion of phthalein. Occasionally when the output of urine is markedly reduced the excretion of phthalein may drop to a very low

level, only because there is insufficient excretion of water to carry the phenolsulphonphthalein through the kidney. The nitrogenous waste products also require considerable dilution for their excretion, hence, when the daily output of urine is less than 250 to 300 cubic centimeters, the concentration of non protein nitrogen of the blood may reach considerable heights.

In spite of the foregoing limitations physicians have correctly depended on the estimation of the concentration of blood urea and the determination of the excretion of phenolsulphonphthalein for the evaluation of possible renal sufficiency in cases of prostatic hypertrophy. Since so much theoretical similarity exists between the excretion of urea and phthalein the data on the estimation of excretion of phenolsulphonphthalein have been omitted from this report. In the present communication, data pertaining only to the concentration of blood urea and serum sulphate will be given.

In previous studies it has been observed that serum sulphate may be increased in cases of early renal insufficiency before either the urea is increased or the excretion of phthalein is decreased. The concentration of serum sulphate alone was increased in 19 cases (Fig. 1) in this study. The patients in these cases all had hypertension and arteriosclerosis. They had no residual urine or at most had less than 100 cubic centimeters. Clinically of course it was impossible to determine whether the nocturia and frequency of micturition which were present in these cases were symptoms of the prostatic enlargement or were attributable to the arteriosclerotic changes which resulted in a renal insufficiency. We often have seen a frank renal insufficiency develop in cases in which there was an increased concentration of

serum sulphate. However, it is not always possible to interpret the significance of an increased concentration of serum sulphate on the basis of one determination. It might well be that the patient has had some acute renal disorder which is clearing up and that subsequent determinations of the concentration of sulphate would give results which were within normal limits. So far as we know, however, an increased concentration of serum sulphate is associated with a failure of renal function.

Under certain conditions which cannot be defined, there may be an increased concentration of blood urea while the concentration of serum sulphate remains within normal limits (Fig 2). The clinical findings in the 31 cases in Figure 2 were the same as they were in the cases in Figure 1 except that hypertension was not present in all of the cases in Figure 2. However, in some there were moderately elevated blood pressures. On an average the residual urine was greater in the latter group.

The patients in the latter group of cases were of greater interest to us, first, because of the increased concentration of blood urea and the normal values for serum sulphate and, second, because of the progress the patients made while they were in the hospital. Figure 3 is a graphic representation of the value for the blood urea when fluids were administered by mouth and intravenously. The value for the blood urea rapidly returned to normal within a few days. In this figure only the value for the first determination of serum sulphate is given since subsequent values were also normal. These patients made uneventful recoveries after surgical relief of the urinary obstruction.

Usually, if there is an increased concentration of either blood urea or serum sulphate the concentration of the other is also increased (Fig 4). This figure shows that in renal insufficiency the general trend is for the concentration of both blood urea and serum sulphate to increase. However, increases of these substances in the blood do not give any definite prognostic criteria.

The subsequent course after the oral and intravenous administration of fluids in cases in which there was an increased concentration of both blood urea and serum sulphate is shown

Fig 1 Increased concentration of serum sulphate and normal concentration of blood urea in 19 cases. Dots, value for serum sulphate, o, corresponding value for blood urea in same case.

in Figure 5. The administration of fluids may cause a rapid decrease in the concentration of blood urea whereas the concentration of serum sulphate is not so quickly affected. This figure shows the general tendency for serum sulphate to be less easily affected by diuresis than the blood urea. However, the concentration of serum sulphate may be lowered by a prolonged diuresis just as is the concentration of blood urea. Occasionally, we have seen a value of 7 milligrams of sulphate (23 milligrams of sulphur) per 100 cubic centimeters of serum and a value of 100 milligrams of urea per 100 cubic centimeters of blood reduced to normal values in 4 or 5 days. It is the rule, however, that a fortnight or more may be required to reduce a value of 7 milligrams of sulphate per 100 cubic centimeters of serum to normal limits.

If one includes all patients who have been admitted to The Mayo Clinic on account of prostatic enlargement of sufficient degree to require a transurethral resection of the prostate gland, it will be found that the concentration of the serum sulphate and blood urea are within normal limits. The clinical examination, however, may be no different from some of those in which there were mild degrees of renal insufficiency. It is for this reason that tests which may indicate the state of renal function are important assets in outlining the future care of the patients who have prostatic hypertrophy and urinary obstruction.

EVALUATION

During the past several years we have determined the concentration of sulphate in the

Fig. 2 Increased concentration of blood urea and normal concentration of serum sulphate in 31 cases. Dots serum sulphate values, o corresponding value for blood urea same case.

Fig. 3 Graphic representation in 17 cases of the effects of administration of fluids in cases of increased concentration of blood urea (indicated by c) and normal concentration of serum sulphate (indicated by dots).

Fig. 4 Increased concentration of both blood urea (indicated by o) and serum sulphate (indicated by dots) in 70 cases.

Fig 5 The effects of administration of fluids when the concentrations of blood urea (o) and serum sulphate (dots) are increased

serum in health and in disease. The concentration varies considerably among normal individuals. In series of 125 normal persons, the range of concentration of sulphates varied from 1.9 to 5.1 milligrams of sulphate (0.63 to 1.66 milligrams of sulphur) in each 100 cubic centimeters of serum. Fifty per cent of these values fell between 3.4 to 4.2 milligrams of sulphate (1.13 to 1.4 milligrams of sulphur) in each 100 cubic centimeters of serum. Statistically and for practical purposes, any value up to 5 milligrams (1.66 milligrams of sulphur) in each 100 cubic centimeters of serum is normal.

An increased concentration of serum sulphate before there is an increase in the concentration of blood urea may occur in arteriosclerotic disease of the kidney and in glomerulonephritis. This, however, is not a regular occurrence because the concentrations of these two substances usually are increased synchronously.

The increase in the concentration of blood urea without a concomitant increase in the concentration of serum sulphate in our experience has not been indicative of a serious disease of the kidney. However, we do not

wish to postulate on this phenomenon with our present data. We have an impression that a patient who is not dehydrated and who has, let us say, from 80 to 100 milligrams of urea in each 100 cubic centimeters of blood does not have normal kidneys; however, in our experience the injury may not be profound. Adequate treatment may restore a normal renal function but not normal kidneys. Our data seem to indicate that an increased concentration of blood urea and a normal concentration of serum sulphate are related in some way to dehydration.

In brief, we believe that some worthwhile information may be obtained from the determination of the concentration of serum sulphate. For instance, if diuresis reduces an increased concentration of blood urea to normal limits and if the value for serum sulphate remains more than 5 milligrams (1.66 milligrams of sulphur) per 100 cubic centimeters, we believe that the increased concentration of serum sulphate indicates a definite renal insufficiency; whereas, if the concentration of serum sulphate is within normal limits, the value for the blood urea may be disregarded.

CLINICAL SURGERY

FROM JAMES BUCHANAN BRADY FOUNDATION, NEW YORK HOSPITAL

THE MANAGEMENT OF BLADDER TUMORS

THOMAS J. KIRWIN, M D., F.A.C.S., New York, New York

THE problem offered by the treatment of tumor of the bladder is not new, but our attempts to solve it have undergone constant change. It is a problem in which every member of the medical profession should take an active interest—whether he be specializing urologist or family doctor. Statistics show that 2 per cent of all tumors are located in the bladder. It is, therefore, a relatively frequent lesion, and one likely to be encountered by anyone engaged in the practice of medicine.

Though this tumor was recognized very early in the history of medicine, modern treatment did not really begin until the year 1910, when Edwin Beer of New York introduced his method of fulguration. Beer's discovery may be said to have revolutionized our whole conception of vesical growths, as well as our methods of dealing with them. Once Beer had led the way, the application of the high frequency current, and the invention of instruments combining cystoscopic and cautery features went rapidly forward, so that we now have at our command three different agents which may be used separately or in combination. These are: (1) surgery, (2) diathermy, (3) irradiation.

They may be employed according to the attending physician's personal judgment, as influenced by his experience and inclination, taking into consideration the location of the growth, its histological structure and stage of advancement. Especially important is the histological structure because of its bearing upon the radiosensitivity of the tumor.

The therapist charged with the treatment of a vesical growth will find plenty of help at hand, but it will often be difficult for him to select the particular method suited to the needs of his individual case. There will be but little trouble in doing this if the diagnosis of either benign or malignant neoplasm can be clearly established. It is with the atypical, border line case that he is likely to come to grief. Therefore, he should always avail himself of every modern means of

diagnosis and correlate the findings of all methods available, namely, cystoscopy, biopsy, and cystography for it is only in this way that he can correctly evaluate the diagnosis.

The ordinary cystoscopic examination is often misleading. Though the foroblique lens system helps to show the tumor in its actual proportions and in proper relation to surrounding structures, no urologist should consider himself properly equipped unless he can also command a retrograde lens system as well as a right-angle lens system, enabling him to view the tumor in all aspects.

X-ray examination of the bladder filled with an opaque medium often gives us much valuable information, for cystography frequently fills in the gaps in the evidence presented by other maneuvers, and enhances their value. At the Brady Foundation of the New York Hospital both umbrathor and diadras are used for this work. Irregularities in the outline of the bladder shadow may serve to locate a growth with accuracy, and though this method used alone might not be of great assistance, in conjunction with other diagnostic means, its importance is much enhanced.

Biopsy is, of course, the criterion by which all other means must be judged. In order to be sure of satisfactory specimens, I have designed a biopsy rongeur which has proved handy and efficient for this purpose. Malignancy often does not appear in a single specimen, if it be taken from one of the tendrils of a bladder tumor, with no part of the tumor-base included. Therefore, the specimen secured must be sizable enough to permit inclusion of "samples" of all constituent cell structures.

In our work at the Brady Foundation for Urology we do not adhere rigidly to any particular "grading" system. Neither do we regularly make use of any of the elaborate systems of classification which have been from time to time put forward for the purpose of differentiation of the intermediate grades intervening between the unquestionably benign and the frankly malignant

Fig. 1. Clamp method. Typical tumor of the bladder suited for excision by this method showing the common position of such a tumor and its most usual dimension. 1 and 2. Tumor as seen through cystoscope. 3. reconstruction of cystoscopic findings showing position of tumor and approximate size.

Fig. 2. Clamp method. Skin incision and the method of freeing the bladder's right lateral wall after it has been opened at the midline.

cell types. More and more we incline to the belief that all bladder tumors are potentially malignant and whatever treatment be elected we must bear in mind the necessity of providing against such future dangers.

The cystoscopist should familiarize himself with the fine differences in the aspect of the varied neoplasms which may possibly arise in the bladder. This can be attained only by constant practice and wide experience but from the outset it should be the aim of all who attempt the treatment of bladder tumors. The surgeon cannot be expected to be also an expert pathologist but he must keep in touch with all advances in the study of neoplastic diseases and be ready at all times to give the specializing pathologist enthusiastic and intelligent support.

When the report from the pathological laboratory is received it should be most carefully considered. Its findings must be compared with those obtained by rectal palpation with the results of cystographic observation and the checkings of cystoscopic study. When all these have been evaluated—separately and in their relations one to another—we should find ourselves in a position to take up consideration of the various possible methods of treatment, so that the procedure best

suited to the needs of the particular case in hand may be unerringly selected.

TREATMENT

We have seen that there are now available for the management of bladder tumors three distinct types of treatment which have been employed—separately or in combination—by the most experienced surgeons in this country and abroad. Considering these somewhat in detail we find:

Surgery. It has been statistically established that the majority of bladder tumors are inoperable from the outset because they are so located as to be inaccessible to surgery. Tumors arising on the lateral walls usually involve one or both ureteral orifices. Lateral wall growths comprise 41.89 per cent and trigone and bladder neck tumors 34.41 per cent of the 854 vesical growths classified in the Registry of the American Urological Association. The Carcinoma Registry Committee points out that this fact has an important bearing on treat-

Fig 3 Clamp method 1, Bladder wall has been freed, and the tumor is exposed in its position upon the posterior portion of the right wall, 2, dividing bladder wall down toward tumor, 3, clamps applied to wall, resection begun, 4, further resection of tumor first applying clamps

ment From the surgical standpoint only 23.4 per cent of these tumors can be excised without interference with urethra or ureters. This means that almost invariably requires transplantation of one or both ureters, while those involving the trigone are surgically inapproachable except by using total cystectomy and bilateral ureteral transplantation. The report concludes "It would appear, therefore, that any method of treatment to become generally acceptable must take into account the high percentage of bladder tumors in these areas, and the hazards of a purely surgical approach."

Some of our ablest surgeons, have recently expressed themselves favorably toward total cyst-

tectomy, but I cannot share this enthusiasm. The indications for cystectomy are very definitely limited. It is applicable only to bladders showing extensive papillomatosis entirely confined to the bladder mucosa, or where one or more larger tumors have infiltrated the bladder wall too widely to permit resection but without extending beyond the bladder mucosa. It is useless to remove the bladder unless the patient can be proved free from metastasis, so a searching x-ray examination of all possible foci of malignancy in lungs, bones, or viscera adjacent to the bladder, is an indispensable preliminary.

As the majority of bladder tumor patients are in the late fifties or sixties, we must also consider their life expectancy. Is it worth while to perform

Fig. 4. Clamp method. The closure of the defect in the bladder wall with placing of drains before sewing up the abdominal incision. 1. Suture of defect in bladder wall after removal of tumor. 2. Closure of bladder drains placed. 3. Final skin suture.

so extensive and hazardous an operation as cystectomy upon a person who cannot expect according to unbiased life insurance tables such as those compiled by John Duff for the Metropolitan Life Insurance Company to live more than a few years at best? As many of these people are greatly depleted by concurrent affections of heart, blood vessel and kidneys their life expectation is still more reduced.

Again, removal of the bladder involves implantation of the ureters into the sigmoid or other portion of the lower intestine. Most of the advocates of removing the bladder with the tumor

pass very lightly over this problem of ureters implantation. I spent more than 3 years in investigation and animal experimentation upon this subject performing the operation upon upward of 80 dogs. In practically every instance although many of the dogs recovered promptly from the effects of the operation they later succumbed to kidney infection or other secondary effects and in those which lived long enough to permit their being sacrificed after a definite period hydro-nephrosis and other sequelae of infection and resulting urinary obstruction were in evidence. This was frequently seen in animals whose opera-

Fig 6 Cautery method 1, Method of "seeding" the cut edges of the remaining portion of the bladder wall before closing it, 2, closure of remaining part of bladder, 3, bladder closed, drains placed, 4, final closing of skin incision

tive wounds were entirely healed so that surgically speaking the operation was a "perfect success." I became convinced that the difficulty lay in the injury sustained by the nerves of the ureteral walls when the ureters were severed from the bladder. The ganglion cells of these nerves apparently play the same rôle in peristalsis as do those of the Auerbach-Meissner plexus in the intestine. When their dendrites are cut, peristaltic waves are halted at the site of injury, even if no actual stricture has been formed. This fact was demonstrated by Alksne and by Gouverneur 25 years before I made my experiments and was observed in a human in whom the ureter had been

cut by accident and had been sutured together when no infection was present. A dilated ureter and hydronephrosis were the result in each case.

In my opinion any operation involving ureteral implantation is not justified upon an elderly or enfeebled patient. If stricture of the ureter occurs at its place of implantation in the intestine, ureteral obstruction will be followed by hydronephrosis or pyonephrosis, with ultimate uremia and death. If actual stricture should not occur, peristalsis will be lessened or altogether inhibited, urine will collect behind the break in the continuity of the ureteral wall, and though it will

Fig 7 Loop ball disc method 1 & 3 Cystoscopic views of a large tumor behind the trigone infiltrating the posterior wall of the bladder 4 reconstruction of condition 5 sagittal section showing position of tumor

soon 'spill over' and partially empty itself by gravity eventual hydro ureter is inevitable. An operation presenting such grave hazards should in my opinion, be employed only in the rarest instances.

Diathermy Since its introduction by Beer in 1910 diathermy or fulguration has been the surgeon's mainstay, in the destruction of benign vesical tumors. For malignant growths it has never been satisfactory as its originator freely admits. Excision by the cauterizing knife followed by irradiation, which may be looked upon as a "diathermic method" has been more successful but recurrence too often follows the use of diathermy alone to make it seem desirable to the majority of operators.

Irradiation While the use of radium and roentgen ray therapy has proved a valuable adjunct to other methods employed in combatting bladder tumors radiation therapy alone has not been satisfactory. This is admitted by practically all therapists.

DESCRIPTION OF MODERN METHODS

After long experience with the various methods just outlined a technique has been worked out which is now proving efficient in the majority of cases. For the minority to which this more or less standardized technique is not applicable variations are necessary but these too have become quite well standardized and their indications clearly established. They may be listed as follows:

Method I Resection using clamps excision by scalpel followed by deep x ray therapy.

Method II Resection by cauterizing knife with radon implantation before wound is closed.

Method III Fulguration by loop and disc electrodes through a suprapubic incision followed by implantation of radon seeds.

Method IV Closed method removal of exuberant portion of growth by the resectoscope followed by intra urethral implantation of radon seeds and in some cases external x ray therapy.

Incisions There are many types of incisions for approaching the bladder. The author usually

uses the midline incision. The director of the Brady Foundation of the New York Hospital, Lowsley, prefers the inverted "V" in most cases feeling it gives him an opportunity to make a wider resection of the bladder if necessary, by the cutting of the recti muscles. There are urological surgeons who prefer the Pfannenstiel incision. These are all personal equations that the surgeon must solve himself and have very little bearing on the actual resection of the bladder tumor itself.

Clamp method. In Figure 1 is shown a typical tumor of the bladder suited for excision by the clamp method, showing the common position of such a tumor and its most usual dimensions. In Figure 2 is shown the skin incision and the method of freeing the right lateral wall of the bladder after it has been opened at the midline. In Figure 3 the bladder wall has been freed, and the tumor is exposed in its position upon the posterior portion of the right wall. The bladder wall is divided downward toward the tumor, the clamps being applied to the wall as resection begins. Figure 4 shows closure of the defect in the bladder wall, with placing of drains before sewing up the abdominal incision. The value of this procedure is enhanced by irradiation after resection is completed, as we thus take care of any possible extension of the malignant process which may have remained outside the line of resection.

Cautery method. Figure 5 (frontispiece) shows resection by cautery—skin incision, opening of bladder wall and removal of large tumor at base of bladder. In Figure 6 we have illustrated, 1, the method of "seeding" the cut edges of the remaining portion of the bladder wall before closing it, 2, closing of the wall about a Pezzer catheter, 3, placing the drains, and 4, final closing of the skin incision. This method may be employed when for any reason loop and disc electrodes are not available.

The technique next to be described is considered preferable by the author whenever possible.

Loop-ball-disc method. For large tumors, impossible to remove by the intra-urethral route, excision with the loop electrode through a midline incision has proved most satisfactory to me. In Figure 7, 1, 2 and 3, are shown cystoscopic views of a large tumor behind the trigone, infiltrating the posterior wall of the bladder. Figure 8 shows details of the three different electrodes employed in carrying out the technique. In Figure 9, 1, the ball electrode is applied to the wall encircling the tumor. In Figure 9, 2, the entire tumor mass is being removed with the loop electrode while Figure 9, 3, depicts the method of applying the disc electrode to the base of the tumor after the

Fig 8 Details of three different electrodes employed in carrying out the technique

exuberant portion has been excised, to control any hemorrhage that may be present. When the entire site has been thoroughly cauterized, radon seeds are implanted, as demonstrated in Figure 9, 4, so as to take care of any infiltration which may have taken place in the muscular wall of the bladder.

Combination closed method. Except when a tumor is too large to be handled by intra-urethral methods, or the conditions under which operation must be performed will not permit the use of the necessary instruments, the following technique will be found by all means the most satisfactory for the ordinary bladder neoplasm. In essence, it is the same as method III just described, although it is performed intra-urethrally instead of through a suprapubic opening.

The size of the tumor is first ascertained. For this purpose I have designed with the assistance of Mr F. C. Wappler, an instrument which facilitates both inspection and measurement, permitting correct estimation of the amount of radon dosage required to irradiate the base after the mass of overgrowth has been removed by loop electrode of the McCarthy or Kirwin resectoscope. When the measurements have been taken the instrument is withdrawn, the resectoscope is substituted, and the growth is cut away with the loop, as shown in the drawing of the suprapubic method, Figure 9, 2.

When the growth has been cut away and the site cauterized by the resectoscope, radon seeds

Fig 9 1 Ball electrode is applied to wall encircling the tumor 2 entire tumor mass is being removed with loop electrode 3 method of applying the disc electrode to the base of the tumor after the exuberant portion has been excised 4 implantation of radon seeds

are at once implanted in the affected area the introducer designed by the author being used. This introducer can be inserted through the measuring arm of the first instrument if it is found desirable.

The Kurwin resectoscope is particularly well adapted for removing the exuberant portions of the tumor because its electrode rotates behind a fenestra and is thus much less likely to cut through the bladder wall, even when it has been weakened and thinned by malignant infiltration. When a special instrument is not at hand ordinary fulguration may be used to remove the visible tumor mass. The important feature is the scraping away of all the projecting mass so that the base may be fully exposed for radon implantation. Application of the disc electrode will then leave a clear surface ready to receive as many

radon seeds as the measuring instrument has indicated to be necessary.¹

This operation by the closed route minimizes shock, produces little or no hemorrhage and can be borne by even a greatly enfeebled patient better than an open operation in which a spinal or general anesthesia would be hazardous. I believe it should be used in preference to any other except in cases of very large tumors when intra-urethral methods are technically impossible. It is only under unusual circumstances that the surgeon will be so situated that he cannot employ one of the combination procedures. However should this situation arise I believe the loop ball disc method is preferable if owing to the size of the tumor a cystotomy is necessary.

¹ For a more detailed description of this instrument mentioned see J. Urol. 1937 38: 2.

CONCLUSIONS

The treatment of bladder tumors still offers many difficulties to the surgeon, despite great advances in pathological study and the design of instruments providing means of intervention which were impossible a few years ago.

Effort has been made to demonstrate that adherence to any one technique in dealing with vesical tumors whenever and wherever found, is a fundamentally unsound practice. No one method can be adapted to all cases.

Radical surgery is still widely practiced by eminent members of the urological profession. Extensive series of cases of total cystectomy have been reported for which considerable success has been claimed. The author regards any operation involving ureteral implantation as unjustified for use upon elderly and enfeebled subjects such as the majority of bladder tumor patients, and at best as a hazardous procedure with a highly uncertain outcome.

The principal methods of treating tumors of the bladder are offered together with a technique which will fulfill the requirements of conservative practice in the great majority of instances. It is recommended as combining the excellencies of all three standard methods, while eliminating the drawbacks to which each is subject when used alone.

SURGICAL FUSION OF THE WRIST JOINT

FREDFRICK LEE LIEBOLT, A B, M D Sc D (Med), New York New York

SURGICAL fusion of the wrist joint for deformities and disease is relatively new. Very little is presented in the literature concerning the subject. No conditions other than tuberculosis poliomyelitis, paralysis of the radial nerve in war fracture of the humerus affection of the wrist joint in syringomyelia, and brachial plexus paralysis have been given as the etiological indications for such operations. Except for tuberculosis no author has presented more than 1 case, and in none of the cases is there a detailed report of the follow up and end result. Ely offered a fusion operation for tuberculosis of the wrist in 1920 and presented 2 cases. Blanco in 1933 published 16 cases after the method of Ely.

This paper is a presentation of 44 consecutive and unselected cases in which fusion of the wrist has been performed for 8 different conditions, namely tuberculosis rheumatoid arthritis obstetrical paralysis, poliomyelitis fracture dislocation, Volkmann's paralysis gonorrheal arthritis and spastic paralysis. The average follow up is 4 1/2 years, and the end results are given in detail.

TUBERCULOSIS

History. The treatment of tuberculosis of the wrist until recent years has been highly unsuccessful. Long ago it was realized that operative treatment was indicated. In fact it has been nearly a hundred years (1839) since Dietz performed the first resection for caries of the wrist joint, and since Dupuytren (1846) wrote it is the slow insidious inflammation of the wrist terminating in the white swelling for which we are so often obliged to have recourse to amputation.

Though resection had its adherents it came more and more into disrepute because it left the hand useless and because excision often was repeated and repeated until pyogenic infection developed, making amputation necessary if the life of the patient was to be saved. Therefore attempts to preserve function of the extremity while curing the disease were inevitable. Fifty years later in 1881 Macnamara suggested ankylosing the involved joint when he said, if we

Fellow of the New York Orthopaedic Dispensary and Hospital
Submitted in partial fulfillment of the requirements for the degree of Doctor of Medical Science in the Faculty of Medicine
Columbia University June 1, 1937

can secure ankylosis without excision, the patient will, as a rule have a much better hand than he is likely to gain after the resection of the bones.

Furthermore, he did not approve of resection for those cases too far advanced for ankylosis and added "If the condition of the patient and the limb is such as to preclude all hope of recovery I should advise amputation rather than resection of the joint and in truth, in several cases of resection of the wrist joint the patient would have been better off with an artificial hand than with the mutilated remains of the one left after the operation (resection)."

Coote in 1867 considered that the maintenance of bodily strength and complete rest for many months or even years, was the treatment of choice. He believed further that, 'No operation can be of any avail,' although he stated that in very severe cases in adults amputation might be necessary.

Injection of iodoform emulsion into each bone and joint at the wrist was described by Senn in 1892 with the admission that the functional results were better than those obtained by resection 'in case the treatment proves successful'.

More accurate descriptions of the disease began to appear around 1900 but it was not until 1910 that Ely offered an operation for fusion of the wrist. By this method a tibial graft is placed between the base of the third metacarpal bone and distal end of the radius. Other types of bone grafts have been suggested also and today fusion is considered to be the treatment of choice, although as late as 1930 Whitman recommended splints and in severe cases early excision of the wrist with amputation as a final resort.

The first wrist fusion performed at the New York Orthopaedic Dispensary and Hospital was by Dr Russell A. Hibbs on April 23, 1919 (case No 27362). Up to July 1935 23 patients were operated upon for tuberculosis of the wrist at this hospital. Twelve of these were females and 11 were males. The disease affected the right wrist 11 times and the left wrist 12 times.

Quite surprising was the fact that in 6 of these 23 patients the disease spread from a primary lesion in the wrist joint to involve the ulnar epiphysis later and conversely in 1 case tuberculosis spread from the primary focus in the ulnar epiphysis to involve the wrist joint. This

Fig 1

Fig 1 Tuberculosis of wrist of many years' duration without operative treatment Anteroposterior and lateral views Note in both roentgenograms that the ulnar epiphysis is not involved

Fig 2

Fig 2 Same case as in Figure 1, 1 year 9 months later Anteroposterior and lateral views Compare with Figure 1 and note in both views that disease has spread and that ulnar epiphysis now is involved

finding seemed most unusual to me because the distal end of the ulna is blocked from the wrist joint by the interarticular fibrocartilage. Therefore, I undertook special work to try to determine the reason for the spread of the disease in this particular area

A THEORY AS TO THE ETIOLOGY OF SECONDARY TUBERCULOUS INVOLVEMENT OF THE ULNAR EPIPHYSIS FOLLOWING A PRIMARY TUBERCULOUS FOCUS IN THE WRIST JOINT

The ulnar epiphysis is not a part of the wrist joint. It is prevented from so being by the interposition of the triangular interarticular fibrocartilage which separates the distal end of the ulna from the lunate and triquetral bones.

In this series of 23 cases, secondary involvement of the ulnar epiphysis, or of the wrist joint, occurred 7 times, or in 30.4 per cent of the patients.

In 6 of these 7 cases, the wrist joint was involved primarily with the disease spreading to the ulnar epiphysis later (Figs 1 and 2). These 6 cases had no symptoms or roentgenographic findings referable to the distal end of the ulna for an average of 18.6 months after the condition present in the radiocarpal joint had been diagnosed as tuberculous.

In the 1 remaining case, the disease spread from the ulnar epiphysis to the wrist joint (Fig. 3). In this instance it is not known how long after symptoms developed in the distal end of the ulna that the radiocarpal joint became involved, but the roentgenograms revealed a large cavity in the ulnar epiphysis while only slight decalcification was present at the triquetral and pisiform bones, and it was much later before destruction occurred at the distal end of the radius. This indicates that the process was of much longer duration in the ulna than in the radius.

It is well known that the articular fibrocartilage excludes the ulna from the wrist joint. It is likewise well known that cartilage is one of the most resistant of tissues to tuberculosis. To try to explain, therefore, the extension of disease from one joint to the other, particularly from the radiocarpal joint to the distal end of the ulna, cadaver dissection was undertaken by the author at Columbia University College of Physicians and Surgeons. Eighty unselected cadavers laid out for anatomical study over a period of 2 years were used and 160 wrists were examined personally. The triangular interarticular fibrocartilage of each wrist was studied carefully. Seventy-four of these were normal, the central portion of the disk being about 3 to 5 millimeters in thickness. Thirty-seven

Fig 3 Tuberculosis of ulnar epiphysis. Anteroposterior views. On the left note large radiolucent area at distal end of ulna and only slight involvement of triquetrum and pisiform bones of wrist. On the right is same case 1 year 1 month later. Note that disease has spread and now has destroyed the wrist joint.

presented only a very thin membrane covering the center of the disk. These membranes were of the thickness of tissue paper and were as easily ruptured. Forty nine, or 30.6 per cent, were definitely perforated the perforation varying in size from 1 to 14 millimeters (Fig 4). The perforation was bilateral in all cadavers except 5 but the 5 disks on the opposite side that were not perforated were extremely thin.

A few books on anatomy do not mention that the articular disk at the wrist may be perforated (Spalteholz 7th edition in English). The latest editions of five standard textbooks on anatomy merely mention the perforation by saying "It (the disk) is in some cases perforated" (Piersol 1930) "the articular cavity (of the wrist joint) is sometimes continuous with that of the distal radioulnar joint" (Morris 1933) "There is no communication between the radio-ulnar joint above and the radiocarpal joint below except when, as occasionally happens, the triangular cartilage has a perforation" (Davis, 1934) "(the disk) is occasionally perforated" (Gray, 1936) and "in some cases the disc is perforated" (Cunningham, 1937). Because the incidence is not given there are no data available with which the findings in this study may be compared.

Upon the figures here obtained it appears that there is a definite relationship between 30.6 per cent of perforations of the articular disk at the wrist and 30.4 per cent of secondary ulnar or wrist involvement when tuberculosis affects pri-

TABLE I—AGE AS TO YEARS

Age—years	Cases
20 to 30	9
31 to 40	5
41 to 50	2
51 to 60	3
61 to 70	1

marily either of the joints. The presence of the opening in the disk destroys the barrier that normally exists between the ulna and wrist. It may be possible, but the above percentages do not substantiate it for the thin membrane across the disk to be ruptured by swelling and pus under pressure.

It seems plausible, therefore to assume that when disease of the distal end of the ulna follows disease of the wrist joint or occasionally vice versa, it is due to a developmental perforation of the triangular interarticular fibrocartilage.

Age. Most authors state that tuberculous disease of the wrist is rare in youth. In this series 3 patients, or 13 per cent of the group, were not over 16 years of age. The ages were 5, 7 and 16.

The 5 year old girl was brought here from an asylum and the duration of symptoms was unknown. She was kept at the country branch of this hospital for 1 year and fusion was performed at the age of 6. She was discharged against advice 4 months later and taken to Italy. The end result remains unknown.

The 7 year old boy had had symptoms for 1 year. Fusion was done 1 month after tonsillectomy had been performed. Refusion was necessary 9 months later and 1 year from the last operation the patient had a solid fusion and was symptom free (Figs. 5 and 6).

The 16 year old girl had had symptoms for 2 months. Fusion was done at once and 9 months later the wrist was solid and the patient was cured.

The number of patients in the other age groups is shown in Table I.

This table indicates that tuberculosis of the wrist is most common during the 2 decades of 20 to 40 years and that it is not unknown in youth or in old age.

Familial history. History of tuberculosis in other members of the family was not conclusive since in 9 of the cases it was not recorded. Eleven patients however denied the presence of familial tuberculosis while there was a positive history in 3 cases.

Previous treatment. The average period of time before proper treatment was instituted for these patients was 4.6 years. In all but 2 cases the previous treatment involved procedures that should have been avoided such as heat, massage, incision of swellings, diathermy, wet dressings and baking. It would have been much better to have given no treatment at all than to have employed such harmful procedures. Stress, therefore should

Fig 4 Interarticular fibrocartilages showing variation in thickness of disks and in size of perforations Top and bottom rows have normal disk on the right for comparison

be laid upon early and accurate diagnosis through aspiration and guinea pig examination so that loss of valuable time and improper treatment may be avoided.

Symptoms. Duration of symptoms varied greatly. The shortest period was 2 months and the longest was 28 years. The onset of symptoms was slow or sudden. Six of the patients had previous tuberculous foci elsewhere in the form of pulmonary, lymph node, fallopian tube, or tendon sheath involvement. Nine attributed the onset to injury. Long hours, hard labor, damp surroundings, and night work, were given by others as the cause of a generalized run-down condition which was present prior to the onset of symptoms. In some patients the original pain was first felt in the index finger, in others in the third and fifth fingers. Stiffness of the fingers was followed by intermittent aching which often increased until the patient was awakened at night by pain. The swelling, pain, and stiffness of the wrist and fingers, slowly but steadily increased until the patient gave up work and finally consulted a physician.

Physical examination. Typical physical findings are those of a swollen wrist joint, held in a protective manner, generally in the position of slight flexion and pronation. Motion is slight and all attempts to move even the fingers are limited by marked pain and spasm. Grip and active muscle power are poor. Localized heat and redness may be present at times to a slight degree but generally are absent. Tenderness about the wrist is exquis-

site. Fluctuation over the ulnar head may occur if the ulnar epiphysis is involved. Bogginess often is present. In contrast to the periarticular swelling is the marked degree of atrophy of the forearm, sometimes measuring 2 inches in comparison with the normal side. Sinus formation is not as frequent as one would think and, before operation, is rare. When the tendon sheaths are involved, fusiform swellings and soft tumors occur about the wrist and hand.

Roentgenographic examination. Roentgenograms early in the disease (Fig 5) reveal smoky decalcification with marked swelling. The cartilage space at the radius is thin. There is no bony productive reaction. Late roentgenograms (Fig 7) show radiolucent areas, erosion of articular surfaces; effusion, often marked and sharply outlined, decalcification, and thin cartilage spaces. Sequestra at times are present.

Procedures preliminary to fusion. Several procedures should be carried out preliminary to fusion of the wrist. Tonsils should be examined and removed if necessary, particularly in children. Duncan states that tonsils were removed from 100 patients with joint tuberculosis and upon microscopic section were found to be tuberculous in 24 cases. Since pulmonary tuberculosis is so often associated with tuberculous wrists, roentgenographic examination of the chest should be made. In this series, roentgenograms were available in 13 cases and of these, 4 were positive before operation for active pulmonary tuberculosis. None that was negative before operation became posi-

Fig 5

Fig 6

Fig 5 Tuberculosis of wrist in child aged 7 years Anteroposterior view of diseased wrist on left compared to normal before operation A roentgenographic example of tuberculosis early in the disease

Fig 6 Same case as in Figure 5 1 year after resection Anteroposterior and lateral views Note ulnar deviation of 20 degrees the third metacarpal being off center and not in straight line with forearm

tive after operation The history and physical examination should be used as further checks upon other tuberculous foci Frozen section examination should be performed in every case at the time of operation and no fusion should be carried out in the presence of a negative report except when the joint is so disorganized that fusion is the procedure of choice, irrespective of diagnosis Upon a negative report with the joint not appearing too diseased and without destruction of cartilage, closure of the wound should be made If the permanent sections or guinea pig inoculation show tuberculosis fusion of the wrist should be performed at a second operation

Tourniquet technique The operative procedure is made easier by the use of a tourniquet This should be applied after all blood has been evacuated from the extremity by carefully carrying an Esmarch bandage up the arm from the finger tips The constricting portion of the tourniquet should be broader than that used upon the lower extremity because the upper extremity presents more superficial nerves and less subcutaneous fat It should be a pneumatic cuff that will not leak because a leaking tourniquet allowing venous stasis is more apt to produce paralysis than a tight tourniquet producing pressure on the nerves In this series, tourniquets were used on all the patients and no paralysis occurred although the

operating time alone varied from a minimum of 47 minutes to a maximum of 1 hour and 37 minutes

Fusion technique Many factors enter into obtaining a solid fusion of the wrist and they are discussed in various parts of this paper Here I wish to mention the difference between small bone chips and large bone grafts in regard to fusion

During the period the bony mass is becoming vital irrespective of whether the mass consists of many small chips or a single large graft, absorption progresses, the mass remains discreet and fractures occur easily Union of the mass takes place quite early in comparison to complete revitalization In the case of bone grafts it takes a great length of time for the transplanted bone to change from an inert state to a vital state This period of time depends upon the cross sectional size of the graft In the case of small chips it takes a much shorter period of time for the bone to change to a vital state because the surface area of the chips is much greater and the cross sectional size of the chips is much smaller The expected time for extensive revitalization to occur when small chips are used is several months while in the large grafts a comparable state does not develop in less than several years

Since it is desirable to obtain revitalization as quickly as possible in order to arrive at a state of

safety (Fig. 7) where the danger of absorption and fracture of the fusion area is eliminated, small bone chips are considered better than large bone grafts

The bone chips are obtained, as the occasion demands, from various parts of the skeleton but usually from the distal third of the radius, which may be exposed through the same incision. Further, the cartilage of each carpal bone to be fused is removed, and portions of these bones are broken down into chips. When these sources are not sufficient, the ilium or the tibia is used. All chips are made quite small, generally about 12 by 3 millimeters. In a few of the earlier cases large bone slabs and grafts, ranging in size from $1\frac{1}{4}$ by $\frac{3}{4}$ inches to $2\frac{1}{2}$ by $\frac{1}{4}$ inches, were placed across the radius and denuded carpal bones. Union in these cases was slower, the average time being 8 months, while in those cases in which small chips were used, the average time was only 6 months.

Operative technique. The skin incision is made dorsally between the extensor pollicis longus and extensor indicis proprius. The incision is a longitudinal one and need not be longer, generally, than 8 centimeters. The subcutaneous tissues and dorsal carpal ligament are incised. The extensor pollicis longus and extensor carpi radialis brevis are retracted radialward while the extensor indicis proprius and extensor digitorum communis are retracted ulnarward. The capsule is opened and the radiocarpal joint exposed.

From this point on the operation depends upon the pathological findings. Generally, only those joints involved are fused although the better functional and cosmetic results in this group were those in which the radius, both rows of carpal bones, and all the metacarpal bones, except the first, were solidly fused. The latter is considered the better procedure.

The distal epiphysis joins the diaphysis of the radius at about the twentieth year. In patients younger than 20, care is taken not to injure the epiphyseal cartilage. However, when the area has been partially destroyed by disease, the remaining portion may be excised to prevent unequal growth, and fusion is carried out as described.

When diseased, the distal end of the ulna is resected. This often gives an unsightly defect, as if the hand were displaced medially, and slight medial motion, in spite of the radius being fused, may be the result. However, fusion of the ulna to the carpus should not be attempted because it would not only be difficult to perform, but also would prevent the movements of pronation and supination and thus produce an incapacitating deformity.

Fig 7 Tuberculosis of wrist. Anteroposterior views before and after operation. The left is a roentgenographic example of tuberculosis late in the disease. The right is same case 1 year 6 months after fusion with fracture of radius and ulna demonstrating strength of fusion area.

It is not considered necessary to remove all the diseased tissue and, in fact, such is impossible at the wrist. However, it is necessary that all cartilage be removed from the joints to be fused, except on the anterior aspect. Often destruction may be so great as to require the complete removal of a bone. Unless diseased, and none was in this group, particular care is taken not to enter the first carpometacarpal joint because complete motion of the thumb is extremely important to the patient. If disease should be present at this joint, resection would be preferable to fusion because of the importance of thumb motion.

An adequate number of bone chips, which means a large amount, are placed in all the spaces where bone destruction has occurred, as well as between the various bones to be fused, and particularly over the dorsum of the radionavicular joint.

Closure is by interrupted sutures throughout because of the danger of the wound breaking down. It is felt, also, that although proper closure will not obviate all sinuses it will materially affect their incidence. Every attempt is made, as difficult as it may be, to close the capsule as far as possible. This aids in preventing adhesions about the tendons as well as leakage from the joint. The dorsal carpal ligament is carefully united. The subcutaneous tissues are closed with interrupted plain catgut sutures and the skin edges with interrupted silk sutures.

Plaster technique. Many casts following fusion are applied no higher than the proximal forearm. This is believed to be wrong because it violates

Fig 8

Fig 8 Tuberculosis of wrist. Wrist in plaster after operation showing in anteroposterior view proper neutral lateral position with third metacarpal in line with forearm and in lateral roentgenograms proper degree of extension (30 degrees)

Fig 9

Fig 9 Same case as in Figure 8 2 years 6 months after operation showing solid fusion Anteroposterior and lateral views Compare with Figure 8 and note that neutral lateral position has been maintained but that proper degree of extension has been lost

the rule of immobilizing one joint above and one joint below the area involved, because the principal area to be fused in a wrist fusion is the radio-navicular joint and a cast that does not immobilize the elbow and thereby eliminate rotation of the radius cannot completely immobilize the radio-navicular joint, and because a cast extending above the elbow allows much more comfort to the patient immediately after operation which fact may be observed at the bedside. In this series the data were not sufficient to offer definite proof that casts applied no higher than the proximal forearm cause failure of fusion but it is felt that the presence of rotation mobility is a factor in some cases of pseudarthrosis.

In addition to extending above the elbow, the cast should always extend to the finger tips. This is also more comfortable for the patient because the hand is better immobilized. If contracture deformity of the fingers is present and often it is, the fingers should be held extended 45 degrees in order to stretch the flexor muscles. When the thumb presents no deformity it should be left out of plaster, and because there is a great tendency for pressure to occur at the base of the thumb the cast should be cut well back of the first carpo-

metacarpal joint rather than just down to the metacarpophalangeal joint, as so frequently happens.

Another point I wish to emphasize is the promiscuous changing of casts in order 'to take a look and get an x ray'. To remove a cast and apply another one produces motion, pain and change of position, at the involved joint. The cast should be changed 2 weeks after operation in order to remove the sutures, inspect and dress the wound and overcome the effects of swelling. Then a lighter more snug and comfortable cast is applied and left on an additional 10 weeks. In this group of 23 cases union took place no sooner than 12 weeks and the average period was 24 weeks. Assuming therefore that at least 12 weeks are necessary for fusion to occur, it would seem unnecessary to change casts before that period except during the second postoperative week as stated, unless there is a better excuse than to take a roentgenogram. There are two reasons for this attitude. First as to fusion it is practically impossible no matter how much one tries, to prevent motion at the involved joint which in turn may not only retard but be the cause of failure of fusion. Second, as to mainte-

nance of position. Normally the flexors at the wrist are much stronger than the extensors. Further, often at operation the fingers are in an already contracted state. Therefore, when support is removed there is a great tendency for the wrist to flex. Assuming that the wrist is in proper extension it is quite doubtful that the same amount of extension will be present, due to the factors named, after the cast is changed. (Compare Figure 8 with Figure 9.) In only 2 of the 23 cases presented here was the same amount of extension present when fusion occurred as was present immediately after operation.

Position of function At the beginning of the twentieth century, mention was first made in the literature that the position of hyperextension should be obtained when splints are applied to a tuberculous wrist. Now that fusion is the accepted treatment for tuberculosis of the wrist, it becomes more necessary that attention be paid to the proper postoperative position. A hand hyperflexed or hyperextended has a poor grip. A hand at 180 degrees, i.e., the metacarpal bones in a straight line with the forearm, is not in the proper position for convenience of gripping or for strength of gripping. The ideal position of function, therefore, lies between 25 and 30 degrees' extension (Fig. 8). I like to remember this by the simple procedure of "making a fist." As the fingers are flexed into the palm, the wrist automatically goes into the proper amount of extension to furnish maximum strength, function, and cosmetic appearance.

I would like to add another "position of function" to that of hyperextension as described by Kanavel and others. It seems to me to be very important, yet I can find no description of it in the literature. I refer to "neutral lateral position" of the hand (Figs. 8 and 9). This means that the hand should not be deviated to either the ulnar or the radial side but should be straight forward on the forearm. For some reason most students of surgery believe that all wrists and hands, when immobilized, should be put up in varying amounts of ulnar deviation. It is held by some that such is the normal anatomical position. If one should believe that the latter is true, let one make a grip with the hand held in ulnar deviation and note how weak the first three fingers are. However, if the hand is held loosely and the fingers firmly flexed into the palm, one will find that the hand assumes neither ulnar nor radial deviation but is straight forward on the forearm in neutral lateral position. This position is demonstrated also by "making a fist." Another way to accomplish the position is to flex the middle finger into the palm,

and whenever the hand is straight on the forearm the flexed middle finger will point up the forearm. From the dorsal aspect the hand is in neutral lateral position when the middle finger is in line with the middle of the forearm.

Besides strength, there are other reasons why the hand should be immobilized in neutral lateral position. These are writing, awkwardness, and appearance, and they can be described best by giving actual cases. One patient was a stenographer whose wrist was fused in ulnar deviation. She suffered great fatigue, numbness, and pain along the hypothenar eminence and fifth finger when writing, because her hand was tilted and could not rest smoothly upon the desk. Another patient whose wrist was fused in ulnar deviation was a man who complained of awkwardness in work as well as in the performance of small acts. The hand being off center made it difficult for him to be accurate in picking up small articles and in grasping. As for appearance, a third patient denied symptoms from the ulnar deviation but admitted embarrassment because it was this deformity alone that attracted attention to her wrist. An example of a wrist fused in ulnar deviation is seen in Figure 6.

In summary, there are two factors in position of function of the wrist: (1) 25 to 30 degrees' extension, (2) neutral lateral position.

Gross pathological findings. Operative findings vary greatly and, of course, every tuberculous wrist does not present the same picture. In every case except 7 the disease appeared to have originated at the lower extremity of the radius. In 5 of the 7 cases the disease was diffuse, and its source could not be ascertained. In the sixth case the ulnar head was chiefly involved, presenting a cavity one-fourth inch in diameter filled with caseous material. The seventh case presented a definite cavity in the greater multangular bone while the navicular and radius were negative.

The distal end of the radius at times is intact but generally it presents an abscess cavity of varying size, sufficient often to destroy the entire distal end and extend proximally up the shaft. These cavities contain in some instances as much as 2 ounces of either caseous material, typical tuberculous pus, or yellow pus of varying consistency. When pus is present, it generally is localized to the radionavicular region, but at times it extends between the two rows of bones, even to the capitate and second and third metacarpal bones.

The synovial membrane is pale and gray, occasionally gray-red from inflammation. It is thick, boggy, or edematous, and generally of soft

TABLE II—END RESULTS AS TO CURE FROM SURGICAL FUSION OF THE WRIST FOR TUBERCULOSIS

or gelatinous consistency. Often the entire carpus is covered with pale, purple gray, tuberculous appearing granulation tissue which at times bulges out upon incision of the capsule.

The cartilage is either eroded, atrophic, thin, friable, or absent. Sometimes it is loose and can be stripped away easily or even picked out with forceps alone. The resistant quality of articular cartilage was again demonstrated in one instance in which the entire proximal row of bones was destroyed but a large cavity in the radius was discovered only after the radial cartilage had been removed. Several cases also revealed cartilage lying free although an entire row of bones was absent. In one case the styloid process of the ulna was separated.

The involved joints are always thin and narrow and very little passive motion can be elicited, particularly when disease is present throughout the carpus. The bones are very soft, decalcified and atrophic often being one half normal size distorted and misshapen. When deep cavities or extreme decalcification are present the bones may be macerated or mashed together after removal of the cartilage. Sequestra occasionally are present. The proximal row of bones is generally diseased and at times entirely destroyed except for the pisiform which is rarely involved. The distal carpal row may be normal and often the carpometacarpal joints are not involved. In cases of long duration it is not uncommon to find natural fusion between the navicular greater and lesser multangular bones. In one case all the carpal bones except the lunate were completely fused together and to the radius. In no case in this series was the first carpometacarpal joint involved.

When tendon and synovial sheaths are diseased, marked swelling is present due to edematous and gelatinous synovial lining. This occurred 3 times in 23 cases.

Proof of diagnosis. Tuberculosis should always be proved either by frozen tissue section permanent tissue section, or guinea pig inoculation. Every case in this series was so proved. Although

one patient died of carcinoma of the throat 15 months after wrist fusion, check up of the original sections of the wrist tissues revealed them to be typical of tuberculosis. In one case no typical tuberculous areas were seen upon inspection at operation but frozen section examination of the tissues was positive for tuberculosis. In another the smear of pus from the wrist was positive for tuberculosis.

In the 13 cases in which it was done the Mantoux test was positive. The Wassermann test was negative in each case except one but in this exception the frozen section and guinea pig diagnoses were positive for tuberculosis.

Sinus formation. Before operation sinuses were not present in any of the 23 cases. Following operation sinus formation occurred 7 times. Three healed within 6 to 8 weeks. Another remained open until refusion of the wrist was performed 6 months later. Two continued to drain until the hands were amputated at 9 and 12 months, respectively. Another drained until the patient died 15 months after operation.

Postoperative treatment. Two weeks after operation if there are no complications, the sutures are removed, a snug well fitting plaster cast is applied, and the patient is discharged from the hospital. The plaster cast is worn from 12 weeks to 6 months depending upon the progress of the fusion. The period of immobilization averages about 3 to 4 months. After removal of the cast a sling is worn temporarily and gentle massage, hot soaks, light elbow and finger exercises are given.

End results. For purposes of clarity the end results are classified in two different ways: (1) As to cure of the disease. This is the most important classification because the primary purpose in the treatment is to cure the local tuberculous lesion. It is well known that a complete and solid fusion be it by surgical or natural means does produce a cure. (2) As to anatomical, symptomatic, and functional results. In this classification which is the most comprehensive not only is the state of fusion considered in regard to the presence or the absence of a cure but symptoms and function are also discussed and evaluated upon a numerical basis.

The end results are based upon a follow up period ranging from 1 to 13 years except for 2 cases of 6 and 9 months each. The 3 patients who disappeared and the 3 who died are not included in these figures. This leaves an average follow up period of 3.6 years.

Results as to cure (Table II). It can be said definitely that 12 of the 23 patients were cured. It is not known why fusion cures tuberculosis but

Fig 10.

observation shows that once a tuberculous joint becomes completely solid, with the disease subsided, disease does not recur in that joint. Eight fusions became solid following the first operation, and judged roentgenographically, fusion in these cases occurred at 3 months in 2 cases, at 6 months in 2 cases, at 7 months in 1 case; at 9 months in 1 case, and at 12 months in 2 cases. Three additional fusions became solid after a second operation and 1 after a third operation.

Another case showed fusion of the radiocarpal joint at 9 months but the ulnar head became involved and had to be resected. At the time of resection, the radiocarpal joint was found to be solid. Since tuberculosis does not spread from a solid fusion area, the ulnar head must have become infected in the manner previously described, during the period the wrist was undergoing fusion.

Eleven patients developed pseudarthroses. Four of these obtained a solid fusion, as stated. Three patients refused to have the pseudarthrosis repaired. One patient with a pseudarthrosis died of carcinoma of the throat 15 months after wrist fusion had been attempted, and another died 3 months after operation from active pulmonary tuberculosis which was present before operation. Amputation was performed in the 2 remaining cases. The latter were white males, aged 58 and 69, who gave a history that 18 and 9 months earlier they had fallen and injured the right and

left wrist, respectively. Both had been treated elsewhere by hot applications and massage. At operation pus was present in each wrist and by guinea pig inoculation the tissues were positive for tuberculosis. Sinuses formed, fusion did not take place, and the wrists and hands became useless from extensive disease. Twelve and 9 months after attempted wrist fusion, amputation at the lower fourth of the forearm was performed. One patient died 3 months later of pulmonary tuberculosis which had been present over 2 years. The older man lived.

2. *Results as to anatomy, symptoms, and function.* The 23 cases were graded on the basis of 4-4-4 for perfect anatomical, symptomatic, and functional results. In discussing Table III inversely, 3 patients moved to Colorado, Italy, and Japan, soon after operation was performed and end-results remained unknown.

Failures occurred in 4 cases through amputation or death. These were discussed previously.

Fig 12

Fig 12 Spastic paralysis affecting wrist before operation. Note flexion of fingers in anteroposterior view and of wrist in lateral view.

Fig 13

Fig 13 Same case after operation. Note extension of fingers in anteroposterior view and of wrist in lateral view after removal of proximal row of bones and fusion of wrist.

In the 3 results rated as poor the fusions were incomplete but the disease was quiescent. The patients were greatly improved and had returned to their vocations of housewife, nurse, and waitress, which they previously had had to give up and which they now accomplished satisfactorily except for fatigue and aching at night after a day's hard work.

A fair result (3 3 2) occurred in 1 case. The disease was cured but because the wrist became solid in slight ulnar deviation instead of neutral lateral position and in 10 degrees extension rather than 25 to 30 degrees extension only an anatomic 3 was given. The patient returned to his old occupation as cabinet maker but because his efficiency was not as great as formerly and because he lacked complete flexion of the fingers, although extension was good, a functional 2 was allotted. With light work he suffered no symptoms, but after heavy work temporary stiffness of the fingers occurred. Also slight twinges of pain were present with changes in weather, so a symptomatic 3 was given.

Good results were obtained in 8 patients the grading being from 3 3 3 to 4 4 4 as follows: three 4 4 3's, two 4 3 4's and one 3 3 4, 3 4 4 and 4 3 3. The joint became solid and a cure was obtained in each case. A 3 instead of a 4 was given, however, because of such conditions as inability to make a tight fist, occasional pain in bad weather, and slight adduction deformity of the hand.

Perfect results (4 4 4) occurred in 4 cases. Such rating indicates that a cure of the local lesion was

obtained with the wrist solidly fused in excellent position, that no limitation of function of the hand and forearm was present, and that the patient was symptom free.

Conservative treatment. For comparative purposes a study was made of all the records from 1905 to 1933 of patients with tuberculosis of the wrist who had been treated conservatively and without operative interference. There were 52 such records. The range of age was from 2 years to 60 years. There were 12 more males than females but the site of affliction was practically equally divided between right and left. Diagnosis of tuberculosis was made by the history, examination, roentgenograms, aspiration, biopsy, in 1 case, sinus formation and the course of the disease. Treatment consisted of immobilizing procedures such as strapping, casts and braces. The follow-up period ranged from 3 months to 18 years with an average of 3.9 years.

Only 8 of the 52 patients were relieved of their symptoms and 1 of these continued to have intermittent pain after wearing a brace for 2 years. Sinuses were frequent, some draining for as long as 2 years. Braces were worn in each case. It is important to note that as the wrists became asymptomatic motion also became markedly limited.

None of the 44 remaining patients was relieved. Many were discouraged. Twenty-seven sought treatment elsewhere. After wearing a brace 9 years, 1 patient still suffered pain and spasm of the wrist and hand. Four died. One of these developed tuberculosis of the knee 3 months after

the onset of the disease at the wrist and died of pulmonary tuberculosis 18 years later, still wearing a brace. Amputation was necessary for 1 patient. Another developed tuberculosis between the tenth and twelfth thoracic vertebrae 3 years after involvement of the wrist. The foot and spine became affected in another case. Active pulmonary tuberculosis was diagnosed in 3, and no doubt existed in many more.

On the other hand 2 patients developed tuberculosis of the wrist from other foci. One of these had had a draining tuberculous hip and shoulder for 10 years before the wrist became diseased, and finally died 2 years later of tuberculous meningitis. The other had a draining tuberculous sacroiliac joint for 5 months before the wrist became affected, and this was followed by tuberculosis of the knee.

Table IV allows comparison of the results obtained from operative and conservative treatment of tuberculosis of the wrist.

CONDITIONS OTHER THAN TUBERCULOSIS OF THE WRIST

Fusion of the wrist was performed upon 21 patients suffering from rheumatoid arthritis, obstetrical paralysis, poliomyelitis, fracture-dislocation, Volkmann's paralysis, gonorrheal arthritis, and spastic paralysis. The cases under each condition will be given in detail. The method of fusion follows the same general principles as were discussed under tuberculosis. Variations of importance, however, are mentioned below.

When adduction deformity of the hand is severe it is necessary, in order to obtain correction, to remove wedges of bone from the lateral aspect of the radius and navicular bones. In addition, lengthening of the flexor carpi ulnaris tendon may be necessary also before the hand can be placed in neutral lateral position.

When flexion deformity of the hand is present or the fingers are contracted, it is wise to remove the proximal row of carpal bones, i.e., navicular, lunate, and triquetrum. The flexion deformity of the hand thus can be overcome easily. At the same time, this will give more motion to the fingers or will allow them to retain the same amount of motion after the wrist is extended as was present in flexion. If the flexion deformity and contracture of the fingers is severe, stretching by the Jones splint should be carried out before operation, and after operation the fingers should be held hyperextended as much as possible.

When tendon sheaths have been destroyed, plastic implantation of adipose tissue may aid materially in improving finger function by pre-

venting adhesions between the bare bone and the bare tendons.

When bone circulation appears to be poor, as it is in hard, eburnated bone, fusion may be aided by placing drill holes in the distal end of the radius and surrounding carpal bones.

Fusion is also encouraged by establishing a stable fusion area. This can be done best at the wrist, in those cases in which it is necessary to remove the proximal row of bones, by cutting a recess into the radius to admit snugly the denuded head of the capitate bone. Such can be performed with impunity when the distal radial epiphyseal line is closed but with care otherwise. When the radial epiphysis is too small to allow for the carrying out of such a procedure, the head of the capitate is removed in order to approximate the carpal bones and radius.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis of the wrist is a very incapacitating condition producing a swollen joint that is painful and weak, allowing little use of the hand. In selected cases in which the joint has become so disorganized that it is not amenable to conservative treatment, elimination of pain and restoration of function to the hand may be accomplished by wrist fusion.

Four patients, 3 females and 1 male, ranging in age from 17 to 37 years, were so treated. Symptoms had been present from 2 to 9 years except for 1 acute case of 2 months' duration. All had received the usual anti-arthritis treatment of heat, massage, exercises, salicylates, supports, x-rays, and attention to foci of infection. Examination revealed warm, red, swollen joints with severe spasm and pain upon attempted motion. Anteroposterior motion was only 10 to 20 degrees associated with full pronation, limited supination, and absent lateral motion. The roentgenograms showed decalcification, thinning of the cartilage spaces, and effusion.

When bone circulation appears to be poor, as it is in hard, eburnated bone, fusion may be aided by placing drill holes in the distal end of the radius and surrounding carpal bones.

Fusion is also encouraged by establishing a stable fusion area. This can be done best at the wrist, in those cases in which it is necessary to remove the proximal row of bones, by cutting a recess into the radius to admit snugly the denuded head of the capitate bone. Such can be performed with impunity when the distal radial epiphyseal line is closed but with care otherwise. When the radial epiphysis is too small to allow for the carrying out of such a procedure, the head of the capitate is removed in order to approximate the carpal bones and radius.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis of the wrist is a very incapacitating condition producing a swollen joint that is painful and weak, allowing little use of the hand. In selected cases in which the joint has become so disorganized that it is not amenable to conservative treatment, elimination of pain and restoration of function to the hand may be accomplished by wrist fusion.

Four patients, 3 females and 1 male, ranging in age from 17 to 37 years, were so treated. Symptoms had been present from 2 to 9 years except for 1 acute case of 2 months' duration. All had received the usual anti-arthritis treatment of heat, massage, exercises, salicylates, supports, x-rays, and attention to foci of infection. Examination revealed warm, red, swollen joints with severe spasm and pain upon attempted motion. Anteroposterior motion was only 10 to 20 degrees associated with full pronation, limited supination, and absent lateral motion. The roentgenograms showed decalcification, thinning of the cartilage spaces, and effusion.

The presence of the above findings caused 3 of the 4 patients to be observed for tuberculosis because it was ruled out. Cultures and Wassermann reactions were likewise negative. But fusion was done because of the pathological findings of thick gray edematous synovial membrane, thin cartilage that separated easily, and soft bones showing areas of erosion. Occasionally fibrous tissue was found between the bones, and in the acute case of only 2 months' duration, the presence of seropurulent fluid and a small amount of caseous material caused the surgeon to make a macroscopic diagnosis of tuberculosis but careful microscopic examination of the tissue did not prove this. The complement fixation test for gonococcus was also negative in this case.

The operations were carried out in the routine manner by removing the cartilage from all bones except the pisiform and the greater multangular, and placing bone chips in the intercarpal spaces.

In one case the sheaths of the extensor tendons had become thickened and edematous with destruction of the anterior portions. As is well known, adherent tendons with resultant impaired finger motion are a serious handicap. Therefore, a layer of fat was taken from the thigh and transplanted over the bone in order to prevent adhesions between the bare bone and overlying tendons through the destroyed anterior portion of the tendon sheaths. Active finger motion was started on the fourth day after operation and in 6 weeks motion of the fingers was complete. Five and one half years later a perfect functional result was still present; furthermore, this was the only one of the 4 cases that did have a perfect end result.

In all 4 cases healing of the incision was *per primam* without sinus formation. Plaster casts were worn from 3 to 5 months and the fusions became solid within 3 to 6 months.

Grading on the basis of 4 4 4 for perfect anatomical, symptomatic, and functional results in the order named, the results were 4 4 4 4 4 3 4 4 2 and 2 4 3. These end results were in turn based upon a follow up period ranging from 5½ to 12 years with an average of 8 years.

Three of the 4 wrists became solid in proper position and received an anatomical 4. But a 2 was given in the other case because the wrist became solid in ulnar deviation rather than neutral lateral position and because rotation was limited.

Each case received a symptomatic 4 because each patient became free of all wrist symptoms. Heavy use of the hand was no longer painful. One patient stated that now he could drive a taxi all

day without pain or fatigue. One woman was well pleased because she could not sew or pick up objects before operation while afterward she accomplished such with ease. Ironing also became a painless task.

The greatest mark down came in the functional group. Arthritis of the fingers limited finger motion and lessened the grip in 3 cases. Although such was present before operation a perfect functional result was not given.

OBSTETRICAL PARALYSIS

The lower arm type of obstetrical paralysis (Klumpke's) offers the best results from wrist fusion because in spite of the drop hand the shoulders and elbow muscles are adequate. The operation can also be of value in the whole arm type of paralysis, but here the musculature of the entire extremity is generally so poor that nothing better than a cosmetic result can be expected. The upper arm type (Erb's) does not give a drop hand thus allowing no indication for wrist fusion.

A 16 year old boy suffered paralysis of the left upper extremity at birth. Treatment elsewhere consisted of electrical stimulation, massage, and transplantation of the wrist flexors to the dorsum of the hand without resultant improvement.

Examination of the musculature of the left upper extremity revealed good power in the flexor and adductor muscles at the shoulder while the remaining shoulder muscles were poor in power. Elbow musculature was good except for fair pronator and supinator muscles. At the wrist the flexors were fair and the extensors poor while the fingers showed good flexor and fair extensor power. The wrist was held in 30 degrees adduction and flexion and no active extension was possible.

At operation the cartilage was removed from the radius, navicular and lunate bones. A wedge of bone also was removed laterally in an attempt to correct the ulnar deviation. The fusion became solid in 4 months and the plaster cast was removed.

Four years 8 months later the patient was rated as a 2 4 4 result. An anatomical 2 was given because although the wrist had become solid in extension a 20 degree adduction deformity persisted which the patient did not like for cosmetic reasons. In addition rotation was limited to 75 degrees pronation and 45 degrees supination.

A symptomatic 4 was given because there were no symptoms even in bad weather.

Excellent function gave a functional 4 result. The patient stated that the operation was of great value and had given more strength to the entire arm. The grip was now almost equal to that of the normal side. Formerly the tighter he grasped the more flexion occurred at the wrist with a corresponding weakness of grip. Now with the hand extended the grip was more certain, stronger and of greater duration. For the first time he could button his shirt and dress himself with this hand.

POLIOMYELITIS

Wrist fusion in poliomyelitis is of value not only in the classical case of good flexor and absent

extensor muscles, but also in combination with shoulder fusion when the extremity is practically flail. It may also be used for cosmetic purposes when the hand is flail, useless, and dangling at the side in poor position.

The ages of the 2 girls and 1 boy so treated varied from 12 to 19 years, and they had not had full use of the affected upper extremity for 10 to 18 years.

One had good musculature at the shoulder and elbow but no power at the wrist and hand except for poor flexors of the fingers, resulting in the hand being held in 70 degrees of flexion and 60 degrees of pronation. After operation upon the wrist, at which time the first row of bones (navicular, lunate, and triquetral) was removed and the radius fused to the capitate and lesser multangular bones, the fusion became solid with the hand in extension and neutral lateral position; there were no symptoms except slight pain in the last 10 degrees of passive extension to 180 degrees due to the fingers remaining somewhat contracted as they were before operation, and the patient was able to drive a car for the first time in his 19 years of life. A grading of 4-3-3, based on a 3 year 3 month follow-up, was given this case.

Another had a flail shoulder and elbow with fair flexors and poor extensors at the wrist in addition to poor power in the fingers. Due to fair adductors and absent abductors the wrist presented an adduction deformity. To correct this the flexor carpi ulnaris tendon was lengthened and a wedge of bone was removed from the navicular and radius. Fusion was carried out by removing the cartilage from the first and second row of bones. Three months later the wrist was solid. Two years and 2 months afterward there were no symptoms. Cosmetically the hand was improved by the better position and for this a 2 was given. Otherwise the hand was no more useful than before. Fusion in good position, without symptoms, and with the hand cosmetically improved, gave a rating of 4-4-1.

The third case presented a flail shoulder and wrist with good musculature at the elbow. The child was 12 years old and fusion of the shoulder and the wrist were performed at the same time, the wrist by macerating the carpal bones, end of the radius, and bases of the metacarpals, after their cartilages were removed. The result 9 years 4 months later was a solid wrist and shoulder with the wrist at 180 degrees and in 5 degrees of adduction instead of 30 degrees' extension and neutral lateral position, for which an anatomical 3 was given. There were no symptoms—a symptomatic 4. Functionally, the patient could now hold a knife and fork, type write, dress herself, and open doors—things she could not do before operation. A firm grasp was present due to good flexor muscles functioning against a fused wrist. The patient herself was well pleased. This was a very good result considering the extensive paralysis, and a functional 3 was granted, making the rating 3-4-3.

FRacture-DISLOCATION

For injuries that completely disrupt the continuity of the wrist, allowing no recourse to open or closed reduction, fusion offers the quickest, most effective, and permanent relief.

In one case a 44 year old man fell 35 feet receiving a fracture-dislocation of the left wrist (Fig. 10) in addition to fractures of the left tibia, second lumbar vertebra, and right radius.

At operation the proximal row of carpal bones (navicular, lunate, and triquetral) was removed. The cartilage was removed from the radius, capitate, and hamate bones. A recess was cut into the radius to admit the denuded head of the capitate bone which was sutured to the radius.

The result 3 years 4 months later was 4-4-4 with the fusion solid in good position; with no pain or other symptoms, and with good function without disability.

Another case was that of a longshoreman who fell from a similar height and received a fracture of the radius which united with shortening and overlapping of the fragments, causing a 30 degree abduction deformity of the hand. Function and strength were so poor that the patient had to give up work. At the time of wrist fusion drill holes were placed in the radius and surrounding carpal bones for stimulation of circulation. The follow-up 4 years 10 months later revealed fusion between the radius and lunate but none between the radius and navicular bones, and motion was from 15 degrees' flexion to 25 degrees' extension. For lack of fusion a zero was given. Symptomatically, however, the patient received a 4 because there was no pain, spasm, tenderness, or swelling, even in bad weather. A 4 also was given for function. There was good musculature and circulation. Finger motion was complete and strong, with the grip being almost equal to the normal side. He returned to work as a longshoreman upon removal of the cast 3 months after operation and stated nearly 5 years later that he could do any work anyone else could. He was very well pleased. The rating given was 0-4-4.

VOLKMAN'S PARALYSIS

Volkman's paralysis (Fig. 11) offers a poorer prognosis than any of the conditions for which wrist fusion may be done because the shiny, stiff, board-like extremity is generally beyond functional improvement. However, the patient can be improved cosmetically when flexion deformity is present by fusing the wrist with the hand in good position.

Such was done for 2 patients who had suffered Volkman's paralysis 1 and 14 years earlier. Both had flexion deformities of the right hand of 25 and 60 degrees, respectively, with only 20 degrees of anteroposterior motion. The flexion deformity had been wedged out by plaster casts and a brace worn, but each time the deformity recurred upon removal of the brace.

At operation the proximal row of bones (navicular, lunate, and triquetral) was removed in an attempt to relax the flexor tendons and overcome their contracture. Though this did not improve the function of the fingers in 1 case it kept them from contracting further because with the hand solid in extension there was as much finger motion as there had been before operation. Grasping in both cases was carried out with the fingers, which moved one-third of normal, and the strong, freely movable thumb. Both patients were pleased and at ease with a stiff wrist in extension rather than with the former one in flexion. One was free of all symptoms while the other continued to be sensitive to burns due to the previously impaired sensation.

Ratings of 2-2-2 and 2-4-0 were given on a follow-up basis of 4 years, and 1 year 5 months.

GONORRHEAL ARTHRITIS

Gonorrheal arthritis rapidly produces fibrous or bony ankylosis at the wrist and if, during the

activity of the disease, the hand is placed in proper position there need be no reason later for wrist fusion. However, when such wrists become ankylosed in poor position they must be corrected. In this case the 30 degree flexion deformity did not allow the patient to flex the fingers completely. She also suffered pain in bad weather and upon lifting.

At operation there were 10 degrees of motion at the radiocarpal joint while the remaining carpus was a solid mass of hard and enurated bone. Chips from the mass were taken to fuse the radiocarpal joint. The wrist became solid within 3 months in 15 degrees extension. Because 30 degrees extension would have been better an anatomical 3 was given. There was no swelling, pain, tenderness or spasm but because of an occasional numbness of the fingers and stiffness after washing clothes a symptomatic 3 was given. Due to 75 degrees of supination instead of 90 and a grasp weaker than the normal side a functional 3 was given.

These findings based on a 3 year 8 month follow up study gave a 3 3 3 result.

SPASTIC PARALYSIS

Wrist fusion offers much for the unfortunate victim of spastic paralysis (Figs. 12 and 13). The usual deformity of a flexed hand which the patient generally is unable to extend actively, associated with hyperextension or hyperflexion of the fingers is a well known condition. In the mild cases fusion improves function by placing the hand in extension allowing better strength and motion of the fingers. In the severe cases the spasticity prevents good finger function, but cosmetically the bad position is overcome by fusion which in turn eases the patient's embarrassment and improves the morale. In a sense also, function of the extremity is improved in that it is much easier to put the straight hand through a coat sleeve or in a pocket than when the hand is in severe flexion.

Eight patients of both sexes ranging in ages from 13 to 25 years and suffering the deformity the same length of time received wrist fusions for deformity resulting from spastic paralysis. Each patient complained of inability to extend the hand completely, lack of strength due to the flexion deformity, inability to eat, write and lace shoes and failure of precision in handling small objects.

All had been under treatment at this hospital from 4 to 19 years receiving exercises, massage and braces. Previous operations included transplantation of the flexor carpi ulnaris and radialis to the extensors of the fingers and cervical resection.

The deformity varies according to the patient but generally the elbow is flexed, the forearm pronated 90 degrees, the wrist flexed 45 degrees and adducted 45 degrees and the fingers extended except for the thumb which is held adducted. Most of the patients can open their hands in flexion but in this position the grip is always poor. Others have full range of finger motion but fine movements are labored, inco-ordinate and uncertain. Rarely is there free motion of the elbow and shoulder but when such is present

the functional result of the hand after operation is much better.

The operating time varied from 39 minutes to an hour and one half. In 5 of the 8 cases the proximal row of bones was removed in order to accommodate the shortened flexors of the fingers. Such was not done in the 3 other cases because good finger motion was present before operation.

When the navicular, lunate and triquetrum bones are removed the cartilage is excised from the distal end of the radius proximal and lateral aspects of the lesser multangular proximal, medial and lateral aspects of the capitate, and proximal and medial aspects of the hamate bones. A cavity is then made in the radial articular process care being taken not to injure the epiphyseal line if it is not closed and the head of the capitate is snugly buried in the radius. Small bone chips from the radius are placed where necessary. A long arm cast with the wrist in 25 to 30 degrees extension and neutral lateral position and the fingers in 45 degrees extension in order to stretch the flexor muscles is applied. The cast should extend to the finger tips and because the thumb generally presents an adduction deformity it should also be encased in plaster and held widely abducted.

Cast is worn from 2 to 4 months. Those worn the shortest period of time showed less finger motion due to the rapid contracture of the fingers indicating that holding the finger flexors stretched for a longer period of time improves finger function. For this reason most casts now are left on for a period of 16 weeks. After removal of the cast, hot soaks, massage and a sling are given for the wrist plus light exercises for the elbow and the fingers.

All fusions became solid within 2 to 4 months except for 1 case which developed a pseudarthrosis.

One patient was omitted from the end result study because she ignored requests to return for observation. The roentgenogram 3 months after operation revealed fusion to be present but because a longer follow up could not be obtained the case was eliminated from this series. The average follow up period for the 7 remaining cases was 1 year 2 months.

A complete failure (0-0-0) was the end result in 1 case. A 90 degree flexion deformity of the hand with the flexor muscles of the fingers tight and spastic was present before operation. After operation the radius became fused to the navicular and lunate bones but after removal of the cast motion was present between the 2 rows of bones and between the distal row and metacarpal bones. Soon thereafter the pull of the tight finger flexor muscles caused the hand to assume the position of 35 degrees flexion. Although this was better than 90 degrees flexion it was insufficient to improve function or appearance. If the proximal row of bones had been removed in order to accommodate the short, spastic flexor tendons and if the carpometacarpal joints had been fused along with the radiocarpal joint a different result might have been obtained. For lack of a complete fusion an anatomical zero was given. Following operation passive motion was painful so a symptomatic zero was given. A functional zero was also allotted because the hand was neither more useful nor better in appearance than before operation.

Fair results (4 4 4 4 4 3 3) were obtained in 1 case. Solid fusion in good position without symptoms occurred in 2 cases for an anatomical and symptomatic 4, while fusion in slight ulnar deviation plus the presence of slight pain reduced the rating to a 3 in the other case. Functionally none of the patients gained much finger motion in spite of the removal of the proximal row of carpal bones and the fingers remained spastic and uncontrollable. However, there was improvement in the appearance of the hand

TABLE V—SUMMARY OF END-RESULTS IN ALL CASES OF SURGICAL FUSION OF THE WRIST JOINT

Condition	Cases	Perfect	Good	Fair	Poor	Fail-ure	Un-known
Tuberculosis	23	4	8	1	3	4	3
Rheumatoid arthritis	4	1	2	1			
Obstetrical paralysis	1		1				
Poliomyelitis	3		2	1			
Fracture-dislocation	2	1		1			
Volkman's paralysis	2				2		
Gonorrheal arthritis	1		1				
Spastic paralysis	8	1	2	3		1	1
Total	44	7	16	7	5	5	4

and this pleased the patients very much. Because of the cosmetic improvement a grading of 1 was given.

Good results (3-4-3, 4-4-3) occurred twice. One patient (3-4-3) had developed a pseudarthrosis following wrist fusion 2 years earlier. A second fusion was done because of pain, weak grip, loss of active extension of the fingers, and poor appearance of the hand. The wrist became solid at 180 degrees instead of 205 to 210 degrees and an anatomical 3 was given. No longer was there any pain, a symptomatic 4. The grip was now strong, there was complete active extension and flexion of the fingers, and the appearance of the hand was no longer embarrassing because it was straight instead of flexed. The patient stated that the whole arm could be used better. Muscle power increased and there was improvement in voluntary function and control. A functional 3 was allotted.

The end-result of the other case (4-4-3) was equally as interesting because operation was agreed to for cosmetic reasons only. Fusion occurred in good position and there was no pain, an anatomical and symptomatic 4. Before operation the grip was quite weak and there was no finger motion except a few degrees' flexion. Eleven months after operation the grip was fair and there was complete active flexion of the fingers. Extension, though, remained limited. She could pick up objects more easily and stated that no longer was it necessary to use her good hand to assist the affected arm in putting on a dress or coat. Being a girl, she was extremely pleased that people no longer noticed the previously deformed hand. A functional 3 was granted.

A perfect end-result (4-4-4) occurred only once. The wrist became solid in proper extension and excellent lateral position. There were no symptoms. The grip was good. There was full range of active extension and flexion of the fingers. The patient stated that cosmetically the hand was very much better and that functionally the wrist and hand were at least twice as useful as before.

SUMMARY

1. Forty-four cases of surgical fusion of the wrist joint for tuberculosis, rheumatoid arthritis, obstetrical paralysis, poliomyelitis, fracture-dislocation, Volkmann's paralysis, gonorrheal arthritis, and spastic paralysis, are presented.

2. A theory as to the etiology of secondary

tuberculous involvement of the ulnar epiphysis in tuberculosis of the wrist joint is offered.

3. Tourniquet, operative, and plaster techniques are discussed.

4. The operative and non-operative treatments of tuberculosis of the wrist joint are compared.

5. The proper functional position for a solid wrist joint is given.

6. End-results from an average follow-up period of 4.1 years are listed in detail.

MACROCHEILIA DUE TO HYPERPLASIA OF THE LABIAL SALIVARY GLANDS, OPERATIVE CORRECTION

HERBERT CONWAY, M.D., F.A.C.S., New York, New York

MACROCHEILIA may be defined as an abnormal or excessive size of the lip. Under this heading the literature includes a number of conditions, either inflammatory or neoplastic in character. Abnormal enlargement of the lip, admittedly rare in occurrence, is given little emphasis in the standard references and texts of this day. One author (19) refers to macrocheilia as due to simple lymphangioma of the lip. Another (35) states that certain of the enlargements of the tongue and lip, known as macroglossia and macrocheilia, are undoubtedly lymphangiomatous in nature. In a third text (5) it is noted that only in recent years have many examples of an exaggerated appearance of the labial glands throughout the mouth been seen. The histories of cases reported in the literature often give such meager accounts of the clinical and pathological data pertaining to the condition that accurate classification of reported cases is not possible. My recent experience with 3 cases of macrocheilia of the upper lip in which pathological examination of tissue removed at operation showed the enlargement to be due to increase in the size and the number of labial salivary glands has led me to the conclusion that this condition is more common than formerly believed and that many cases of this type are erroneously diagnosed as lymphangiomas.

Macrocheilia, when associated with ulceration usually may be diagnosed clinically. Syphilis, carcinoma, and tuberculosis of the lip may be differentiated by the well known characteristic signs of these pathological entities. In the absence of ulceration, however, the diagnosis is more difficult. Macrocheilia without ulceration may be due to simple hyperplasia of the submucous salivary glands, to lymphangioma or lymphangiectasis, to elephantiasis or to hemangioma. Of these hemangiomas are easily differentiated by the compressibility of the swelling, its increase in size when the head is placed in the dependent position, the presence of varicosities beneath the surface of the skin or mucous membrane and by the usually asymmetrical contour of the swelling. True elephantiasis of the lip may be ruled

out by the characteristic appearance of its thickened and hypertrophic folds of skin and mucous membrane. Macrocheilia due to hyperplasia of the labial salivary glands is not easily differentiated clinically from lymphangioma in the same location. Both conditions present a diffuse enlargement of the lip, non edematous, non compressible, non ulcerative. The etiology of both is obscure. To add to the diagnostic difficulty, perusal of the literature reveals that there also exists confusion in nomenclature. The term macrocheilia has been used to group a number of cases in which the reports give no data regarding histopathology but the lesion is presumed to be lymphangiomatous. Again, cases of simple hyperplasia of the labial glands are referred to as adenomas of the lip though no evidence of encapsulation of tumor tissue is present. Under the term double lip, a few authors have reported cases with details of operative correction of the deformity but without complete data regarding histopathological examination of the tissue removed. In the German literature there are several records of cases of macrocheilia associated with blepharochalasis and enlargement of the thyroid gland. Referring to these as cases of Ascher's syndrome, subsequent authors attempted to set aside a new clinical entity. Records of similar cases do not appear in later years. Under the names, cheilitis glandularis apostematosa or myxadenitis labialis, Volkmann described as macrocheilia a lesion characterized by elevations representing muciparous glands with dilated follicular orifices which admitted a fine probe and from which mucoid mucopurulent or serous fluid could be expressed. A recent report by New and Kirsch attempts to set aside a new clinical entity based on records of 67 cases of permanent enlargement of the lips and face secondary to recurring swellings and associated with facial paralysis. Their information on pathological examination of biopsy tissue is very meager. They state: "Specimens of tissue were taken for biopsy in a few cases before treatment but nothing was found other than edematous tissue containing lymphocytes." Touraine and Salente have emphasized the precancerous nature of the condition which they designate cheilitis glandularis.

From the Department of Surgery of the New York Hospital and Cornell Medical College

One of the 3 cases which have been under my personal observation and treatment presented the "double lip" appearance as described in the German literature, this patient has developed mucous fistulas of the type described by Volkmann. Another exhibited recurrent swellings followed by permanent enlargement of the lip associated with facial paralysis as described by New and Kirch. Yet, all 3 have shown the same underlying pathological changes in the tissue of the enlarged lip, namely, hyperplasia of the labial salivary glands. In the case in which there was an associated paralysis of the facial nerve (Case 2), microscopy revealed, in addition, a diffuse inflammation of the submucous tissue. I have preferred to classify these 3 cases under the name "hyperplasia of the labial salivary glands" rather than under the older term "cheilitis glandularis," recognizing that the hyperplasia may occur either with or without evidence of inflammation.

LITERATURE

Bouisson in 1869 referred to tumors of the labial salivary glands and stated that, as yet, these conditions had not been subjected to numerous precise observations. In 1870, Volkmann gave the name *cheilitis glandularis apostematosa* or *myxadenitis labialis* to a syndrome which he had observed in 5 cases, 3 of which had syphilis. The lower lip was affected in all 5. In these cases, careful examination showed that the salivary glands of the lip had become "hempseed size," were swollen and were palpable as uneven masses in unusual number. Everting the mucosa of the lip outward one could see that the excretory ducts were so dilated that a probe could be inserted. By pressure, which caused only mild pain, an opaque, mucous or purulent secretion could be expressed. Wright in 1884 described a case in an 18 year old boy. Swelling of both lips had been present since birth. The glands were palpable beneath the intact mucosa. Successful removal was accomplished by a 2 stage operation. There was no evidence of infection. No microscopic examination was made. In 1892, Miles reported a case of enlargement of the upper lip in which, on gross examination, the labial glands were found to be hypertrophied. In the same year Fraenkel attached the name macrocheilia to an enlargement of the lower lip due to an adenomatous tumor of this region. Reproduction of the drawings of the gross specimen and the microscopic picture are shown in Figure 1. The gross specimen was described as a "pearl-like string of tumors." This patient was a youth of 19 years, and the swelling of the lower lip had been present since the age of

4 years. The lip was so enlarged that closure of the mouth was difficult. The patient was operated upon and a successful plastic result was achieved by Dr Schede. A similar case was reported by Eisendrath in 1904. The patient, a 16 year old boy, had noticed swelling of the lips when 10 years old. Microscopic examination of the tissue removed showed "normal labial mucous gland substance." There was associated ptosis of both eyelids. In 1905, Lindenberger described the case of a man in whom the swelling followed a blow on the lip received 15 years earlier. Gross pathological examination revealed a number of small glands "slightly larger than buckshot." No microscopic examination was made. Donati in the same year described the same condition in a 20 year old man. The swelling in the upper lip had been present for 8 years. The excess tissue was excised and microscopy revealed that the overgrowth was due to enlarged mucous glands. Masera reported 2 cases in 1911. One occurred in a 24 year old woman; another in a youth of 19 years. Microscopic examination proved the tissue to be composed chiefly of numerous acinous labial glands with many excretory ducts. This author believed the macrocheilia of the upper lip to be due to hypertrophy and hyperplasia of the labial mucous glands. Roussel, in 1906, reported a case in which the lower lip had been swollen for 3 years. Mucous fistulas and luetic skin lesions were also present and no report of microscopic examination is given. In 1915, Stelwagon advanced the theory that the enlargement of the lip is due to adenoma of the mucous glands of the lips and is not due to syphilis. He based his conclusion on the clinical reports by Volkmann (5 cases), Sutton (3 cases), Fox (1 case), Schamberg (1 case), and Purdon (4 cases). In the year 1920, Ascher (1) described a case presenting the syndrome of blepharochalasis, struma and double-lip. Wirths (1920) reported a case with similar lid changes and double-lip without the enlargement of the thyroid gland. In 1921, Weve described as "syndrome Ascher" the case of a 27 year old healthy soldier who exhibited blepharochalasis and double lips, both present since the patient was 4 years of age. Later (1922) Ascher (2) described 2 additional cases of the same syndrome. One occurred in a 16 year old school girl, the other in a man of 39 years, who had swelling of the eyelids, double-lip, and painless swelling of both parotid glands. Ascher remarked that, in view of the rarity of blepharochalasis and as well the infrequent occurrence of double-lips, the simultaneous appearance of the two conditions in patients with severe struma was noteworthy. In 1920, Hatton described a case of

macrocheilia of the upper lip due to adenoma of the mucous glands. The patient was a man, aged 26 years. Microscopic section showed numerous mucous glands. Dorrance (1922) reported a case of double lip present for 9 years in a patient 21 years of age. Gross examination of the specimen removed from the upper lip showed enlargement of the labial salivary glands. No microscopic report was given. In 1922, Roedelius described a case of macrocheilia of the lower lip with several small sinuses which admitted a probe and from which mucus was discharged. Roedelius' patient was a 45 year old man. The enlargement of the lip had been present since childhood. In infancy the patient had a plastic operation for harelip. Roedelius advanced the opinion that in patients with congenital harelip the protrusion of the lower lip might be a factor in exciting activity of the mucous glands thus leading to their over growth. In 1930, Meyer reported 2 cases, one a 10 year old school boy and another, a young woman of 23 years. The author commented on the marked abnormality in shape of the alveolar process of the upper jaw in both cases. The operative procedure used in these 2 cases follows: To reduce the enlarged lip to normal size 2 transverse elliptical incisions were made on either side of the midline. Another vertical elliptical incision was made in the midline. Wedgeshaped sections of tissue were removed from all 3 areas. Meyer chose to call the condition ectropion of the lip and stated that the histological examination in the 2 cases showed the membranes, the labial glands and the surrounding tissues to be normal. Rosenstein, in 1932 reported a case of Ascher's syndrome in a 16 year old school girl. In this patient there was enlargement of both lips, a tendency toward hyperthyroidism, and enlargement of the eyelids. Because the enlargement of the lips developed at the onset of menstruation, Rosenstein believed the macrocheilia to be due to a disturbance of the endocrine glands. In 1933, Bejarano reported 2 cases of cheilitis glandularis in association with epithelioma. In both cases it was the lower lip which was involved. The authors admitted that it would be a grave error to generalize on cheilitis glandularis as a genetic factor in epithelioma of the lip. Touraine and Solente (1933-1935) described 2 cases and reviewed 41 cases from the literature. One of their cases was a lesion of the lower lip of 6 months duration in a man 62 years of age. The second enlargement of the lower lip occurred in a woman of 60 years. The lesion was of a few months' duration. In the first case a small spindle cell epithelioma was found at the base of the in-

fundibulum. Of the 41 cases in the literature which they reviewed 12 per cent showed malignant changes and were considered by them as precancerous. Either reported 9 cases in 1933. Of these, 3 showed enlargement of the eyelids in addition to the double lips but none exhibited signs of enlargement of the thyroid gland. The pathological examination is not reported. In 1933 New and Kirch presented 67 patients with localized swellings of the face. Regions involved by the swellings were as follows: upper lip, 38 cases; cheeks, 12 cases; lower lip, 9 cases; nose, 4 cases; eyelids, 3 cases; upper alveolar process, 3 cases. As already stated, in 13 per cent of these there was an associated facial paralysis. No reference is made by these authors to Ascher's reports and they do not comment on the concomitant swelling of eyelids and lips in the same patient. As stated before, the data regarding pathological examination are very meager in this report. Possibly many of the cases of macrocheilia in this series were due to hyperplasia of the labial salivary glands. Their treatment as outlined involved repeated injections of boiling water into the swollen area. After fibrosis occurred, the redundant tissue was removed by surgical excision. In discussion of the pre-entiation of New and Kirch, Beck has given a meager account of 3 cases, 2 of which had a history of facial paralysis and Wilson briefly reported 4 cases of facial swelling, 1 of which involved the lips.

CASE REPORTS

CASE 1. J. S. (New York Hospital Case No. 15843.) In April 1936 a 28 year old white man a tannery driver by occupation presented himself at the plastic surgery clinic of the New York Hospital with the chief complaint of swelling of the upper lip. He stated that without trauma or other antecedent cause he was startled one morning to find his upper lip previously normal in size swollen to huge proportions. He denied any fistula or counter. There was no injury. The swelling persisted for the 6 years prior to his admission to the clinic without marked variation in size. There was no facial paralysis at any time, no history of any allergic disease. Patient had received frequent treatments for chronic sinusitis of both antra during the previous 6 years. He had reported at several clinics in New York City asking for correction of the deformity of the lip. Each time treatment was deferred. At one institution complete allergic examination was done without significant findings.

Physical examination showed a diffuse enlargement of the entire upper lip so that it protruded in unsightly manner. Palpation of the lip revealed that the enlargement was not due to edema and it was not compressible. There were no varicosities over either the cutaneous or mucous surfaces. No bruit could be heard. On digital pressure the swelling felt shotty. Lowering of the head did not cause an increase in the size of the lip. Examination of the mucous membrane showed no ulceration, fissures or fistulas. The tongue was not enlarged or furrowed. There

was no cervical adenopathy and the thyroid gland was not palpably enlarged. The mucous membranes of the rhinopharynx were hypertrophic, and both antra were cloudy on transillumination. The teeth were in good condition. Pre-operative photographs are shown in Figures 2 and 3. Blood count showed white blood cells, 11,300; hemoglobin 104 per cent.

On April 22, 1936, plastic excision of a large U-shaped wedge of hypertrophied labial tissue was done through an incision in the mucous side of the lip (Fig. 15).

Operation and result. At operation, the tissue was roughly nodular, cut section allowed for the bulging of minute yellowish nodules the size of a pin-head. The fibers of the orbicularis oris muscle were hypertrophied. Bleeding points were ligated with fine catgut and the edges of the wound were approximated with on-end mattress sutures of fine silk. Immediately after operation there was intense swelling of the upper lip. The postoperative edema continued for 6 days despite the constant application of compresses moistened with hypertonic saline and mouth irrigations with the same solution. From that time on the lip slowly decreased in size. Five weeks after operation it appeared approximately normal. The swelling has not recurred since operation was performed 20 months ago. Postoperative photographs are shown in Figures 4 and 5.

Pathology. Pathological examination was made by Dr. N. C. Foot. The specimen consisted of tissue removed from the lip. It measured 6 centimeters in length, 1 centimeter in thickness, and 1 centimeter in width. It was apparently composed of the normal constituents of the lip, but there were numerous node-like masses at the core within the layer of the muscle. There was no evidence of encapsulation. Microscopic examination of the specimen did not show any of the characteristics of lymphangioma. The size of the lip was increased mainly by excessive hyperplasia of the labial salivary glands. These were predominantly mucous in type although some serous cells were found. There was an apparent increase in fibrous tissue. Photomicrograph is shown in Figure 6.

Diagnosis. Macrocheilia due to hyperplasia of the submucous, labial, salivary glands.

CASE 2 B. L. (New York Hospital Case No. 169560) This patient was a 28 year old Jewish housewife, mother of 2 children, who presented herself for treatment for the first time in May, 1937. A year before admission she awakened one morning to find her upper lip intensely swollen. There was no known related cause. The swelling increased for the next 2 months and then during a 4 month period decreased somewhat but the lip did not return to normal size. For 6 months prior to admission to the hospital, the patient had attacks of vertigo, chills, hot flashes, occurring at about 3 week intervals and always followed by an increase in the degree of swelling of the lip. In about 12 hours the swelling would reach its maximum and thereafter for 7 to 8 days it would decrease until the next cycle started. Menstruation ceased in 1936 following the birth of her last child.

Seven years before admission to the hospital and again 6 years before admission the patient described what apparently was a paralysis of the left side of the face, evidenced by inability to close the left eye or to use the facial muscles on both occasions. There was no history of idiosyncrasy to food or drugs. Patient had not used lipstick in 7 months. Several times leeches had been applied to the lip in unsuccessful efforts to reduce the swelling. The appearance of the patient before the onset of the deformity is shown in Figure 7.

When the patient was presented at the plastic surgery clinic of the New York Hospital, facial examination showed a diffuse swelling of the upper lip (Figs. 8 and 9). The en-

Fig. 1. Reproduction of drawing of specimen and microscopic field from Fraenkel's case of macrocheilia due to "adenomatous tumor" of the labial salivary glands.

largement caused ectropion of the mucous membrane and allowed the upper lip to protrude in unsightly fashion. The swelling was not compressible. There was no pitting of the skin and there were no varicosities over the surface of the lip. The lip was not tender. There was no bruise. Close inspection of the mucosa of the lip showed the presence of numerous submucous yellowish white nodules varying in size from 1 millimeter to 1 centimeter. The lip felt "shotty." Lowering of the head caused no increase in the swelling. Inspection of the mouth showed that the tongue was larger than normal and its surface presented the furrowed appearance of the geographic tongue. The teeth were in good condition. There was no evidence of disease of the paranasal sinuses. General physical examination revealed nothing remarkable. Blood count showed white blood cells, 9,400, hemoglobin 104 per cent. Kline exclusion and Kline diagnostic tests were negative. Differential blood count: adult polymorphonuclears, 35 per cent; immature polymorphonuclears, 32 per cent; lymphocytes, 33 per cent.

Operation and result. On May 25, 1937, the patient was operated upon under colonic ether anesthesia. The lip was

Fig 2

Fig 2 Case 1 Front view Enlargement of upper lip of 6 years duration No variation in size of swelling No trauma

Fig 5 Case 1 Postoperative profile

reduced to approximately normal size by the excision of a transversely placed elliptical wedge of mucous membrane submucous glandular tissue and adjacent hypertrophied musculature of the orbicularis oris muscle (Fig 1c). Profuse bleeding was controlled with ligatures of triple plain catgut. Edges of the wound were approximated with on end mattress sutures of fine silk. Twenty four hours after operation the patient had a violent chill and the temperature rose to 40 degrees C (rectal). A blood culture taken at this time showed no growth. Over a period of 4 days the temperature dropped slowly to normal. It was a full month after operation before the postoperative edema subsided completely. The cosmetic result as shown in Figures 10 and 11 was maintained for 6 months after operation. At that time the patient again experienced a mild chill vertigo and fever after which moderate swelling of the lip was again in evidence. A normal menstrual period followed (after an 18 month period of amenorrhea) and the lip returned to normal size. Two subsequent menstrual periods have occurred to date without recurrence of the symptoms or of the swelling of the lip.

Pathology The microscopic section of tissue removed by biopsy preliminary to the plastic operation showed

hypertrophied labial mucous glands which were increased in number. In addition there was evidence of acute inflammation. They showed no evidence of malignant change and were contained in a fibrous tissue stroma. Examination of the specimen removed at operation is described by Dr N. C. Foot as follows: Sections through the lip show a very marked hypertrophy of the mucous glands which are increased in number and show complete structure with ducts. Just beneath the mucosa there is a diffuse inflammation of the submucous tissue in which numerous tubercles are present with giant cells epithelioid cells and lymphocytes. This has the appearance of a rather diffuse sarcoid. Tubercle bacillus stains show numerous diplococci and other bacteria but tubercle bacilli as such are not found. There are large numbers of mast cells. The lesion then has some resemblance to that of lupus vulgaris grafted upon the glandular hyperplasia already noted. Other sections show extensive inflammatory reactions probably secondary to biopsy. Ictomicrograph is shown in Figure 12.

Diagnosis Macrocheilia due to hypertrophy and hyperplasia of the labial salivary glands in association with non specific cheilitis.

From the viewpoint of the clinician these findings in microscopy in association with the unusual postoperative febrile reaction the transient facial palsy (most probably inflammatory), and the intermittent increase in size of the swelling of the lip before operation gave evidence of the fact that in addition to the hypertrophy and hyperplasia of the labial salivary glands, there was also present some degree of non specific cheilitis.

CASE 3 M. I. (Case of Dr W. DeW. Andrews.) A 33 year old white woman presented herself for correction of a deformity of the upper lip which had been noticed for the first time following an injury (fall down the stairs) sustained 25 years earlier. The enlargement had persisted without variation in size. There was no history of facial paralysis. In childhood the patient had measles mumps whooping cough and chicken pox. There was no history of disease of the paranasal sinuses and no evidence of allergic disease. The history was otherwise irrelevant. Patient desired operative correction of deformity for its cosmetic effect.

Fig 9 Case 2 Pre-operative profile showing the excessive enlargement of the upper lip

Fig 10 Case 2 Postoperative front view showing the condition of the lip 6 months after plastic operation.

Fig 11 Case 2 Postoperative profile taken 6 months after plastic operation

Physical examination showed diffuse enlargement of the upper lip with a transverse furrow which was most pronounced when smiling or laughing This conformed to the description in the German literature under the term "double-lip" There was indentation in the mucous membrane at the point of attachment of the frenum Palpation of the lip revealed that the enlargement was not due to edema and it was not compressible No varicosities were in evidence No bruit could be heard over the swelling Lowering of the head did not cause an increase in the size of the lip On digital pressure the lip felt nodular There were no ulcerations, fissures, or fistulas Examination of the neck revealed no enlargement of the cervical glands or of the thyroid gland There was no evidence of disease of the nasal sinuses and the teeth were in good condition The remainder of the physical examination was negative Laboratory data white blood cells, 9,450, hemoglobin, 90 per cent, blood, Kline, negative, Wassermann, negative Photograph of patient is shown in Figure 13

Operation and result On August 4, 1934, Dr Andrus excised an elliptical segment of mucous membrane and underlying tissues approximately 3 by 1 centimeters in size from the right upper lip and a similar segment from the left upper lip The wounds were closed with interrupted sutures of catgut After operation there was moderate swelling of the lip This receded to normal in 10 days

Pathology Gross examination of the specimen showed hyperplasia of the submucous tissue There was no tendency toward encapsulation of the hyperplastic tissue Microscopic examination showed excessive hypertrophy of the submucous salivary glands These tended to arrange themselves in small nodules as shown in Figure 14 The cells were both serous and mucous in type There was an increase in fibrous tissue

Diagnosis Macrocheilia due to hyperplasia of the submucous salivary glands with "double-lip" formation

Three years later the patient reported for examination because of a recurrent swelling on the right side of the upper

lip In the interim there had been no swelling Examination showed that a nodule 1 centimeter in diameter was present in the line of closure on the mucosal side of the lip It was punctured and saliva exuded A small fistula remained Photograph of the patient at that time showed that a suggestion of "double-lip" formation was still present At a second operation the excess labial tissue was excised Microscopic examination of the tissue removed showed a picture similar to that described The patient has remained well to the present date, 5 months after the second operation

After a careful review of 129 cases of macrocheilia collected from the literature and a personal

Fig 12 Case 2 Low power photomicrograph Tissue adjacent to hyperplastic labial salivary glands shows much evidence of chronic and subacute inflammation

Fig 13 Case 3 Front view showing the double lip formation of the upper lip apparent on laughing

study of 3 additional cases, it is strikingly apparent that the etiological factor in this local alteration of the labial salivary glands has not been determined. Because the enlargement of the lip was present in some cases from early childhood certain authors have held to the theory that the abnormal enlargement of the lip is congenital in origin. The underdevelopment of the upper jaw as a cause of over activity of the under lip with consequent stimulation of the mucous glands as observed by one author has been not regularly noted by others. The presence of mucous fistulas with associated infection (cheilitis) in certain

cases has given rise to argument for the infectious nature of the disease. In none of these cases was the bacteriological examination adequate. Regarding specific infection many of the later case records state that serological tests for syphilis were negative. In the earlier cases in which the patient exhibited clinical signs of syphilis at the same time that the lip was enlarged, there is no conclusive evidence that the macrocheilia was a manifestation of that disease. A few of the descriptions of cases associate the onset of the enlargement with an antecedent trauma. The vast majority, however, do not give a history of injury and the evidence, on the whole, is against previous trauma as a causal factor in hyperplasia of the submucous glands. That the hyperplastic condition of the labial salivary glands is not neoplastic in origin is favored by the fact that not one of the cases has shown true tumor formation although many of them have been recorded as adenomas. The formation of adenoma in the submucous glands of the lip appears improbable because of the rare occurrence of true adenomas in the major salivary glands, namely the parotid, the submaxillary and the sublingual. The occasional reports of adenoma of these glands have always excited academic discussion as to whether or not the tumor was a true adenoma or a mixed tumor. On the basis of a few reports of hypertrophy of the labial salivary glands in association with carcinoma of the lip, it has been suggested that the condition is precancerous. This belief is not strengthened by this study.

Regarding therapy, it may be stated that surgical excision has given highly satisfactory results. Radium therapy, x-ray therapy, and injections of

boiling water have been suggested. Adequate follow-up notes are not available on the cases in which these methods have been used

On the basis of a few reports of hypertrophy of the labial salivary glands in association with carcinoma of the lip, it has been suggested that the condition is precancerous. This belief is not strengthened by this study.

Regarding therapy, it may be stated that surgical excision has given highly satisfactory results. Radium therapy, x-ray therapy, and injections of

high percentage of acute sprains are secondary to an insufficiency.

The functional decompensation of the back is associated with so called poor posture which means an increase of all the normal curves and a shifting forward of the body center of gravity. If the rounded dorsal kyphosis has been of long standing there is a tendency to fixation in this area, this fixation must be broken down and the abnormal curvature corrected.

The principle by which this correction is accomplished is based on the fact that 80 per cent of the motion of the spine is in the lumbar area which is mobile. With the patient bending forward, a body jacket is applied to fix the pelvis and the lumbar area. Any correction that occurs must, of necessity, be above the cast and in the dorsal area. The body-righting reflex automatically requires the patient to correct the rounded dorsal kyphosis (4). The bending forward plus overhead extension by means of a Sayre head-piece, tends to decrease the lumbar curve, this correction is retained since the cast is applied in an over-corrected position.

The technique by which this method is carried out is as follows: The patient is fastened to a crossbar on a vertical frame and the head-piece adjusted so that a satisfactory overcorrected position is established, the patient is tied to the crossbar and the Sayre extension is fixed so the position is retained until the cast can be applied (see photographs). The average cast requires eight rolls of fast-setting, 6-inch orthoplast plaster. After the cast is applied it is trimmed above and below, above, so that the cast comes to about the tenth dorsal vertebra in the back and slightly above the umbilicus in front, and below, so the patient can sit comfortably and is able to lace his shoes. To correct the deformity completely it is sometimes necessary to change the cast as many as three or even four times, occasionally a single cast is all that is required. The length of time that the cast is worn is determined by the rapidity with which the correction is accomplished. The recognition of correction is very simple since the cast becomes too loose and the patient pulls out of it. It is obvious that the cast does not change, therefore, the patient must have changed, and the change—if the position were correct—necessarily, will be in the nature of a correction of the deformity.

It is necessary not only to correct the deformity and protect the back against further irritation, which is accomplished by the cast, but it is also essential to re-establish the normal capacity of the back. When the cast has been applied, strain can

no longer occur in the lumbosacral or sacro-iliac areas; the weight is transmitted from the dorsal area onto the pelvis by means of the cast. This protection permits the inflammation to subside even though the patient is up and about. A proof that this actually occurs is the frequency with which patients who have had low back pain for years are relieved immediately upon application of the cast.

To increase the capacity of the back it is essential that the structures have normal exercise, without strain. We have already learned how the cast protects against the strain. Since the cast ends in the lumbar area it is possible for the patient to pull himself up so that the cast does not support him. This stretching is the primary functional exercise. In addition, a system of exercises is prescribed with this fundamental principle as the basis (3). These exercises are supervised so that they are carried out with accuracy. As the muscle control and strength of the patient increase, more exercises are added, the exercises must always be practical. Since there is a general fatigue present in cases of functional insufficiency of the back, periodic rest is prescribed. This is done to avoid chronic strain and means that the patient lies down in any position he desires (he may read or listen to the radio) for from 10 to 30 minutes every 2 to 8 hours, depending upon the need of the individual. After each rest period the patient carries out the exercises. As soon as it is physically possible, sports are permitted. Frequently it is possible for the patient to play golf or tennis while the cast is being worn.

The secondary deformities are automatically corrected by means of the cast and exercises. The costal angle is increased, the lung expansion is enhanced, which means an increase of vital capacity, the pendulous abdomen disappears as soon as the muscles become strong enough to hold the abdomen flat, which results in a decrease of the waistline. Often the waistline decreases as much as 5 inches during the course of treatment, which is very gratifying to the patients, particularly the women. The association of weak feet and pes valgo planus with the functional decompensation is very frequent. Corrective shoes are prescribed and correct gait is taught, which means holding the erect position of the body and walking with the rolling gait.

Very frequently the fatigue is due, at least in part, to malnutrition; this phase is studied and proper diet and tonics are prescribed. In consideration of Schanz's findings of osteoporosis of the vertebrae in cases of functional decompensation, it has been customary to prescribe calcium

THE TREATMENT OF LOW BACK PAIN DUE TO FUNCTIONAL DECOMPENSATION

EMIL D W HAUSER, M D F A C S Chicago, Illinois

FUNCTIONAL decompensation is an imbalance between the capacity of the structures of the back and the physiological demands made upon them (1). A decompensation implies an insufficiency of structure and resultant disability. Just as cardiac decompensation does, so a decompensation of the back gives rise to certain symptoms and findings.

The symptoms are low back pain and tiredness, this fatigue of the back is often associated with a general fatigue. The primary symptom, however is pain which is variable in character. The first pain noted is usually generalized and is in the muscles, with associated stiffness on arising after rest. Later the pain localizes and may involve the lumbosacral angle or the sacro-iliac joint. The interpretation is that the ligaments have been stretched and are inflamed. If the condition persists the joint becomes inflamed and a true arthritis develops.

The objective findings in decompensation of the back are impaired muscle tone and an increase of the normal curvatures of the spine, with tenderness over the lumbosacral and sacro-iliac areas. This means poor posture, a rounded dorsal kyphosis and increased lumbar lordosis and in extreme cases a right dorsal and left lateral lumbar curvature. The abdominal muscles are weak and the abdomen sags. In the acute phase of this condition there is a sudden catch associated with lumbar muscle spasm, loss of the lumbar curve, a protective list with a pelvic tilt, and limitation of motion in the lumbar area. Associated with this condition we frequently find a low blood pressure, secondary anemia, nutritional deficiency and a low metabolic rate. These are, in reality, causative factors. Sciatica is a frequent complication, explained on the basis of repeated stimuli caused by strain together with a low nervous threshold due to fatigue. In other words, a neuralgia (2).

The essential pathological change is an inflammation in the region of the lumbosacral angle and the sacro-iliac joints. The alteration in posture is secondary to a functional decompensation which, after all, is the basis of the entire symptom complex.

TREATMENT

The treatment consists first, in relieving the inflammation, second in correcting the deformity and third in re-establishing normal capacity. The acute inflammation caused by a sudden strain requires immediate bed rest, if it occurs during the course of the individual's occupation, he is advised to lie down until the muscle spasm relaxes. As soon as the acute spasm has subsided sufficiently, the patient is either strapped with adhesive or hospitalized. He is allowed to lie in the position he finds most comfortable which is usually on the back with a small soft pillow in the lumbar area and the knees flexed. The amount of rest required depends upon the severity of the injury to the ligaments, a criterion to guide the surgeon is the rapidity with which the muscle spasm subsides, this varies from 12 hours to 10 days. If the patient is treated immediately after the injury, the usual time required is about 3 days. With the subsidence of the muscle spasm there is relief from the pain, the ligaments, however, are still far from healed. It is necessary further to protect the back in order to permit the patient to be up and about. The most simple method in order to accomplish this is to fix the lumbosacral and sacro-iliac areas with adhesive strapping.

The technique for proper strapping is to have the patient stand facing a table or desk, assuming the tallest attitude possible, with the abdominal muscles contracted, and to run strips of 2 inch adhesive from below the greater trochanter on one side to above the anterior sacro-iliac spine on the other side. Horizontal strips are then applied from the sacrum well up into the lumbar area. This retains a fixation and at the same time insures correct carriage. The adhesive is worn for 3 to 5 days when it is reinforced, since it tends to loosen. After from 7 to 10 days it may be necessary to restrap entirely the lumbosacral area. The back should be protected for from 10 to 21 days. The patient in the meantime is permitted to be about. If no previous functional insufficiency has been present he will be able to continue with his usual work and obtain a complete recovery. Since a functional insufficiency of the back predisposes to these acute attacks, a very

overstrain. These strains, however, subside promptly after a short rest period. The exercises are then carried out as usual. It is advisable to observe the patient at intervals of from 1 to 3 weeks to guard against strains and to encourage exercises until the maximum capacity of the back has been reached. Once normal capacity has been re-established, the patient no longer has any symptoms of backache while carrying on his normal occupation, without wearing a support. Not only has the backache been relieved during the course of treatment but the fatigue syndrome has also been lessened.

This treatment has been successfully carried out over a period of about 10 years. The primary objective of the treatment is relief of the backache and the secondary neuralgias, but just as important to the patient are the relief of the fatigue syndrome, the re-establishment of a normal outlook, and the improvement in appearance. In other words, the disability is cured and the deformity corrected.

To demonstrate these principles of treatment, I wish to cite 5 cases:

CASE 1 Miss N H, 34 years of age, a school teacher, complained of nervousness, intermittent lumbago and low backache which had been present for 4 years, she was irritable, worried, and tired all the time, her back felt stiff on getting up, the pain was worse after prolonged sitting or standing, she obtained relief by lying down. For 5 months before she was seen she had had pain down the lateral side of the right thigh and leg, which had become worse until finally she was unable to walk. Relief was obtained only by constant rest and continued local heat.

At examination it was evident that she was suffering pain, she could not stand erect, any attempt at motion in the lumbar spine caused pain. There was a definite list to the left and slight atrophy of the right thigh and leg, there was lumbar muscle spasm, and the Lasègue sign was positive. The blood count and urine were normal, the blood Wassermann was negative. Roentgenogram of the lumbosacral area showed no abnormal change. A diagnosis was made of muscular insufficiency of the back, sacro-iliac strain, and right sciatica.

The patient was admitted to Passavant Hospital and bilateral Buck's extension was applied with the knees in flexed position. Local heat (an electric pad) was applied to the back, and she was given 10 grains of salicylate three times a day. After 5 days the muscle spasm in the back was relieved and a lumbar curve re-established. A small pillow was applied in the lumbar area and the patient was allowed to turn over on her abdomen, hot packs were applied for one-half hour three times a day. By the eighth day the back was well relaxed and the pain had disappeared. A plaster-of-Paris cast was then applied in the upright frame. The slight discomfort noted during the first night after the cast was applied was not sufficient to interfere with her sleep, the following day she was able to stand and walk, holding herself erect, with comfort. Exercises were started immediately and increased on the fifth day following the application of the cast. She was then seen at weekly intervals, and each time the exercises were increased. She left the hospital 2 days after the cast was applied.

On the twelfth day she had improved to such an extent that the cast was loose and no longer giving any support, a new cast, taking more correction, was applied and exercises and periodic rest carried out as before. In the beginning she rested 20 minutes out of each hour, by the time the second cast was applied the rest periods were lessened to five a day. She wore the second cast for 3 weeks. At that time she had a full correction with normal curves in the spine but, as there was still some tenderness over the right sacro-iliac joint, a third cast was applied which held the corrected position for another 2 weeks, after which a fitted cloth and steel corset was worn for another 5 weeks. During this period the patient was entirely free of pain, but the capacity of the back and abdominal muscles was still below normal. At the end of 9 weeks complete relief had been obtained. She continued her exercises without observation and was next seen 1 year later, she had remained well during this entire period. Two years later she reported again, simply to say that she had had no further symptoms during the 3 years since her dismissal.

This case typifies the care of patients suffering with sciatica associated with low back pain due to muscular insufficiency of the back. The presence of nervous fatigue and the symptoms of muscular decompensation are characteristic for this group. The treatment consists in removal of the functional decompensation by the method described, and care of the nervous strain. The condition is explained to the patient, vitamins B and G are prescribed, and the social and economic problems are taken into consideration. There is a definite response to treatment.

CASE 2 Mrs H B, 26 years of age, a housewife, complained of pain in the lower part of the back, which had been present for over 10 years, worse after childbirth, very severe after birth of her second baby, she was exceedingly tired all the time, the backache had been continuous for 2 years with periodic exacerbations. A diagnosis of right sciatica had been made following her first pregnancy, this pain in the right thigh had recurred periodically ever since. She had had trouble with her feet, slightly relieved by the wearing of stiff-shanked shoes, she had had some osteopathic treatment. Her general health was excellent.

Examination showed an intelligent young woman with a rounded kyphosis in the dorsal area and a slight right dorsal scoliosis, the lumbar curve was increased and the abdomen tended to sag, the muscle tone in the extremities was good but the abdominal and back muscles were weak. A diagnosis of muscular insufficiency of the back with sacro-iliac strain and right sciatica was made.

The back was strapped with adhesive as a test, on the third day she returned stating that she had had more relief than she had had for 3 years. The following day the adhesive was removed and a plaster-of-Paris jacket applied, this gave her immediate relief. Exercises were started at once. After 10 days the cast was cut to the level of the twelfth dorsal vertebra in back. The dorsal curve showed correction. She used a sand-bag and the exercises already described, these were gradually increased. After 2 weeks the cast was so loose that it no longer gave support, a new cast was applied, at which time her back was found to be in normal position. She continued her exercises and wore corrective shoes. At the same time the periodic rest which was started at the onset of treatment was decreased from 20 minutes every 2 hours to three rest periods of 20 minutes

Fig 1 a Modified Haglund frame b Patient in position of correction of frame c Modeling cast d Lateral view of finished cast.

gluconate and dicalcium phosphate together with viosterol. When the deficiency is definite large doses are used. Anemia and low hemoglobin are counteracted by means of lextron or ferrous

sulphate. For the convenience of the patient who is carrying out his normal occupation wherever possible, the tonics are prescribed in the form of capsules or tablets. When the nervous fatigue is great, vitamins B and G are prescribed. The low metabolic rate usually rises automatically as the fatigue decreases. The discriminate use of Lugol's solution has been found more effective than the thyroid extract which has been so frequently prescribed in these cases.

The cast is worn until the correction is attained. The normal position is held with the last cast for a period of from 10 days to 4 weeks depending upon the length of time the condition had been present before treatment was instituted. After removal of the cast, a corset is worn during the day to guard against strain the corset is worn whenever prolonged sitting is necessary it is advised particularly for those who earn their living by riding in a car. The exercises and periodic rest are continued until the capacity is sufficient to carry out all the requirements of the individual, which is usually about 3 months.

The re establishment of capacity in the back prevents recurrences. During the process of re establishing normal strength as one might expect acute attacks occasionally recur. In the desire to increase strength rapidly the individual may

Fig 2 a Anterior view of finished cast b Posterior view of finished cast c Patient dressed wearing cast

little prominent, and a third cast was applied, this he wore for 2 weeks. He was then put into a form-fitting corset; he took a vacation, continued his exercises, began to play golf again, and took up swimming, gradually he left off his support. He has continued to feel well for a period of about a year.

This is an example of static arthritis, secondary to mechanical strain, in older patients. The treatment is practical in that even a man of 57 years does not find it too strenuous. This patient felt that his general improvement justified the treatment. The back pain and sciatica disappeared with the cure of the decompensation.

CASE 5. Mr J. R. W., 32 years of age, a gas-house foreman, in 1931 he had twisted his back and noted sharp pain, his physician made a diagnosis of lumbago and wrenched back and treated him, with some benefit, at intervals since then he has awakened mornings with a tightness in the back, and has had recurrent sharp attacks, lasting from 2 to 3 days, attacks gradually became more frequent and more severe until finally he had a constant backache while at work, 6 months before he was seen his legs had begun to ache, he felt tired all the time. He had been examined and treated for sacro-iliac arthritis, definitely shown by the x-ray. Chronically infected tonsils and several infected teeth had been removed, he had been given salicylates and tonics—all without relief.

Examination showed an increase of all normal curves, lumbar muscle spasm, tenderness over the lumbosacral angle and in the sacro-iliac area. A diagnosis was made of muscular insufficiency of the back with sacro-iliac strain.

Treatment was started immediately. A plaster-of-Paris cast was applied and he obtained immediate relief. He continued to work while wearing the cast, resting at noon and again immediately after work, he carried out his exercises after these periodic rests. In addition he was given corrective shoes and taught the normal gait, a sandbag was used to get proper posture. After 2 weeks the cast was changed. He lost no time from his work and had no further pain after the application of the first cast. He continued to gain strength, the capacity of the back improved so that the cast was lowered each week. The second cast was worn for 3 weeks, after which he was fitted with a corset. He was also given calcium gluconate and viosterol.

He has remained well for more than a year. He has no backache and no feeling of fatigue, and he states that he has not felt so well in 5 years.

This case is typical of a group of adults who are dependent on hard labor for earning their living. Though of long standing and recalcitrant to medical treatment, the response to measures directed against the functional decompensation was

immediate. The treatment was executed with the patient ambulant and able to do his work.

CONCLUSIONS

1 Functional decompensation of the back (an imbalance between the capacity of the back and the load or the work demanded of it) is a very common cause of low back pain.

2 Anything that increases the demand or decreases the capacity of the back is, therefore, a causative factor.

3 The backache is primarily due to an inflammation at the lumbosacral angle and sacro-iliac joints.

4 The treatment consists first, in relieving the inflammation by proper adhesive strapping of the back, second, in re-establishing normal posture by the application of a corrective or active plaster-of-Paris cast, and third, in re-establishing the normal capacity of the back by means of a system of practical exercises.

5 Dietary deficiencies frequently cause a decrease in physical capacity. These deficiencies are evaluated by the attending physician who outlines a proper diet, viosterol and calcium are useful in bringing about a restoration.

6 Anemia, which is frequently present, is treated with liver extract (Iextron) and iron (ferrous sulphate). Nervous fatigue is combated by means of vitamins B and G.

7 Low back pain is, thus, frequently a part of a general condition and is treated accordingly.

each daily. Four weeks later the cast was removed and she was fitted with a corset.

During this entire period she had had no pain in the thigh. The backache was relieved but did recur after severe strain incident to the care of her sick child lasting about 1 week. *She has been well ever since. She is able to play tennis and golf and carry out her usual duties. She gained three-fourths of an inch in height. The dorsal kyphosis which had been present since her adolescence was entirely relieved. For the first time her posture was satisfactory to herself and to her parents. The abdomen was flat and her hip measurement was 2 inches less than before treatment. She is no longer fatigued but energetic and active.*

This case is characteristic of a group of neglected adolescent scolioses who develop a functional decompensation as young adults or in later life. The cure of the functional decompensation relieves the symptoms of which the patient complains and corrects the deformity present.

CASE 3. Mrs. C. D., 38 years of age, a housewife, complained of backache which had been present for 10 years worse after the birth of her only child. She was awakened mornings by the pain in her back which increased after driving a car or sitting in a chair. Back felt stiff on arising, pain worse with change of weather. She was tired most of the time. She was an active woman but because of her backache was unable to do the things she liked to do and had gained about 10 pounds in weight. During the last few months before she was seen she had had pain in the lower extremities limited to the thighs. Sometimes one thigh was involved sometimes the other never both at the same time. She had obtained some relief from lying in the sun and the backache had subsided while she was in bed following an operation. She had received various types of medical care including salicylates, bed rest and heat. She had been placed on a Bradford frame and had worn a belt—all with out relief. She did obtain relief during her rest periods but on getting up again the back seemed worse than before. Orthopedists had advised a fusion operation.

At examination the back showed an increased rounded dorsal kyphosis, an increased lumbar lordosis, sacro iliac tenderness on both sides and tenderness over the lumbo sacral angle. X-ray examination of the lumbar spine was negative. The abdomen sagged and she had gained weight especially about the thighs. The costal angle was narrow. She walked with a shuffling gait and had a facial expression of fatigue and strain.

She entered the hospital for 2 days for a general examination. During this time hot packs were applied three times a day. On the third day a body jacket was applied which gave prompt relief. General exercises were started and gradually increased in the usual manner. She was given corrective shoes and taught the normal gait. On the second day after the cast was applied she was permitted to return home—an overnight journey.

When seen 2 weeks later the cast was loose. She had already obtained a great deal of correction in the dorsal area. A new cast was applied with further correction of position. Viosterol 15 drops and calcium gluconate 7½ grains three times a day were prescribed. She felt very much better.

Two weeks later the cast was trimmed and made lower. Periodic rest was continued. She still had some pain at the lumbosacral angle particularly after strain or prolonged sitting.

After another 2 weeks a third cast was applied. The position of the back was then entirely corrected and the new

cast applied in the overcorrected position. This gave complete relief. She continued her exercises, began taking walks and playing tennis.

Four months after the institution of treatment the third cast was removed and a satisfactory corset fitted. Her general condition was very good. She had lost 1 inch in hip measurement and had gained about 1¼ inches in height. The costal angle was broader and she no longer felt fatigued. Her backache had entirely disappeared. For a period of 2 months however she had to guard against prolonged sitting particularly riding in a car which would cause some stiffness in the morning on arising. She has now been entirely well for a period of 6 months.

This case is typical of a group of cases in which the condition was of long standing and in which medical care and orthopedic measures had been attempted until finally a fusion operation had been advised. The immediate response to treatment in the way of relief of symptoms even though of long standing was striking. With relief of the backache the general health of the patient is improved, the functional capacity is increased, they have a feeling of well being and in many instances the blood pressure and the metabolic rate are increased, as is also the vital capacity.

CASE 4. Mr. D. J. M., 57 years of age, a retired business man, complained of pain in the right lower extremity and lower part of the back which had been present for over a year. He first noticed a constant fatigue so marked that everything he did was an effort. He decided to take a vacation and play golf. Enroute to Florida he developed pain in the right sacro iliac area and right thigh which became progressively worse and radiated down along the knee and into the calf. Pain was worse when riding in a car, playing golf or walking over rough ground. He obtained some relief by lying in the sun in the warm sand on the beach but on his return home the pain continued. He was stiff on arising in the morning and was unable to play golf. His general fatigue, the pain in the back and the nagging pain in the sciatic region continued to get worse and he consulted a physician for a general examination. Several teeth were extracted and a tonsillectomy done without improvement. He had his shoes made by a special shoemaker.

Examination showed an elderly man definitely overweight with a pendulous abdomen. The abdominal muscles had very poor tone so that he could draw the abdomen up only slightly. He wore an abdominal support. There was marked valgus at the ankle and at the knee and pronation of both feet. X-rays showed slight hypertrophic arthritis in the lumbar area. A diagnosis of muscular insufficiency of the back with sacro iliac strain and pes valgo planus with foot strain was made.

His back was strapped with adhesive and his shoes padded. He obtained immediate relief. Two days later he returned eager to carry out further treatment. The adhesive strapping was removed and a plaster-of-Paris cast was applied with corrected position. The following day the cast was trimmed. Two days later he stated that he was comfortable and had no backache. Exercises were started. He was given corrective shoes and taught the normal gait. When seen 10 days after the application of the second cast, he had gained a great deal of correction and was delighted with his improvement. He stated that he had not felt so well in years. After he had worn the second cast for 2 weeks his posture was satisfactory but the abdomen was still a

Fig 3

Fig 4

Fig 5

Fig 3 Pentonealization finished. The cervix is elevated 1 to 1½ inches, and to that extent the vaginal wall, including the rectocele and cystocele, is elevated. On account of the difficulty of illustrating the actual elevation of the vaginal wall, this phase of the operation is left to the imagination.

Fig 4 (Old technique) The round ligament pedicles are brought down to prolapsed cervix. Position of vaginal wall, including cystocele and rectocele, remains unchanged.

Fig 5 (Old technique) It shows the round ligaments long and relaxed and the uterus retroverted and prolapsed. In procidentia the uterus is as a rule retroverted.

6 other cases about 1/5 of the original cystocele would still come down on straining. This is undoubtedly due to the uterus not having been amputated low enough. But we get such degree and percentage of failures even after cystocele operations. Of rectoceles it was mostly successful in cases associated with prolapse or sagging of the posterior vaginal wall. Judging from results obtained, it seems that there is sagging of the anterior vaginal wall in all such cases and of the posterior wall to the extent of a varying fraction.

In those conditions in which supravaginal hysterectomy (without procidentia) is indicated, but in the presence of cystocele and rectocele, I obtain a preknowledge as to results and indication for operation on the latter, as follows.

I hook a tenaculum on the anterior lip of the cervix, through a speculum. I then remove the speculum and elevate the uterus by pushing up on the tenaculum. Now I ask the patient to bear down. If the cystocele and rectocele do not come down they can be left out of consideration, depending for their automatic correction on the

hysterectomy technique. Lately I employ a simpler test. I elevate the cervix with a dressing forceps holding a short tampon of cotton.

I am frequently told by men who have watched my technique and who concede that the vaginal wall is thus elevated, that they fail to see how the round ligaments could be depended upon for permanent support of the structures. The objection is unsound practically. First of all and foremost there is no longer present the large and heavy uterus with its overstretched supports (non-supports), which acts adversely by its own weight and upon which intra-abdominal pressure is directed. Second, the overlapping tense bridge removes any "sag" in the round ligaments as well as of the broad ligaments, the cervix, relatively light, is attached to the undersurface of the bridge, the attachment of the tubo-ovarian pedicles to the cervix and the peritonealization with the bladder fold covering all the superimposed structures on the cervix and beyond, form one consolidated, well distributed support, invincible to caprices of intra-abdominal pressure.

CORRECTION OF CYSTOCELE AND RECTOCELE IN THE PROCESS OF SUPRAVAGINAL HYSTERECTOMY

LOUIS DROSIN, M D New York, New York

THREE years ago I was confronted with a case of myomatous uterus in the third degree of procidentia with a cystocele and rectocele, the uterus being too large to be removed *per vaginam*. In addition the condition of the patient did not warrant an operation entailing the time necessary for the systematic correction of all the pathology present. I have accordingly devised a technique whereby the cystocele and rectocele would be automatically eliminated by a few modified steps in the technique of supravaginal hysterectomy.

After the round ligaments were ligated close to the uterus, and the rest of the steps completed the body of the uterus was severed from the cervix. A taut bridge was then formed of the round ligament pedicles by overlapping them as shown in Figure 1. This forms the cardinal step in the mechanism of the new technique. In the next step I elevated the stump of the cervix and attached it to the undersurface of the ligament bridge (Figs 1 and 2). This is in the reverse order of the usual technique in which the round liga-

From the Gynecological and Obstetrical Services, Beth David Hospital

Fig 1 A perfectly horizontal taut bridge has been formed of the round ligament pedicles by 3 or 4 sutures placed and tied in a manner so that 1/2 of the long section of each pedicle remains free (circulation not obstructed). It also shows 2 sutures (more if necessary) passed through the bridge and the cervix as the first step in the elevation of the cervix to the undersurface of the bridge. It will be noticed that here likewise, the sutures are passed through the bridge with the view of guarding against obstruction of the round ligament circulation. As stated in the context

ment pedicles are attached loosely to the prolapsed cervix (Fig 4) and in which the vaginal wall and cystocele and rectocele maintain their status quo (Figs 4 and 5) unless repaired.

With the elevation of the cervix the vaginal wall, including the rectocele and cystocele came along to the extent of obliteration of the latter two. Peritonealization was carried out in the usual manner (Figs 3 and 4).

Since then I have had three other such cases which I have operated upon in the same technique with the same uniform good results. At the present time the cervix, in all these cases, is still on a high level and the rectocele and cystocele do not come down on straining.

The relaxed vagina, whether it be due to cystocele or rectocele or to prolapse or relaxation as a result of procidentia will be obliterated to the distance between the round ligament bridge and the location of the prolapsed cervix. And that usually is a distance of from 1 to 1 1/2 inches (compare Fig 1 as contrasted with Figs 4 and 5).

Encouraged by these results I proceeded to employ this method in all cases of supravaginal hysterectomy without procidentia, but with rectocele and cystocele. In 37 of 43 such cases the cystocele was corrected completely. In the

the round ligaments should be cut as closely as possible to the uterus and for two reasons: (a) if they are short a bridge cannot be formed; (b) the larger the pedicles are the more they will overlap each other thus enforcing the ultimate support against theoretical or probable ravages of the intra abdominal pressure.

Fig 2 Shows the cervix united to the undersurface of the bridge. Here the cervix does not appear to hug the round ligament snugly. This is done with the object of more clearly showing the steps of the technique.

The first step in attempting to remove a stone or foreign body from the common duct is to provide for the free egress of ductal contents into the duodenum. The lower end of the duct is guarded by the sphincter of Oddi which is probably associated with a pseudo-sphincteric action of the muscular fibers of the duodenal wall itself. At the American Medical Association meeting in 1936, we presented a paper (4) on cholangiography which proposed that nitroglycerin encouraged relaxation of the sphincter¹ and permitted the contrast medium to pass easily from the common duct to the duodenum. Also in 1936, Walters (9) and his group reported their experiments on common duct pressure as affected by spasm of the sphincter and the decrease in pressure afforded by both nitroglycerin and amyl nitrite. More recently, Doubilet and Colp have corroborated the effect of nitroglycerin. Our observations upon the spastic or non-relaxing effect of morphine certainly agree with those of Walters and Doubilet and Colp. The experiments of the latter two men also concur with ours in showing that atropine may relax or at least lessen the tension in this irritable sphincter area in some instances. We have previously reported upon the apparent soothing or relaxing effect of warm olive oil or iodized oil upon the choledochal side of the common duct sphincter when instilled through a T-tube or fistula. The effect of magnesium sulphate or fats such as olive oil or cream upon the duodenal surface has also been mentioned.

The second problem is to dislodge the foreign body by increasing the pressure behind it. If the stone or foreign body is below the T-tube, catheter, or fistula opening, this is easily accomplished by the injection of warm saline solution, olive oil or iodized oil through the tube or fistula.

It is also reasonable that increasing the flow of bile by stimulating its formation will augment the intraductal pressure. Neubauer in 1924 determined by experiments on animals and humans that sodium dehydrocholate, the sodium salt of dehydrocholic acid, increased the secretion of bile. We have, therefore, been experimenting with pressure changes effected by dehydrocholic acid, and Figure 1 is an example of increased intraductal pressure brought about by this means. The usual dosage has been 3 tablets (3¼ grain or 0.25 gram each) four times a day. A rise in pressure occurred in most instances, but there was considerable variation in the degree of change. At times it would increase 200 millimeters of water, while at other times a change of only 10 to 20 millimeters was apparent. We have also used the

Fig 1 The general level of intraductal pressure during the administration of dehydrocholic acid is definitely higher than during control periods. With the intravenous injection of sodium dehydrocholate there was a sudden rise in intraductal pressure. Case A S cholecystostomy and choledochectomy.

sodium salt of this drug intravenously but do not feel that we have had sufficient experience as yet to advocate its routine use. This added pressure is of maximum value when the foreign body is below the T-tube or catheter inlet or when only a biliary fistula exists, as it tends to force the impediment through the sphincter during a momentary relaxation. The secretory pressure of the liver is said to lie between 200 and 300 millimeters of water while the sphincter resistance or breaking point is about 150 millimeters, but our experience with the breaking point in the postoperative case shows it to vary from 0 to 175 millimeters. Clamping the tube or lightly packing the fistulous tract may or may not be necessary. Our experience has not been sufficient to warrant a definite statement.

If a stone is lodged above the upper limb of the T-tube or tip of the catheter, it is necessary to remove the tube before the stone can pass to the lower end of the common duct. An increased pressure in the biliary ducts may also wash smaller stones down from the liver, as definitely proved in one of our cases.

The first case presented illustrates the pos-

CHOLANGIOGRAPHIC DEMONSTRATION OF THE REMAINING COMMON DUCT STONE AND ITS NON-OPERATIVE MANAGEMENT

R RUSSELL BEST M D F A C S Omaha, Nebraska

SINCE adopting the rule several years ago of making delayed cholangiographic studies in all cases of common duct drainage or biliary fistulas, we have been able to prove, for ourselves at least, that thorough exploration of the common duct at operation by palpation, probing, scooping irrigation and suction does not always verify the presence of stones. If they are present and are not identified by palpation they may not always be removed by such measures. Also it is plausible that these remaining common duct stones may frequently be stones which have descended from the liver. This can be fully appreciated only by those who have investigated the postoperative status of the common duct through delayed cholangiography. If abdominal palpation alone were used as the basis of determining the frequency of cancer of the stomach, before it invades other organs the figures would be far amiss as x ray examination with the use of a contrast medium is essential. We believe that this holds true also with the remaining common duct stone. We all appreciate that patients not infrequently continue to have right upper quadrant distress after an apparently successful cholecystectomy. At times this has been proved due to spastic dysynergia of the sphincter of Oddi, or to cholangitis, pancreatitis or hepatic disturbances. That remaining stones, mucous plugs, blood clots, or organized debris within the intrahepatic or extrahepatic biliary ducts account for some of the postcholecystectomy syndromes has been forcibly brought to our attention by our experiences with cholangiography.

Just how frequently the common duct should be opened and explored is difficult to ascertain but no doubt it should be done more often than is commonly advocated. Lahey's statement that between 1910 and 1926 his group had opened the common ducts in 15.5 per cent of their gall bladder patients and had discovered stones in 8.4 per cent is illuminating. They gradually began to explore the common duct more frequently until be-

tween 1930 and 1931, of 138 patients operated upon 4.5 per cent were explored and stones were discovered in 21 per cent. It is noteworthy that approximately 50 per cent presented stones, regardless of the number of common ducts explored. It is also significant that 38 per cent of their patients with common duct stones were not jaundiced. Secondary attacks upon the common and hepatic ducts are not only difficult but hazardous resulting in a rather high mortality. Fully cognizant of these facts, we have attempted to dislodge remaining stones and other foreign bodies by various measures.

Our first attempts consisted merely in following the established method of irrigation through the T tube or catheter, with or without the use of atropine and morphine, alone or in combination. We feel confident that in the past smaller stones, mucous plugs or debris were not infrequently washed into the duodenum, thus obviating secondary attacks upon the biliary tract with their attendant mortality. After deriving more knowledge of the pathological physiology of the common duct from cholangiographic studies, a more scientific and practical attack was formulated.

That spasm of the sphincter of Oddi may exist is no longer a debated question. It has been proved by Westphal, Newman, Ivy and Sandblom, Saralegui and Best and Hicken, among others. This sphincter may be either in a completely relaxed, unrelaxed (achalasia) or spastic state (spastic dysynergia). The work of Meltzer and of Lyon in non surgical drainage of the gall bladder by means of tube and magnesium sulphate hypothesized the necessity of a relaxed sphincter of Oddi in order that bile might pass freely into the duodenum. The administration of fat (cream) by mouth in cholecystography to empty the gall bladder also suggests direct or indirect relaxation of the sphincter area to permit free drainage of bile into the duodenum. For years atropine has been considered efficacious in relaxing the sphincter, but recent studies have proved that it is variable and not to be entirely depended upon, although it should by no means be discarded.

From the Department of Surgery, University of Nebraska College of Medicine.
Presented at the meeting of the Western Surgical Association on Indianapolis, Indiana, December 3, 1937.

Fig 2 a, left. The cholangiogram reveals a stone lodged at the lower end of the common duct. There is an associated pancreatitis and the pancreatic duct is well visualized. b, The stone has been dislodged. Pancreatic duct still visible.

revealed no stones. A catheter was then placed in the common duct and the abdomen closed.

Cholangiogram. One week after operation a cholangiogram made with 20 cubic centimeters of hippuran solution revealed multiple stones in the common duct (Fig 3a). This was repeated several days later with the same picture.

As soon as the patient's condition warranted it, the previously described therapeutic measures were begun. After the first course of treatment, 10 stones were recovered from the stools. The cholangiogram was repeated and one stone was found remaining in the ampulla (Fig 3b). A second course of treatment resulted in passage of the 11th stone (Fig 4a). Two subsequent check-ups were negative. The fistula soon closed and now, 10 months later, the patient feels perfectly well.

We have been able to depict apparent foreign bodies in two other common ducts by postoperative cholangiograms, with defects irregular and inconstant in shape and position. It is highly possible they were small blood clots, mucous clumps, or lumps of inspissated bile which were dislodged (Fig 5). In any event, they disappeared under the described treatment. In a recent case, although none could be palpated, a very large stone was revealed in the common duct on the postoperative cholangiogram. Repeated efforts to dislodge it have been ineffectual and ether as advocated by Pribram has also failed to break it up (Fig. 6). We have also had a failure

with ether in an elderly woman with a gall-bladder fistula and cystic duct stone. However, from the report of Pribram, it is a method which has possibilities.

SUGGESTED TECHNIQUE FOR REMOVAL OF REMAINING COMMON DUCT STONES

When a stone or foreign body is identified in the common duct by delayed cholangiography, the following 3 day regimen is begun. On the first day a 1/100 grain tablet of nitroglycerin is dissolved under the tongue 3 times during the day; on the second, 1/100 grain of atropine is given 3 times, either by mouth or hypodermically, on the third day, the nitroglycerin is repeated. Each morning the patient is given 2 drams or more of magnesium sulphate in warm water and at bedtime, 1 ounce of olive oil (preferably) or thick cream. The common duct is gently irrigated every day through the drainage tube or fistula with warm normal saline solution, and after removing as much of this solution as possible with the syringe or by permitting the tube to drain for 5 minutes, 10 to 30 cubic centimeters of warm sterile olive oil are instilled. At times, lipiodine or lipiodol seems to exert a more beneficial effect. If the patient does not complain of distress, the tube

sibility of dislodging a stone from the common duct by this method after first permitting the edema in the sphincter area to subside

CASE 1 Mr O M aged 35 years had recurrent attacks of indigestion over a period of 16 months accompanied by pain in the upper abdomen nausea and vomiting Morphine was required for relief and upon one occasion he became slightly jaundiced The week before he entered the hospital he developed a severe pain in the upper abdomen which necessitated several hypodermics of morphine for relief and within 3 days he became icteric When examined the patient was very apprehensive definitely jaundiced and moderately tender over the gall bladder His icteric index was 75 the van den Bergh direct delayed reaction was moderately positive the stools contained bile his temperature was 99.8 degrees and he had a leucocytosis of 10 600 By conservative management the icteric index was brought down to 35 and after 5 days of observation and preparation the patient was operated upon with the diagnosis of cholecystitis cholelithiasis and common duct stone

First operation Under spinal anesthesia the gall bladder thick walled definitely inflamed and adherent to surrounding structures was removed The common duct was about twice normal size and was angulated at its junction with the cystic duct by inflammatory adhesions These were freed and the duct opened Thorough palpation probing scooping and irrigation revealed no stone The head of the pancreas was thickened and harder than normal A T tube was placed in the common duct for drainage purposes

Cholangiogram On the sixth day after operation a cholangiogram was made by injecting 20 cubic centimeters of hipuran solution into the common duct through the T tube No stone was visible but the sphincter appeared contracted This spasm was relaxed by dissolving 1/100 grain of nitroglycerin beneath his tongue The T tube was removed on the tenth day after operation following a check up cholangiogram which again revealed some sphincterismus but no stone The patient was discharged from the hospital a few days later with a remaining biliary fistula During the next 2 months he had continued attacks of chills fever upper abdominal distress and intermittent jaundice The sinus tract would close off only to reopen and drain pus and bile This occurred a number of times

Cholangiogram About 10 weeks after the first operation another cholangiogram with 30 cubic centimeters of hipuran solution revealed 2 stones in the common duct which had not been visible previously Operation was advised

Second operation An attempt was made to locate and move the stones from an enlarged common duct The head of the pancreas was also larger than normal quite hard and irregular as is consistent with marked chronic pancreatitis or new growth There was a pronounced inflammation around the common duct and duodenum The duct was explored as thoroughly as possible in the presence of this inflammatory reaction using finger probe scoop irrigation and suction but no stone could be palpated or dislodged The patient's unsatisfactory condition contra-indicated a transduodenal attack Therefore a T tube was hurriedly placed in the common duct and the abdomen was closed

Cholangiogram Because of digestion of the tissues around the wound a cholangiogram was not taken for 3 weeks at which time the picture was a little suggestive of a single stone in the region of the ampulla A recheck 4 weeks later definitely revealed a stone at the lower end of the common duct (Fig. 2a) The entire length of the pancreatic duct was easily visible

Cholangiogram The previously suggested regimen was immediately started and was repeated every 10 days In the intervals the duct was washed out on alternate days with sterile olive oil or lipiodine With each oil irrigation 1/100 grain of nitroglycerin was placed beneath the tongue After 1 month a follow up cholangiogram showed the stone still present but the opaque medium entered the duodenum more readily After a second month of treatment no evidence of a filling defect could be found at the lower end of the common duct (Fig. 2b)

The T tube was then clamped off except at night, for another 30 days when a recheck showed no indication of stone in the duct This warranted removal of the T tube and now 10 months later the patient weighs more than he ever did feels perfectly well and is back at his regular duties

Evidently in this case common duct drainage and time were needed for the pancreatic inflammation to subside and then proper measures dislodged the stone

We have come to believe that stones are present in the larger biliary ducts of the liver more frequently than is recorded More detailed examination of the liver at autopsy would support this statement, for during the last year we have demonstrated such stones in two instances but only after thorough search One of these was a patient with a postoperative common duct stone who also had an unrecognized carcinoma of the kidney The other case was one in which a routine autopsy was performed after the patient had succumbed to cardiovascular disease

The following case is presented because it demonstrates more vividly the release of intrahepatic stones into the common duct These stones were detected in the common duct by cholangiography and then were successfully dislodged by the aforementioned regimen

CASE 2 For 5 years Mrs R C aged 28 years had been having attacks of nausea and vomiting which were associated with loss of appetite slight upper abdominal distress but no true pain Removal of her appendix did not alleviate the symptoms but rather the attacks became more frequent Three days before entering the hospital she was suddenly seized with a sharp pain in the right upper quadrant which radiated to the right scapular region The paroxysm subsided under morphine She presented no history of jaundice but for some years she had noticed a pressure sensation immediately following meals which would last for half an hour and was not relieved by soda

Examination revealed a well developed young woman in no apparent distress The only positive finding was slight tenderness over the gall bladder No rigidity and no definite masses were palpable Her temperature and pulse were normal The white blood count was 10 400 and the icteric index was 10

Operation The large distended gall bladder was adherent to the duodenum The common duct appeared two or three times normal size with no stones palpable in its lumen After the gall bladder was removed it was incised and found to contain about 200 pea size stones The common duct was opened through the stump of the cystic duct by palpation probing scooping suction and irrigation re-

Fig 5 a, Cholangiogram at the table reveals no filling effect of the narrow common duct b, After 2 months with persistent draining biliary fistula, a defect inconstant in

recovered no stones from the stools in such instances, but the patient's search for these is not always exacting Again, dislodgement of mucous plugs or inspissated bile may account for the therapeutic result. One should always keep in mind the potential danger of such treatment, and

until further investigative studies have been made, the dehydrocholic acid products should be prescribed cautiously in any degree of jaundice with supposition of stones in the common duct. If the jaundice is marked and the stools are acholic, great damage might be done to the liver

Fig 6 a, left, Stone is lodged above the upper end of the T-tube b, After removing T-tube and increasing biliary pressure, stone arrived at lower end of common duct. It could not be dissolved by Pribram's ether method nor could it be forced into the duodenum

Fig 3 a. left The cholangiogram reveals multiple stones in the common duct b. After the first course of treatment all but one stone had been removed and so recovered from the stool. Note rounded filling defect at lower end of common duct.

should be clamped off during the course of treatment except for 1 hour after each instillation of oil. Three to five decholin or procholol tablets ($3\frac{3}{4}$ grain) are given 4 times a day to increase and maintain the pressure within the common duct so that during some momentary period of relaxation the stone or foreign body may escape from the duct.

This treatment may be repeated after a day's rest and as in the second case reported, it may be administered as many as ten times over a period

of 2 months. It may prove rather exhausting at times, and a little caution must be exercised.

The question arises as to the indications for this form of treatment where no fistula or catheter set up for irrigation exists. If obstruction is complete there may be danger of hastening liver destruction by increasing biliary pressure. We have ventured to use this method in several cases in which obstruction was not complete with no evident harmful effects and with definite clearing up of the apparent biliary condition. We have

Fig 4 (same case as Fig 3) a. left After the second course of treatment the single remaining stone was dislodged and the contrast medium freely entered the duodenum b. The group of stones were recovered first. Later the single stone was recovered.

Fig 5 a, Cholangiogram at the table reveals no filling defect of the narrow common duct b, After 2 months with a persistent draining biliary fistula, a defect inconstant in

size and shape was revealed on the cholangiogram c, After described treatment, the defect disappeared and in 7 days the fistula was closed

recovered no stones from the stools in such instances, but the patient's search for these is not always exacting. Again, dislodgement of mucous plugs or inspissated bile may account for the therapeutic result. One should always keep in mind the potential danger of such treatment, and

until further investigative studies have been made, the dehydrocholic acid products should be prescribed cautiously in any degree of jaundice with supposition of stones in the common duct. If the jaundice is marked and the stools are acholic, great damage might be done to the liver

Fig 6 a, left, Stone is lodged above the upper end of the T-tube b, After removing T-tube and increasing biliary pressure, stone arrived at lower end of common duct. It could not be dissolved by Pribram's ether method nor could it be forced into the duodenum

and dehydrocholic acid should definitely not be prescribed

This method of postoperative biliary tract flush is being instituted in more and more of our routine gall bladder cases in the hope of washing out remaining mucous plugs, blood clots that may originate from trauma, or inspissated bile which might be the nucleus of a stone, as well as to remove any remaining smaller stones, and thus avoid the later appearance of the so-called postcholecystectomy syndrome

Decholin (Riedel de Haen) and procholon (Squibb) were the dehydrocholic acid products used

RETRACTION RING DYSTOCIA

Its Cause and Correction

W. T. PRIDE, M D, F A C S, Memphis, Tennessee

FOR many years uterine rings have been recognized as a cause of dystocia, yet the subject is one upon which the obstetrical world still seems to be rather confused. In a review of the literature, one finds that Braune, in 1872, wrote of a ruptured uterus from ring dystocia. Bandl, in 1875, defined a ring at the juncture of the upper active uterine body and the lower inactive cervix. Schroeder described a ring in normal labor at the union of the upper and lower uterine segments, which he designated a "contraction ring." Barbour and Lusk, also, were familiar with this ring, but, on account of the increased thickening of the body of the uterus, called it "retraction ring." More recently, Holmes, White, Harper, Fitzgibbon, and others, have written upon the subject.

During the past year, Rudolph, of Chicago, read a paper before the Obstetrical Section of the American Medical Association, on constriction ring dystocia. His report covered a series of 371 cases of ring dystocia, in which the maternal mortality was 15 per cent and the fetal mortality 46 per cent. No doubt these figures are not exceptional, yet, obviously, something is wrong with a situation in which the mortality could be so high. A clearer conception of ring obstructions from the anatomical, physiological, pathological, and therapeutic standpoints might go far toward reducing the number of fatalities for which they are responsible.

In the hope of throwing further light upon this subject, I shall give herein a report of my own experience with ring dystocias within the past several years. At the meeting of the Southern Medical Association in Dallas, Texas, November, 1925, I discussed before the obstetrical section my findings from research and practice through the years 1919 to 1925, inclusive. The cases upon which the present report is based have been observed since that time. They were, moreover, taken from my private practice. I make a point of this statement because I feel that private cases afford the most exact information. In the department for teaching of the University of Tennessee we have delivered over twenty thou-

sand infants throughout the same period of years. This work, on the whole, has been done by a number of persons, and, although the cases have been studied and evaluated, it is apparent that, in the circumstances, records of such rarely recognized conditions as uterine rings could hardly be accepted as accurate. My private patients, on the other hand, have received my personal attention.

According to my observations, retraction and contraction rings are by no means identical. The uterine retraction ring is a definite entity. It has certain distinguishing features:

1. The retraction ring is always at the juncture of the upper and lower uterine segments, in the annular layer of the submucous coat.
2. It is always palpable behind the symphysis at this juncture.
3. The body of the uterus is tense and painful on pressure so long as the ring persists.
4. The ring is found more often in long labors caused by malposition of the fetus.
5. The carbon dioxide combining power of the blood usually is low.
6. The ring is relaxed only by analgesia and anesthesia, and relief of acidosis when this condition exists.

7. Disproportion is often present.

Contraction ring, on the other hand, is characterized by the following:

1. It can take place at any point of the uterine musculature, since the active fibers run in both the circular and longitudinal directions.
2. The ring can occur after delivery if the placenta is retained.
3. The uterine body is not tense above nor below the ring, hence there is no pain on pressure.
4. Contraction ring is not especially related to malposition of the fetus.
5. All contraction rings are physiologic, they become obstructive only when some of the factors which produce the retraction ring are present.
6. Contraction rings are easily relaxed by mild analgesia and anesthesia.
7. There is no disproportion.

The validity of these observations can easily be appreciated by a study of the muscular structure of the uterus in pregnancy. The uterus is composed of three muscular layers of tissue: the

Fig 1 Schematic drawing showing the muscular layers of the pregnant uterus A Longitudinal muscle and the outer coat B central muscular layer composed chiefly of spiral and longitudinal fibers C the submucous coat D the annular layer of the submucous coat where the retraction ring always occurs E B C and D the layers from a different view

submucosum the stratum vasculare and the subserosum. There is no sharp demarcation between the layers of the uterine wall as is found in the walls of the intestine in the uterus the several layers of the myometrium interlace.

In the thin layer of muscle just under the serosa the fibers run principally in a longitudinal direction. At the juncture of the fornices with the vagina these fibers continue on to form part of the muscular wall of that organ. Between these longitudinal fibers are the transverse fibers which are active in contraction ring formation.

The fibers of the middle layer which run radially, constitute two thirds of the entire thickness of the wall. Because of its thickness and the numerous blood vessels which it contains the middle layer is known as the stratum vasculare. Its outer fibers adjacent to the stratum subserosum, are sometimes described as a distinct

layer, the stratum supravasculare. Aside from the fact that the muscles of this outer layer of the vascular area entwine about the blood vessels in a sort of figure eight arrangement no good reason exists for the special designation.

The innermost layer or stratum submucosum, as its name suggests, under the endometrium. This layer contains a large number of circular and oblique fibers which, at the fundus form the muscular rings around that portion of the tube and continue into the tube to form its circular layer. Below just above the internal os, is a thicker segment of annular fibers and it is at this point that the retraction ring is encountered.

An illustrative drawing of the musculature of the uterus is shown in Figure 1.

During pregnancy, the normal structures undergo profound anatomical changes. The individual muscle fibers are greatly augmented in number—not by a process of division of elements already present but by conversion of non muscular into muscular elements. At the same time the fibers increase at least ten times in size swelling from 40 to 500 micra in length. The nature of the physiological changes if any occur, can only be conjectured at the present time. It is unlikely that such enormous changes in anatomy would not be accompanied by equally important changes in physiology.

In the anatomical distribution of the muscular fibers of the uterus lies the mechanical basis for the waves of contraction that sweep over the organ during parturition. These waves begin at the fundus and involve for the most part the three layers, continuing to do so until the uterine contents engage the cervix the circular fiber then contract more vigorously in the wake of the fetus. Normally the circular contractions produce rings of constriction which are alternately loosened by the retraction of the longitudinal fibers. By this combined effort the fetus is pushed toward the outlet while accidentally the uterine rings are pulled back and slipped over the fetus in much the same manner as the snake pulls him self around his prey.

It is conceivable that failure of the longitudinal fibers to loosen these rings of constriction can throw the entire uterus into a state of contraction thus preventing its contents from moving outward. As has been stated constrictions of this type may occur at any point (Fig 2). They are initiated by some of the same factors which produce retraction rings but may be easily relaxed by mild analgesia and anesthesia. However, when the longitudinal fibers fail to loosen the segment of circular fibers composing the

annular layer of the submucosum, which is known as the physiological retraction ring, the other layers are engaged in the constriction, the ring becomes thickened and rigid, causing obstruction, the cervix relaxes, the uterus above the ring becomes tense, and the abdomen is painful upon pressure. The physiological retraction ring then becomes pathological (Fig 3).

This pathological ring may obstruct with varying degrees of force. In the most severe form, every muscle fiber of the uterus is contracted and retracted, allowing no relaxation and producing in the uterus a condition of tetany. The tenseness may be so acute and so forceful as to compress the blood vessels supplying the fetus and lead to its asphyxiation. Occasionally, one sees a rupture of the lower uterine segment from overstretching and thinning of the walls (Fig 4). Microscopic sections have shown all the uterine muscle fibers retracted, that is, shortened and thickened, and the number, particularly the

spiral and transverse fibers, markedly increased. Rudolph described this development as a permanent, non-reversible constriction ring, which does not relax under anesthesia or drugs, or even after death. We have had 2 cases of this type, and an additional 2 have been observed by my associates White, Phillips, Carson, Hannah and Massey, and others, have reported similar cases.

ETIOLOGY

Bearing in mind the anatomical structure of the uterus, it would seem that there are four major causes of retraction ring dystocia. A number of minor factors may contribute, but in the final analysis these are basic: (1) malposition of the fetus, (2) early rupture of the membranes, (3) disproportion, (4) the response of the musculature to an abnormal blood chemistry.

If labor is severe from any cause, the normal chemistry of the blood may be altered, the carbon dioxide combining power is reduced, and

Fig 2 A Full dilatation B retraction ring C contraction

acidosis supervenes. Several years ago we observed that a number of our ward patients after being in labor for more than 18 hours suffered shock, and a few succumbed suddenly from the anesthetic. To our surprise we discovered that the anesthetist had ordered nothing to be given by mouth during the second stage of labor in order to prevent nausea in anesthesia. As a consequence the carbon dioxide combining power of the blood was found to be excessively low. It was these patients who suffered from ring formation.

Alkalosis also, may influence the development of pathological retraction ring but in our experience this condition has been so rare as to be regarded as an almost negligible possibility.

DIAGNOSIS

In making a diagnosis of retraction ring dystocia the following signs are to be considered:

1 Prolonged labor, that is from 12 to 36 hours.

2 Malposition and slight advancement of the fetus, the head or presenting part within the dilated cervix.

3 The appearance of a sulcus across the lower abdomen above the symphysis pubis at a level corresponding to the peritoneal attachment where the coronary vein crosses body of uterus.

4 Tenseness of the uterine body above the sulcus, and pain on palpation of the abdomen.

5 On vaginal examination a freely movable presenting part and a cervix dilated sufficiently to permit passage of the examining hand beyond the portion where the ring is found.

6 Low carbon dioxide combining power of the blood.

TREATMENT

The most important part of any medical procedure is treatment. In these cases the treatment consists of both preventive and curative measures. We believe that the great majority of uterine ring retractions can be prevented. Upon reviewing our cases since 1925, we found that the number of rings and long labors followed very closely the manner in which the patient was treated. Since we have had no retraction ring dystocias during the past 12 months we feel justified in concluding that our present method is successful. This method is given herein.

When the patient in labor arrives at the hospital, following the usual preparation she is examined both abdominally and vaginally. She then receives a rectal injection of 3 to 6 grains of one of the barbiturates. If this brings about cessation of pain and sleep during the intervals nothing further is given. When she begins to awaken and complain morphine sulphate $\frac{1}{4}$

Fig 3 A, Dilatation, B, retraction ring, C, insert, where retraction occurs

grain, and scopolamine $1/200$ grain is given hypodermically. A smaller portion of this, alternating with 1.5 to 3 grains of one of the barbiturates, with scopolamine $1/300$ grain is administered thereafter as necessary. Fluids are given, if labor is prolonged, they are injected intravenously. Analgesia must be complete if good results are expected. It does not prolong, but, rather, shortens labor, and it does not affect the baby. By this method, the patient can be carried along for many hours in comparative comfort.

If the foregoing measures fail to prevent the development of a ring, or if a ring is already present when the patient is examined, a test is made for the carbon dioxide combining power of the blood. When this is found to be low, an intravenous injection of 1 to 2 per cent sodium bicarbonate is given. The analgesia is continued. If the ring persists when the patient is ready for delivery, 6 minims of adrenalin solution are given hypodermically for relaxation, and ether is administered. It is essential that both analgesia and anesthesia be allowed to take full effect before an attempt is made to deliver. If, in spite of analgesics, adrenalin, anesthetic, and sodium bicarbonate, the uterine retraction is not relaxed, tetany develops and the baby shows signs of distress, a cesarean section is indicated.

Since this treatment of sodium bicarbonate was instituted, about 2 years ago, we have not had the opportunity of giving it an extensive trial. In 2 of the 6 cases in which it was followed, delivery was made with low forceps, and in 2 delivery was spontaneous. In these 4, the ring disappeared entirely, and the uterus was slightly relaxed. In the 2 remaining cases the treatment had no effect.

Of vital importance is the correction of the acidosis or alkalosis before inducing profound anesthesia to relax the ring. We caused the

Fig 4 Ruptured uterus. Protrusion of extremity from the os and rupture below. Retraction ring at A.

Fig 5 Uterine retraction ring Sukus above the symphysis

death of several dogs before realizing that failure to correct the imbalanced chemical ratio before giving the anesthetic was responsible. In the past, I have known fatalities to occur, no doubt from this combination, which were attributed to cardiac thrombosis or embolus.

Our reasons for using sodium bicarbonate in preference to glucose or Hartmann's solution might well be explained. In carrying out some experiments upon dogs with acidosis, we found sodium bicarbonate much more effective, in fact, we produced an extreme acidosis in dogs by giving 2 per cent lactic acid solution. The normal ratio was restored by the use of a 2 per cent solution of sodium bicarbonate.

In this connection, I should like to state that sodium bicarbonate should never be given intravenously to a diabetic. Further glucose and sodium bicarbonate should not be given together, we killed 5 dogs with this combination.

Neglect of early treatment by proper analgesia and the prevention of acidosis or alkalosis may lead to the development of a severe type of retraction ring. The following case which was one of a series recently reported by an essayist, is a typical example of the effect of inactive treatment.

Fig 6 Cesarean section for unrelaxed retraction ring Uterine tetany

The patient was a primipara aged 20 years. Labor began September 4 at 12:00 o'clock noon. The cervix was partially effaced. The right occiput was in the anterior position. On September 5 the cervix was dilated to 6 or 7 centimeters. By September 6 the cervical dilatation had not increased and routine treatment for exhaustion was given. The acetone test was negative. At 7:00 o'clock on the morning of September 7 the patient was shown the strain of labor; the cervix was dilated to 8 centimeters. Intra uterine examination revealed a ring around the neck of the fetus. Morphine and scopolamine were given as well as an intravenous injection of glucose. At 7:57 o'clock in the evening epinephrine was administered and at 6:30 a spontaneous delivery occurred.

It is my opinion that, if efficient analgesia had been given early in this case labor would have terminated at the end of 2 days rather than have been prolonged through the 4 days.

METHOD OF DELIVERY

Several years ago we regarded podalic version under deep anesthesia as the best method of delivery in retraction ring dystocia. In analyzing our cases from 1925 to 1930 we found 10 versions, 9 midforceps and 7 low forceps (Table I). From 1931 to 1936 there were only 5 versions, 24 midforceps and 10 low forceps (Table II). The fetal death rate was 14 per cent in the first group and 0.6 per cent in the second. There

JAMES R. REINBERGER, M.D.

was no maternal mortality in either. In the light of our present knowledge, an attempt to turn a fetus in a tense uterus is a procedure which is open to criticism.

A statistical résumé of this study of 2,987 private patients is given in Table III.

One of my associates, Dr James R Reinberger, has tabulated a report of 17 cases from his private practice, which is presented in Table IV. Although the infant mortality of 17.6 per cent in his cases seems high, when one considers the number of cases and the fact that the series covers a period of years during which there was no well known routine treatment, the result is good. His operative incidence was 94.1 per cent. Ours was 91.2 per cent. In his series, also, there were no maternal deaths.

In closing, I should like to present two photographs loaned by Dr Raymond Wallace, of our staff. These show an interesting case of tetany uteri, caused by a retraction ring which failed to relax under analgesia and sodium bicarbonate. A section was performed, and both mother and baby survived. The rather high position of the sulcus, as shown in Figure 5, is due to the manner of photographing. In Figure 6, the tetanoid condition of the uterus is clearly apparent.

SUMMARY

- 1 Retraction rings are found, as a rule, in long labors.
- 2 Contraction rings are physiological, but become pathological under some of the conditions which produce retraction rings.
- 3 Retraction rings always occur at the junction of the upper and lower uterine segments, the annular layer of the submucous coat.
- 4 Tetany uteri develops when the force of the retraction is exaggerated.
- 5 Retraction ring may be prevented by effecting early analgesia and, when indicated, instituting measures to combat acidosis or alkalosis.
- 6 We have found a combination of the barbiturates, morphine, and scopolamine affords the most satisfactory analgesia.
- 7 Labor is shortened by proper analgesia, and the mother and baby suffer no harm.

8 The carbon dioxide content of the blood usually is low when retraction ring is present.

9 Sodium bicarbonate will restore a low carbon dioxide content to normal.

10 Lactic acid will correct an excessive alkalinity of the blood.

11. We have never found cesarean section necessary in ring retraction except in the presence of uterine tetany.

12. Fetal mortality from ring dystocias should be approximately 10 per cent. There should be no maternal mortality.

death of several dogs before realizing that failure to correct the imbalanced chemical ratio before giving the anesthetic was responsible. In the past, I have known fatalities to occur, no doubt from this combination, which were attributed to cardiac thrombosis or embolus.

Our reasons for using sodium bicarbonate in preference to glucose or Hartmann's solution might well be explained. In carrying out some experiments upon dogs with acidosis we found sodium bicarbonate much more effective. In fact, we produced an extreme acidosis in dogs by giving 2 per cent lactic acid solution. The normal ratio was restored by the use of a 2 per cent solution of sodium bicarbonate.

In this connection I should like to state that sodium bicarbonate should never be given intravenously to a diabetic. Further glucose and sodium bicarbonate should not be given together, we killed 5 dogs with this combination.

Neglect of early treatment by proper analgesia and the prevention of acidosis or alkalosis may lead to the development of a severe type of retraction ring. The following case which was one of a series recently reported by an essayist is a typical example of the effect of inactive treatment.

Fig 6 Cesarean section for unretracted retraction ring, Uterine tetany

The patient was a primipara aged 20 years. Labor began September 4 at 12:00 o'clock noon. The cervix was partially effaced. The right occiput was in the anterior position. On September 5 the cervix was dilated to 6 or 7 centimeters. By September 6 the cervical dilatation had not increased and routine treatment for exhaustion was given. The acetone test was negative. At 7:00 o'clock on the morning of September 7 the patient was showing the strain of labor; the cervix was dilated to 8 centimeters. Intra uterine examination revealed a ring around the neck of the fetus. Morphine and scopolamine were given as well as an intravenous injection of glucose. At 7:30 o'clock in the evening epinephrine was administered and at 8:30 a spontaneous delivery occurred.

It is my opinion that if efficient analgesia had been given early in this case labor would have terminated at the end of 2 days rather than have been prolonged through the 4 days.

METHOD OF DELIVERY

Several years ago we regarded podalic version under deep anesthesia as the best method of delivery in retraction ring dystocia. In analyzing our cases from 1925 to 1930 we found 1 version, 9 midforceps and 7 low forceps (Table I). From 1931 to 1936 there were only 5 versions, 24 midforceps and 10 low forceps (Table II). The fetal death rate was 1.4 per cent in the first group and 0.6 per cent in the second. There

JAMES P. REINBERGER, M.D.

The local application for 10 minutes of a pledget of cotton containing 25 per cent cocaine or other topical anesthetic agent usually will provide sufficient anesthesia to permit a gentle digital examination but not enough for a complete, painless instrumental investigation. The injection of a local anesthetic (preferably in oil) underneath the fissure usually is not necessary, although there is no objection to this procedure if it seems desirable to rule out malignancy before proceeding with surgical treatment.

The acute fissure of the anus is superficial, presents no appreciable induration, and is not accompanied by the so called "sentinel pile." There is usually marked spasm of the external sphincter ani.

The chronic fissure presents a more marked lesion associated with greater fibrosis (Figs. 7 and 8). Through the examining finger the surgeon senses more or less induration in the base of the lesion. Spasm of the sphincter varies from slight to marked.

The permanent cure of chronic fissures of the anus almost invariably requires operation, although some acute fissures can be treated successfully without operation mainly by measures to soften the stool. However, since we are dealing with the operative treatment of fissures, we shall reserve discussion of the treatment of acute fissures, and confine our remarks to the operative handling of chronic pathology.

A fibrous tissue mass or so called "sentinel pile" (Figs. 3, 7, and 8) usually overhangs the outermost extent of the chronic fissure or ulcer. It is not a true pile but results from chronic irritation following prolonged infection in the fissure or crypt.

ANAL PAPILLA

In addition to the "sentinel pile" there is frequently associated with the fissure an enlarged anal papilla or fibroma of the anal canal at the upper limit of the fissure (Figs. 3, 7, and 8). This is an enlargement of a normal structure, as the result of chronic infection at its base and repeated trauma from the passage of hard stool over the resistant pectinate line. This structure acts like a foreign body. At stool it is forced downward and insinuates itself into the fissure. It thus causes increased pain and mechanically prevents healing. Not infrequently it becomes long enough to protrude at the anal orifice.

CHRONIC CRYPTITIS, ABSCESSSES AND FISTULAS OF THE ANUS

It is easy to confuse the typical fissure just outside the pectinate line with a small ulcer which

forms locally as a result of infection in a crypt of Morgagni or the adjacent vestigial anal gland. (7) The pathology is different fundamentally. The fissure is located distal to the mucosal margin and primarily involves transitional epithelium. On the other hand, an ulcer resulting from an infected crypt is found to involve the mucosa just above the pectinate line, as well as the crypt itself beneath the shelving edge of transitional epithelium at the mucocutaneous margin. A "sentinel pile" often overhangs the chronically infected crypt.

In many cases, the fissure or infected crypt is associated with considerable active infection. The location of the fissure or crypt deep in the anal canal beneath the "sentinel pile" and between the folds of peri-anal skin tends to prevent free egress of infected discharge. The infection may spread upward to form a perirectal abscess in the submucosal space. Much more often, however, the infection spreads downward beneath the skin to form a subcutaneous, peri-anal abscess, which ruptures through the skin to form an associated fistula. This fistula is usually superficial and its external opening is most often located near the base of the fissure or "sentinel pile". There may be multiple external openings at varying distances from the pectinate line, due to extension of the initial inflammatory reaction, through liquefaction of the peri-anal fatty tissue. Rarely does the infection spread from a fissure or infected crypt into the space below and lateral to the levator ani to form a true ischioirectal abscess.

In selecting a fistula for operation in an ambulatory patient, one must be extremely cautious. Very frequently, it is most difficult to determine before operation the extent of the fistulous ramifications. One should select for this type of operation only those simple, uncomplicated cases in which the fistula is superficial and through which a probe can be easily passed.

INTERNAL HEMORRHOIDS

A satisfactory diagnosis of internal hemorrhoids can be made only by viewing them through the anoscope. Palpation is of no definite value. Except in extenuating circumstances, one should operate upon and keep ambulatory, only those patients who have one enlarged, protruding internal hemorrhoid. The others with more extensive pathology should be operated upon in the hospital.

OPERATIVE TREATMENT

The majority of patients suffering from anal disease present themselves for treatment after the lesion has become chronic. The chronic well

AMBULATORY OPERATIVE TREATMENT OF ANORECTAL PATHOLOGICAL CONDITIONS

194 Consecutive Operations Performed Under Local Anesthesia of Prolonged Duration

C V BURT, A B M D, F A C S, New York New York
J GORDON RENNIE, A B, M D, Richmond, Virginia

THE pathological entities of chronic fissures and cryptitis, hypertrophied papillae, simple uncomplicated fistulas of the anus, and single internal hemorrhoids are amenable to ambulatory, operative treatment in selected cases

There is some nervous and physical strain associated with this form of treatment. Patients who are highly nervous, and those who are in poor physical condition should not be subjected to this additional emotional trauma. The more affluent patients will prefer to be admitted to the hospital for any operative procedure.

By operating upon and keeping these patients ambulatory we have been able to save them their hospital expenses and in many cases have reduced their economic loss by returning them to work earlier than would have been possible had they been admitted to the hospital for the same operations.

We have included in this series (up to April 19 1937), 194 operations performed under anesthesia in 181 or 182 patients. Of these 194 operations, there are 124 for fissure, 34 for fistula, 10 for internal hemorrhoids, 4 for chronic cryptitis, 12 for chronic papillitis, 6 for combined cryptitis and papillitis and 4 for unhealed postoperative wounds.

From a practical standpoint typical chronic fissures and the chronic cryptitis lesions require the same treatment, namely excision and we have included both entities in our series under the caption of 'fissures.'

FIGURE OF THE ANUS

A true fissure of the anus begins as a linear laceration in the epithelium just distal to the mucocutaneous line (Figs 3 and 7). The lesion most commonly results from the passage of hard fecal

matter over the resistant pectinate line. Less frequently it is due to overstretching of the anus at childbirth. The presence of large internal hemorrhoids and particularly of hypertrophied anal papillae also contribute materially to the production of fissures. These structures exert their influence mechanically through the variation of stress as the stool passes by these masses at the pectinate line.

Symptoms. A fissure is one of the most painful anal lesions with which we have to deal. The anal canal distal to the mucocutaneous line abounds in sensory nerve terminals; hence it is extremely sensitive to contact with stool or other foreign objects. The most characteristic symptom of a fissure is a sharp knife-like pain during the passage of a hard stool followed by a dull aching pain for a few hours. In the chronic form there is usually a history of recurrent attacks of sharp pain at stool when the patient is constipated. These attacks last for periods of days to weeks and recur at intervals of weeks to months. The pain is frequently relieved when the stool becomes soft. The fissure not operated upon frequently heals and is broken down subsequently by the passage of a hard stool. Because of the pain the patient is afraid to move his bowels and increased constipation is the rule. The passage of hard fecal matter further traumatizes the lesion, sphincter spasm increases and a vicious cycle is established.

Examination. The fissure can be seen by properly retracting the perianal folds (Fig. 1) at the anterior or posterior commissure where nearly all of these lesions occur.

In a nervous patient with an active fissure, to complete the examination causes great pain and actually serves no useful purpose. It is far better to complete the instrumental part of the examination after the pain from the fissure has been relieved by appropriate surgical means. Every patient, before he is discharged, should have a sigmoidoscopic examination to rule out malignancy.

From the Department of Surgery, Prebyterian Hospital, College of Physicians and Surgeons, Columbia University, New York, New York.

Fig 4 Skin incision extends above the mucocutaneous line to include the fissure, subfissure fibrosis, sentinel pile, and enlarged papilla

We have used benacol, anucaine, nupercaine, butecaine, and neothisol, as anesthetic agents. We have had the most satisfactory results with neothisol, the component parts of which are

Procaine base	1
Methyl methylene para amino phenylformate	2
Hydrobenzocarbinal	5
Refined French almond oil—q s ad	

Following the use of this formula we have seen none of the redness and severe itching which has been noted with some of the other formulas. The postoperative discomfort and pain, and particularly the wound necroses, have been lessened.

TECHNIQUE OF INJECTION OF ANESTHETIC IN OIL

A dry 20 cubic centimeter syringe is used. The anesthetic material is drawn into the syringe through a large caliber needle (gauge 15). This needle is replaced by one of much smaller bore (gauge 20), and of 2 to 2½ inches in length.

Fig 6 A, Hypertrophied anal papilla, B, fissure of the anus, C, sentinel pile

Fig 5 After removal of the fissure and its concomitants, the subcutaneous, external sphincter is incised. The incision extends into the deeper portion of the external sphincter. Sufficient skin is removed to permit free escape of the serosanguineous discharge. Short strips of plain gauze packing are laid into the entire wound.

The peri-anal skin is shaved. The anus and surrounding skin are cleansed with alcohol. The anal canal and rectal ampulla are not prepared other than with the enema. The skin through which the needle is to be introduced is prepared with tincture of iodine.

At the point of election for the introduction of the anesthetic, a novocain wheal is made with a hypodermic needle. The larger needle is introduced through this wheal. By passing this needle slowly in a circum-anal direction in the subcutaneous space, complete peri-anal anesthesia of

Fig. 1 Anatomical structures of the anal region. 18CD show the subcutaneous injection area on the left for posterior or lateral lesions. When this is repeated on the right, peri anal dermal anesthesia is produced for the posterior two thirds of the anal region. A similar injection in the right and left anterior quadrants produces complete cutaneous anesthesia for anterior pathology. A combination of these injections anesthetizes the complete cutaneous peri anal region.

established lesion requires operation. Palliative treatment is of little real value.

Pre operative preparation. The patient takes a soap suds enema and eats a light meal before he comes for operation. Our patients usually are not given any pre-operative sedation although there is no real objection to 3 grains of sodium amytal or other similar medication the night before and again 1 hour preceding the operation.

Position of the patient. Any position which is convenient and comfortable for the operator and patient is quite satisfactory. We prefer the knee chest position, although the Sims posture is very satisfactory.

Fig. 3 Exposure of the fissure and enlarged anal papilla after relaxation of the sphincter. Triangular lines show the area of excision of the skin, sentinel pile, fissure and papilla.

Fig. 2 Injection of the external sphincter. With the finger in the anal canal, the anesthetic material is laid down in the subcutaneous sphincter in the region of the dotted line. The needle is then passed in the same perianal direction but in a deeper plane to inject the deeper and more extensive portion of the external sphincter. A cone is placed in the ischio rectal fossa.

Selection of anesthetic. Our principal desire in the selection of an anesthetic for anal operations is to establish instantaneous and complete aresthesia with prolonged effect to relieve the pain for at least 10 to 14 days. After this time has elapsed granulation tissue has covered the sensory nerve terminals and there is no longer need for analgesia.

The effect of water soluble anesthetics—novocain for example—is of too short duration to provide the desired effect. The use of anesthetics in oil provides quite a satisfactory means of eliminating or greatly reducing pain and tenderness after operations for chronic anorectal pathology. Leomans, Gorsch and Mathesheimer in 1917 introduced the use of anesthetics in oil and thereby made an exceedingly important contribution to proctologic surgery. Since that time this method of administering anesthesia has been improved and used in various forms throughout the world.

The effect of this type of administration is instantaneous and complete. The duration of the anesthesia is difficult to determine because of the difference in the reactions of patients. Conservatively the duration of good analgesia may be said to be 2 to 3 weeks.

The oil should not be injected into the epidermis for an oil in the skin will cause a pressure necrosis. In the absence of frank infection, it may be introduced safely into the subcutaneous or deeper structures. There should be no pooling of the oil; this is assured by constant progress of the needle as the oil is injected.

mucosal region can thus be injected underneath the local lesion. Except when the lesion is extensive, it is not necessary to inject the entire submucosal region. It is entirely unnecessary and undesirable to inject into the ischioanal space. In many of our earlier cases we injected this space without untoward effect, yet the satisfactory results with perfect anesthesia in the absence of this injection, convinced us that it was unnecessary. The elimination of this step has removed the possibility of a deep abscess.

Amount of anesthetic agent In general, 15 to 20 cubic centimeters of the oil anesthetic agent is adequate for most anal operations. However, 25 cubic centimeters may be required for hemorrhoidectomy. Although the amount of anesthetic material will vary with the extent and location of the pathology, the following general distribution may be used in the case of a fissure of the anus:

- 3 c cm subcutaneously on each side
- 3 c cm in the subcutaneous and deep external sphincter on each side.
- 3 c cm underneath and around the local lesion

OPERATIVE PROCEDURE

Fissure or infected crypt An Allis clamp is placed in the lesion, and a hemostat is applied to the mucosa well above the pectinate line in the region of the local lesion to prevent retraction of the incised edge. The incision is made to include the sentinel pile, the fissure or crypt and the papilla above (Fig. 3). This incision is made generally in the shape of a triangle with its apex within the anal canal. The skin excision is made sufficiently wide externally to permit free egress of the serosanguineous discharge. If this excision is inadequate, the outer part of the wound will heal too fast, and the deeper portion will be very slow in healing or may even fail to heal.

Great care should be exercised to remove any enlarged papilla above or adjacent to the local lesion, as its presence will mechanically prevent healing and necessitate a second operation.

When the external skin incision is made, the skin edge is grasped and dissected free from the subcutaneous sphincter underneath, thus removing the fissure or crypt with the underlying fibrosis (Fig. 4). The dissection is carried to a point well above the pectinate line, where the pedicle is ligated for complete hemostasis. The subcutaneous, as well as part of the deep, portion of the external sphincter ani is incised, to produce satisfactory relaxation of the anal canal and to promote proper healing (Fig. 5).

It is particularly important not to incise completely through the deep portion of the external

sphincter ani. Permanent incontinence will not result if a portion of the true anal canal, including the innermost margin of the levator ani (puborectalis), is left intact. If the entire anal canal is incised, partial incontinence may result.

Plain packing is placed in the wound, preferably in short strips of $\frac{1}{2}$ inch width. A pad of gauze is then placed over the anus, and the buttocks are pulled tightly together with adhesive for hemostatic purposes.

Postoperative care At the end of 48 hours (second day), the external padding is removed. The packing is not disturbed because bleeding is likely to occur if it is removed at this time.

The patient is instructed to take 2 ounces of milk of magnesia on the morning of the second day, to be followed by a soap suds enema later in the same day if he has not had a satisfactory movement. He is also instructed to take hot sitz baths for 20 minutes, twice a day. The water should be gradually made hot to avoid weakness and should be cooled off at the end of the bath to prevent the patient from taking a cold.

The packing is permitted to come away with the first or second stool. If it has not been expelled by the end of the third or fourth day, it is removed. The danger of hemorrhage incidental to pulling the packing away has passed.

During the first 48 hours after the operation, the patient is given a light diet of tea, toast, milk, cereal, and eggs. After 48 hours, a regular diet is prescribed. If a movement becomes necessary during the first or second day after operation the patient is told to take off only the outside dressing. The packing is usually not expelled and we have not seen any hemorrhage as a result of a movement prior to 48 hours. Sufficient codeine is administered to eliminate any pain.

After the packing has been removed and the bowels are functioning adequately, it is important to dress the wound frequently, say every second or third day, to be sure it closes from within and not from the adherence of the raw surfaces. This can be most easily done by passing the index finger into the anal canal and bringing it out through the depth of the wound, which continues anesthetized for some 2 to 3 weeks after the operation.

Fistula of the anus A probe is passed through the fistula, or the tract is injected with methylene blue. The anesthetic material is injected around the local lesion, and not throughout the peri-anal region, as would be required in a more extensive operation. The skin overlying the tract is excised widely so as to permit free drainage. Great care must be exercised to remove, if possible, the internal opening, which is usually to be found in an adja-

Fig. 8 Low power of a typical fissure *A* is seen between the sentinel pile *B* and a small anal papilla *C*. The longitudinal smooth muscle bands of the intestine are visible at *D* and the circular muscle fibers at *E*.

Fig. 9 High power of the fissure as shown in Figure 8 presenting the fibrous tissue and cellular infiltration *I* underneath the fissure with the squamous epithelium of the sentinel pile *B*.

the skin can be produced (Fig. 1). Great care must be exercised to prevent intradermal deposit of the oil, which will produce necrosis.

If the lesion is located only in the posterior region, the anesthetic agent can be introduced through one skin puncture about 1 to 1½ inches posterior to the anal ring. If it is located anteriorly it is desirable to introduce the anesthetic material through the skin in either or both the right and left anterior quadrants about 1 to 1½ inches from the anal verge. In this way more complete and satisfactory anesthesia can be produced than through one puncture wound.

If hemorrhoidectomy or excision of multiple crypts is to be done, the posterior and the two anterior injections should be combined.

After the anesthetic material has been introduced into the subcutaneous space around the anus, the index finger is introduced into the anal canal, the needle is passed on either side into the subcutaneous portion of the external sphincter and this structure is thus completely injected. Then the deeper and more extensive part of the external sphincter is infiltrated with the oil (Fig. 2). Should this deeper portion including the puborectalis be too extensively infiltrated a temporary incontinence may result. If this should occur it is of little consequence as the sphincter tone returns in about 10 days when the major portion of the anesthetic effect has disappeared.

If the needle is passed deep to and somewhat above the subcutaneous sphincter the sub-

mucosal region can thus be injected underneath the local lesion. Except when the lesion is extensive, it is not necessary to inject the entire submucosal region. It is entirely unnecessary and undesirable to inject into the ischioanal space. In many of our earlier cases we injected this space without untoward effect, yet the satisfactory results with perfect anesthesia in the absence of this injection, convinced us that it was unnecessary. The elimination of this step has removed the possibility of a deep abscess.

Amount of anesthetic agent In general, 15 to 20 cubic centimeters of the oil anesthetic agent is adequate for most anal operations. However, 25 cubic centimeters may be required for hemorrhoidectomy. Although the amount of anesthetic material will vary with the extent and location of the pathology, the following general distribution may be used in the case of a fissure of the anus:

- 3 c.cm subcutaneously on each side
- 3 c.cm in the subcutaneous and deep external sphincter on each side
- 3 c.cm underneath and around the local lesion

OPERATIVE PROCEDURE

Fissure or infected crypt. An Allis clamp is placed in the lesion, and a hemostat is applied to the mucosa well above the pectinate line in the region of the local lesion to prevent retraction of the incised edge. The incision is made to include the sentinel pile, the fissure or crypt and the papilla above (Fig. 3). This incision is made generally in the shape of a triangle with its apex within the anal canal. The skin excision is made sufficiently wide externally to permit free egress of the serosanguineous discharge. If this excision is inadequate, the outer part of the wound will heal too fast, and the deeper portion will be very slow in healing or may even fail to heal.

Great care should be exercised to remove any enlarged papilla above or adjacent to the local lesion, as its presence will mechanically prevent healing and necessitate a second operation.

When the external skin incision is made, the skin edge is grasped and dissected free from the subcutaneous sphincter underneath, thus removing the fissure or crypt with the underlying fibrosis (Fig. 4). The dissection is carried to a point well above the pectinate line, where the pedicle is ligated for complete hemostasis. The subcutaneous, as well as part of the deep, portion of the external sphincter ani is incised, to produce satisfactory relaxation of the anal canal and to promote proper healing (Fig. 5).

It is particularly important not to incise completely through the deep portion of the external

sphincter ani. Permanent incontinence will not result if a portion of the true anal canal, including the innermost margin of the levator ani (puborectals), is left intact. If the entire anal canal is incised, partial incontinence may result.

Plain packing is placed in the wound, preferably in short strips of $\frac{1}{2}$ inch width. A pad of gauze is then placed over the anus, and the buttocks are pulled tightly together with adhesive for hemostatic purposes.

Postoperative care. At the end of 48 hours (second day), the external padding is removed. The packing is not disturbed because bleeding is likely to occur if it is removed at this time.

The patient is instructed to take 2 ounces of milk of magnesia on the morning of the second day, to be followed by a soap suds enema later in the same day if he has not had a satisfactory movement. He is also instructed to take hot sitz baths for 20 minutes, twice a day. The water should be gradually made hot to avoid weakness and should be cooled off at the end of the bath to prevent the patient from taking a cold.

The packing is permitted to come away with the first or second stool. If it has not been expelled by the end of the third or fourth day, it is removed. The danger of hemorrhage incidental to pulling the packing away has passed.

During the first 48 hours after the operation, the patient is given a light diet of tea, toast, milk, cereal, and eggs. After 48 hours, a regular diet is prescribed. If a movement becomes necessary during the first or second day after operation, the patient is told to take off only the outside dressing. The packing is usually not expelled and we have not seen any hemorrhage as a result of a movement prior to 48 hours. Sufficient codeine is administered to eliminate any pain.

After the packing has been removed and the bowels are functioning adequately, it is important to dress the wound frequently, say every second or third day, to be sure it closes from within and not from the adherence of the raw surfaces. This can be most easily done by passing the index finger into the anal canal and bringing it out through the depth of the wound, which continues anesthetized for some 2 to 3 weeks after the operation.

Fistula of the anus. A probe is passed through the fistula, or the tract is injected with methylene blue. The anesthetic material is injected around the local lesion, and not throughout the perianal region, as would be required in a more extensive operation. The skin opening the tract is excised widely so as to permit free drainage. Great care must be exercised to remove, if possible, the internal opening, which is usually to be found in an adja-

Fig 8 Low power of a typical fissure *f* is seen between the sentinel pile *B* and a small anal papilla *C*. The longitudinal smooth muscle bands of the intestine are visible at *D* and the circular muscle fibers at *E*.

Fig 9 High power of the fissure as shown in Figure 8 presenting the fibrous tissue and cellular infiltration *f* underneath the fissure with the squamous epithelium of the sentinel pile *B*.

the skin can be produced (Fig 1). Great care must be exercised to prevent intradermal deposit of the oil which will produce necrosis.

If the lesion is located only in the posterior region the anesthetic agent can be introduced through one skin puncture about 1 to 1½ inches posterior to the anal ring. If it is located anteriorly it is desirable to introduce the anesthetic material through the skin in either or both the right and left anterior quadrants about 1 to 1½ inches from the anal verge. In this way more complete and satisfactory anesthesia can be produced than through one puncture wound.

If hemorrhoidectomy or excision of multiple crypts is to be done the posterior and the two anterior injections should be combined.

After the anesthetic material has been introduced into the subcutaneous space around the anus the index finger is introduced into the anal canal the needle is passed on either side into the subcutaneous portion of the external sphincter ani and this structure is thus completely injected. Then the deeper and more extensive part of the external sphincter is infiltrated with the oil (Fig 2). Should this deeper portion, including the puborectalis be too extensively infiltrated a temporary incontinence may result. If this should occur it is of little consequence as the sphincter tone returns in about 10 days when the major portion of the anesthetic effect has disappeared.

If the needle is passed deep to and somewhat above the subcutaneous sphincter the sub-

Chronic crypto-papillitis. Six, or 3 per cent, of our operations were performed for a combination of chronically enlarged crypts and papillæ

Postoperative wounds. Four, or 2 per cent, of these operations were performed for persistent postoperative wounds, following excision for local anal pathology. We were unable to explain the persistence of these wounds except for the possible inadequate excision of skin surrounding the local lesion at the time of the previous operations. These wounds healed firmly after the additional skin was excised

POSTOPERATIVE HEMORRHAGE

In our earlier cases we inserted considerable packing and removed it at the end of 48 hours. This resulted in bleeding in a number of the cases. Since we adopted the principle of inserting a small amount of packing in short strips and permitting this to come away with the stool, we have had almost no bleeding. Up to the time the method was changed, we experienced slight bleeding in 13 patients, moderate in 13, and marked hemorrhage in 5 cases, although not of sufficient magnitude to impair the hemoglobin balance. Packing was reinserted in 10 instances, and ligation was done in 3 patients. In only 1 instance in our series of 194 operations, was it necessary, on account of hemorrhage, to keep the patient in the overnight ward for 1 night. One other patient with slight loss of blood felt weak following operation and was confined to the overnight ward

INFECTIONS AND REACTIONS

Following the use of the prolonged anesthesia in 194 operations, we have observed two generalized reactions. Whether these represented toxic manifestations or were emotional responses, we are unable to say.

Immediately after the injection was completed, the patients lost consciousness to regain it in a few minutes, after which they alternately responded and failed to respond every few minutes for about one-half hour. At the end of this time, consciousness was permanently regained. At the onset, the pulse became very weak and seemed to alternate with consciousness. The skin was dry at all times. There was no twitching or other localized sign. These patients were kept in the overnight ward and were discharged the next morning in a normal state. There was no subsequent reaction.

We have experienced a few untoward local reactions, but these have been so few as to be almost negligible, and certainly would not interdict the use of this type of anesthesia by an experi-

enced surgeon. The indiscriminate use of local anesthesia by means of oil injections by inexperienced operators is certain to result in unfortunate complications.

In a few of our early cases, we noted the appearance of much redness and severe itching, with slight induration of the entire peri-anal region, beginning 2 to 5 days after the operation and lasting for 7 to 10 days. This could have been due to iodoform in the packing, but its appearance in some cases in which plain packing was used, leads us to believe it was due to the anesthetic agents. Since we have been using neothisol, we have noted none of these reactions.

In one of our earlier cases (464,518) necrosis of the skin followed the introduction of the oil into the skin around part of the wound. In one operation for fissure (282,339) a posterior, midline fistula was discovered deep to the wound after healing had progressed almost to completion. This fistula was complete, its walls were thick, and we believe that it had been overlooked as a blind, internal fistula at the time of the pre-operative examination. Excision of this fistula with patient under prolonged anesthesia resulted in complete, satisfactory healing. In another patient (M.D.) a blind external, incomplete fistula, without well formed walls was discovered deep to the fissure wound several days after the operation. We believe that this resulted from pooling of the oil. A simple incision through the intervening tissue, without anesthesia, resulted in an open wound, which healed satisfactorily in about 10 days. One other patient presented a blind external fistula, which extended upward and lateral to the anal canal wall. This was believed to be due to infection in the presence of pooling of the oil. Excision of this fistula resulted in complete healing.

In six instances there was superficial necrosis in the area of maximum deposit of the oil underneath the local lesion. The patients were not aware of these local reactions, and they were of no clinical significance.

In two of our more recent cases of fissures, in which we were operating with new anesthetics, we observed extensive, subcutaneous abscesses around the anus. These necessitated confinement of the patients to bed intermittently for a few days. Neither was admitted to the hospital. One of these required incision and drainage of the abscess. The other ruptured spontaneously. Each of these healed up satisfactorily and the patients presented no incontinence or other complaint.

In considering all of our patients operated under anesthesia, administered in oil, 12, or 6 per cent, presented necrosis of the tissue. Of this number,

cent crypt of Morgagni. Although desirable, it is not necessary to excise the entire circumference of the tract, as the granulation tissue will be covered with epithelium if the tract is laid open and adequate drainage is established. The insertion of packing and the postoperative treatment is exactly the same as for the fissure of the anus.

Papilla, hypertrophied. The anesthetic agent is injected only underneath the immediate lesion and local excision is performed. It is usually not necessary to incise the subcutaneous sphincter except if spasm is marked. The insertion of packing and postoperative care are the same as for fissure.

Internal hemorrhoid. The anesthetic agent is introduced as described under 'fissure'. The internal hemorrhoid, together with its external counterpart, is dissected down to a pedicle of mucosa, which is ligated. Hemostasis is established, plain packing is inserted in short strips. Postoperative care is that described under 'Fissure'.

ANALYSIS OF CASES

A total of 211 consecutive operations were performed on 181 patients. Most of these were done in the Vanderbilt Clinic by, or under the direct supervision of the senior author. A few operations were performed on private patients. In 194 operations the anesthetic was injected in oil. In the 17 remaining cases 2 were given spinal anesthesia, 6, novocain 3 had no anesthetic given and 6 were given a general anesthetic. Twenty two of the 181 patients required a total of 50 operations, and in 34 of these the anesthetic was given in oil.

Sex. The female seems to be more susceptible to this general type of pathology. 117, or 64.6 per cent of the 181 patients were females. 64 or 35.4 per cent were males.

Age. The average age of the 181 patients on whom these operations were performed was 39.8 years. The average age of the males, 42.2 years was slightly above that of the females who averaged 37.6 years. The youngest patient was 18 and the oldest 62 years.

General reactions of patients. While most of our patients have experienced no pain others have complained of more or less pain for a few hours after the operation. We believe that incomplete initial anesthetic effect prevails when these patients complain of severe postoperative pain. Their pain is not very severe, as it is relieved by one to three doses of codeine, $\frac{1}{2}$ grain and aspirin 5 grains. When the initial discomfort subsides usually within 5 hours the patient is almost invariably comfortable throughout the postoperative course.

Some of our patients, a minority, have complained of slight weakness for a few days but all of them have remained ambulatory and have reported to the office or clinic for dressing on the second postoperative day. In the majority of instances these patients have been able to perform their essential household duties within 2 or 3 days and have resumed regular work within a week.

Fissures. Of the 194 operations which we considered it safe to perform in ambulatory patients, 124 or 63.9 per cent, were performed for fissures of the anus. Of this number 107, or 86.3 per cent were in the posterior commissure. The remainder of 3, or 2.4 per cent, were located in both the anterior and posterior commissures.

Fistulas. A total of 34 or 17 per cent, of the 194 operations done under prolonged anesthesia were performed for fistulas of the anus. Twenty nine of the patients were operated upon for primary fistulas, and the 5 remaining occurred or were discovered subsequent to one or more operations for pre-existing anal pathology. Twenty eight or 82.3 per cent, of these 34 were located in the posterior anal region. Five, or 14.7 per cent were located in the anterior region of the anus. The remaining case, or 3 per cent, was in the lateral (left) wall of the anus. Two, or 5.8 per cent, of the fistulas presented upward extensions into the submucosal space, in addition to the usual subcutaneous advance and external rupture. Of the 5 fistulas which are included in the re-operated upon group their presence is explained as follows. One was thought to have been overlooked prior to the first operation as it presented thick walls, 1 definitely was due to retained linen ligature knots at the time of a previous operation. 1 was an old ramification from an extensive posterior fistula of the anus which had been previously operated upon twice for other extensions, the fifth one was not satisfactorily explained.

Internal hemorrhoids. Ten or 5.1 per cent, of the 194 operations were for one or two large internal hemorrhoids. In this group we prefer to include those patients with only one large hemorrhoid.

Chronic cryptitis. Although we might easily say that almost all of the patients with fistulas were operated upon for chronic cryptitis and fistulas we have operated upon only 4 or 2.0 per cent of our cases for chronic cryptitis alone. These patients complained principally of anal pain and presented enlarged crypts associated with local tenderness.

Papillitis. Twelve or 6.1 per cent were operated upon for enlarged anal papillae all of which were protruding at the anus or causing discomfort at stool.

patients, 6 presented persistent pruritus ani, which was the principal pre-operative complaint. Seven of these 115 patients continued to have occasional bleeding from internal hemorrhoids. One of these was sent into the hospital subsequently for hemorrhoidectomy. The 6 other patients received injections for the hemorrhoids. One patient complained of chafing, and another of some anal pain, the causes for which were not apparent.

CONCLUSIONS

1 It is safe to operate upon selected ambulatory patients under prolonged anesthesia administered in oil for chronic anorectal disease.

2 Great caution must be exercised in the use of this type of anesthetic, because of the potential danger of infection and peri-anal necrosis. Much experience is required for its proper management.

3 Anesthetics injected in oil are slowly absorbed and produce prolonged, effective anesthesia for 2 to 3 weeks or more.

4 This prolonged anesthesia not only greatly reduces the postoperative pain and tenderness but permits the patient to be ambulatory and often to return to work earlier than would be possible under other types of anesthesia.

5 In 194 operations the anesthetic was administered in oil on 181 patients.

6 An average number of 8.58 dressings were required per case in the entire series.

7. A healing time of 44 days per patient was recorded in the healed cases.

8. One hundred and sixty-one, or 88.9 per cent, of these patients were known to be healed, while the remaining 20, or 11.1 per cent, were lost to follow-up before they were recorded as healed. These results are based on personal observation in

155, or 96.2 per cent, of the healed patients. The 6 others replied by letter.

9 One hundred and fifteen, or 71.4 per cent, of the 161 healed patients were followed for more than 6 months which is considered to be a fair follow-up period in these cases. One hundred, or 86.95 per cent, of these 115 patients were symptom free after 6 months.

only 6 or 3 per cent were of clinical significance. In reality, only 2, or 1 per cent, of the cases could be said to present infection of clinical significance directly and definitely attributable to the anesthetic.

CAUSES FOR RE OPERATION

Twenty two patients required a total of 50 operations. Only one of these was not healed when last seen. Thirty four of these operations were performed under prolonged anesthesia: 5 under novocain, 6 under general, 2 under spinal, and 3 had no anesthetic. Of the 22 primary operations, 18 were for posterior fissures, 1 for chronic cryptitis, 2 for fistula and 1 for external thrombosed hemorrhoid and excess skin. Seventeen patients required 2 operations each, 4 required 3 operations and 1 necessitated 4 operations. One of the patients suffered from a very extensive fistula of the anus and had had 2 operations under spinal anesthesia in the hospital prior to the third one which was done under prolonged anesthesia and which cured the condition. The patient requiring 4 operations had the first one in the hospital for fistula of the anus, which failed to heal apparently because of the presence of enlarged papillae. General anesthesia was used.

Secondary operations were made necessary for the following reasons: in 1 case recurrent fissure; in 2 cases insufficient skin excisions; in 1 case, an infected crypt; in 1, a retained non absorbable ligature knot; in 2 unhealed wounds without apparent cause; and in 9, enlarged papillae which had been overlooked at the time of the primary operations.

In the 21 cases in which 2 and 3 procedures were required, the intervals between operations varied from 1 to 8 months. The average time elapsed was approximately 2 months. The patient who required 4 operations was given intervals of 6 months, 2½ years, and 3 weeks respectively.

These facts are of sufficient magnitude to emphasize the necessity of great care in removing any enlarged anal papilla and in preventing pooling of the oil. Any ligature material of the non absorbable variety should be cut long so that a small knot will not be retained to prevent proper healing. Sufficient skin should be removed to prevent premature healing of the skin over the deeper portion of the wound and to permit adequate, prolonged drainage.

NUMBER OF DRESSINGS REQUIRED FOR EACH PATIENT

Taking into consideration all of the 160 operations performed under prolonged anesthesia, an

average of 8.58 dressings was required for each patient. In this group we considered only the number of dressings after the final operations in the re operated upon group. Of these cases 88 fissures required an average of 8.3 dressings, 25 fistulas averaged 8.76 dressings, 20 patients in the re operated upon group showed an average of 9.14 dressings following each of the final operations; the 14 cases of cryptitis and papillitis averaged 7 dressings, the 8 hemorrhoid excisions, 7.6 dressings, in the miscellaneous cases, in which two severe perianal abscesses occurred, an average of 10.4 dressings were required for each patient.

HEALING TIME

In 157 patients in this group in which the healed dates are recorded an average of 44 days was required for healing. In 157, or 97.5 per cent of the 161 patients known to be healed the date on which healing was known to have been complete is accurately recorded. In 85 fissures the wounds were known to be healed on an average of the forty fourth postoperative day. Twenty five fistulas required an average of 46 days to heal. In 20 of the re operated upon patients, and in 14 who were operated upon for cryptitis and papillitis, the average healing time was 41 days. The patients operated upon for internal hemorrhoids required 38.6 days to heal, and the miscellaneous group containing two severe perianal infections required 56 days to heal.

FOLLOW UP

Of a total of 181 patients operated upon under prolonged anesthesia, 161 or 88.9 per cent were known to be healed when last seen. The remaining 20, or 11.1 per cent, were lost to follow up before they were healed. The follow up results presented herein are based upon personal observations in 155 or 96.2 per cent, of the 161 known healed patients. The 6 remaining healed patients, 3.8 per cent, replied by letter to persistent follow up inquiries. Of the 161 patients known to be healed 136 or 84.5 per cent, were followed for more than 3 months, 115 or 71.3 per cent, were followed for more than 6 months, 68 patients or 42.2 per cent, were under observation for more than 1 year, 14, or 8.7 per cent, were followed for more than 2 years.

SYMPTOM FREE

We shall consider 6 months as a satisfactory follow up period in these cases. Of the 115 patients followed for more than 6 months, 100 or 86.95 per cent, were symptom free at the end of 6 months following their operations. Of these 115

sedatives and heat supplied by the use of warm blankets and hot water bottles, or by placing the patient in a tent or room kept at 90 degrees F. A lowered blood pressure must be treated by the administration of stimulants and fluids given intravenously. Of equal importance in preventing shock is the gentle handling of the patient in quiet and peaceful surroundings. The cleansing of the wound should be done with the greatest of care and without trauma. The insensible loss of body fluids as determined by blood concentration tests must be relieved promptly by the administration of fluids. The best way to do this is by the intravenous administration of blood plasma. This, of course, must be typed as for a blood transfusion. In addition to this, sufficient intravenous infusion of normal or hypertonic salt solution must be given to maintain the blood chlorides at a normal level.

The aseptic treatment of burns was long completely disregarded especially during the period of the use of carron oil. Burn wounds must be treated as carefully as other surgical wounds to avoid infection, and good results cannot be expected simply from the tanning alone. The surrounding unburned skin must be kept scrupulously clean being frequently washed with an antiseptic solution, 70 per cent alcohol being a satisfactory one. Sterile bed linen must be used if infection is to be avoided. No attempt to dissolve the coagulum or to loosen it by the application of wet dressings should be made. This is well illustrated in Davidson's original paper: a convalescing patient so treated was thrown into a condition of marked toxemia within a few hours.

The question of whether or not there ever is actually a toxemia of burns remains unanswered. There is considerable evidence that it does occur even though the toxic substance itself has not yet been isolated. The important thing, however, is a rational treatment of the

patient which includes the prevention or treatment of shock, the prevention of infection and the production of an aseptic protective coagulum. The latter in its turn prevents fluid loss and is an aid in preventing infection and we believe may be of some value in the prevention of dissemination throughout the body of toxic substances.

This modern treatment of burns accurately followed has resulted in a noteworthy saving of life, in markedly lessening deformities, in decreasing hospitalization, and in abolishing expensive dressings. ROY D. McCLURE.

IN recent years there has been a more general recognition of the requirements for the proper care of burns. Linked with this changing attitude there is an increasing appreciation of the nature of the profound systemic changes which so often complicate these injuries.

Because they represent the commonest variety of burns, those produced by heat of a degree incompatible with proper functioning of the tissues have been most intensively studied. The symptoms following the infliction of a severe burn may be divided into three groups: the period of initial shock; the period of secondary or so called toxic burn shock; and the period of repair, which may or may not be complicated by infection. The cause of the constitutional symptoms immediately following burns has long been a matter for speculation and research, both clinical and laboratory. The term "shock" has been loosely applied in clinical medicine, and failure to define accurately conditions under discussion has given rise to confusion in the study of the clinical pathology of burns. Primary shock is neurogenic in character, and is associated with vasodilatation and a decrease in blood pressure, and a consequent reduction in cardiac

THE MODERN TREATMENT OF BURNS

PERHAPS not in this century has one surgeon accomplished so much in the saving of life, the lessening of suffering, and the saving of patients' time and money, as has E. C. Davidson by his work first published in 1925. Since that time there has been an enormous amount of work done on the subject and many chemicals have been used in the treatment of burn wounds. It is questionable, however, whether any of these offer any improvement over the tannic acid treatment if this is carried out properly. Those of us who worked with Davidson for two years before the method was described in the literature and have since tried the different methods suggested, find merit in some of them but not enough, we believe, to affect the death rate materially. The most significant result, however, of Davidson's work is the tremendous renewal in the interest in the subject of burns. To avoid any controversy over the

chemical to be used the French have appropriately introduced the term "tanning method of treatment."

Davidson pointed out in his original contribution the equal importance of the prevention or treatment, of shock and the need of absolute asepsis. We still feel that the tannic acid treatment is most satisfactory if surgical principles are observed. Aseptic methods are always of much more importance than are antiseptic solutions. Two great principles should be observed in the treatment of burns. These principles are fundamental in all types of wounds. They are the treatment of shock and the practice of asepsis. Therefore, if the physician or surgeon would simply regard a burn as a surgical wound to be kept surgically clean, much of the problem would be solved.

Some of the difficulty perhaps lies in the fact that except in larger centers the individual practitioner rarely has the opportunity of observing and treating severe cases. Last year in the United States there were approximately 7,000 deaths resulting from burns. If these cases were equally distributed among the 130,000 practicing doctors each would see only one fatal case in each 18 years of practice. For this reason it is difficult for the physician to bear in mind the details of treatment and natural for him to place his faith in applications to the burned area rather than in the adjunct treatment so essential for a success.

The injury produced by burns, whether by flame, hot water, or electricity, is very prone to result in shock. No satisfactory response to any type of treatment therefore can be expected until the condition of shock is either prevented or relieved. Pain and restlessness should be alleviated by the administration of

colored membrane which acts as a protective coating against chemical, bacterial, and mechanical action, as well as against sensory irritation from other sources. One striking effect of the use of tannic acid is the relief of pain, which occurs promptly and often makes further use of sedatives unnecessary. Various modifications of this treatment have been proposed.

The tanning process is a complicated one, and the importance of using solutions of a normal hydrogen-ion concentration has been well demonstrated. The acid solutions usually used produce a very rapid fixation of tannin on the surface and have a tendency to augment the edema of the underlying tissues. McClure recently demonstrated that evaporation from the burned surface has a negligible effect in producing dehydration after a burn. For this reason the early arguments advanced for the use of tannic acid, on the basis that it prevents water loss from the surface, cannot be given much weight. Regardless of its ultimate place in the therapy of burns, Davidson's contribution served to stimulate a revival of interest in this subject. At the present time it is not possible to demonstrate by the statistical method the effect which the tannic acid method of treatment has had upon mortality. It is probable that a more general appreciation of the nature of the systemic changes has had as much to do with any apparent decrease in the death rate as has any single method of treating the local wound. The routine use of blood transfusion and the addition of fluids and chlorides to the depleted vascular supply have been important factors in reducing the mortality rate during the first few days. In some reported series more patients survived than formerly the periods of initial and secondary shock only to die at a later stage of exhaustion, sepsis, or pneumonia.

The fact that the mortality rate in the early stages may be lowered means that more pa-

tients will reach the stage of the large granulating wound. The treatment of these wounds offers a challenge which is worthy of any surgeon. These patients present the problems of maintenance of body nutrition, the control of infection, the preparation of the granulating surface for the reception of skin grafts, the grafting of skin, and the prevention of contractures and ankylosis. Mastery of the techniques involved in the accomplishment of these various objectives is far from being universal. The application of pressure dressings for the control of exuberant granulations is an old method which has assumed only within recent years a place consistent with its value.

Large granulating wounds should be covered with epithelium at the earliest possible moment. The derma, or true skin, is derived from the mesoderm and is, therefore, a tissue which is not designed to serve as a source of epithelial development. While small areas of the stratum germinativum of the epidermis may remain viable in extensive burns, and at times undestroyed hair follicles may act as centers for the growth of epithelium, one should not delay too long in the hope that epithelization will be brought about in this manner. Ingrowth from the margins of the wound is to be relied on only in burns of small area. Delay in epithelization means an increase in scar tissue and greater deformity.

The protracted suffering of the unfortunate victims of these tragedies, and the resulting disfigurement and loss of morale present important economic as well as surgical and medical considerations. In the past the management as well as the care of these patients has been relegated too often to the youngest house officer. It is encouraging to note that within recent years leaders of surgical thought have given these problems a degree of consideration more nearly consistent with their importance.

STANLEY J. SEEGER.

output While this syndrome should always be looked for, it is usually found only in wide spread burns affecting numerous nerve endings in the skin It is concerning the so called secondary toxic burn shock that much controversy exists The controversy concerns both the mechanism of its production and the time factor involved Two schools of thought predominate regarding the fundamental character of this reaction One maintains that at the site of the burn a toxic substance is elaborated by the action of heat on proteins It is presumed that the absorption of this toxin gives rise to the symptoms grouped under the term "toxic burn shock" Other workers maintain that it is unnecessary to postulate the existence of a specific burn toxin, and substitute the theory that the symptoms can be explained by the shifting of fluids in the body

In 1898 Bardeen reviewed the various theories on this subject His conclusions, based on observed changes in the entire lymphatic systems of five children who died several hours after being burned, were a substantiation of the theory that death at this stage is due to toxemia Blalock and others have done important work which does not confirm the presence of a toxin such as earlier experimental results seemed to prove Wilson has come to the conclusion that evidence for a specific burn toxin is inconclusive although much of it is suggestive He maintains that proof of the toxin theory requires the demonstration and identification of the toxic substances not only in the burned area, but also in the circulating blood Working with others he demonstrated in experimental animals the development of toxicity in the edema fluid which accumulates in a burned area, this property being gradually acquired over a period of 48 hours Controversy exists as to the possibility of absorption of toxic material from a burned area Underhill maintains that fol-

lowing a burn the permeability of the capillaries is in one direction only, namely from the capillaries to the tissues Recently Mason has demonstrated the absorption of potassium iodide from burned areas, the excretion of this substance being the same as in normal animals

The confusion regarding the use of the term "toxic burn shock" is exemplified by the existing opinions concerning the time of onset of this syndrome One author states that it occurs 1 hour after the infliction of a severe burn, another, that it may occur from 6 to 50 hours afterward, and a third states that all shock seen during the first 24 hours is primary in character Harkins' experimental demonstration that in a burned extremity half of the fluid lost from the blood vessels to the tissues is lost within the first hour is of importance in considering the time of onset of secondary shock Some evidence has been advanced which tends to show that infection plays a rôle in the production of this early toxemia Infection is probably not an important factor earlier than the second day in many cases The early theories which attributed the reaction to burns as due to interference with the functions of the skin have been generally discarded although it is becoming apparent that our knowledge of the physiology of the skin is far from complete

In 1925 Davidson suggested the possibility of limiting the absorption of toxic material from burned surfaces by coagulation or precipitation of injured proteins His studies of the efficiency of various agents led to the development of the tannic acid method of treating the local wound Because tannic acid possesses the property of precipitating protein Davidson assumed that through its use fixation of the burned tissues could be accomplished and the absorption of toxic material prevented The effect of tannic acid is to produce a firm, smooth, mahogany

Edward Martin

MEMOIR

EDWARD MARTIN

EDWARD MARTIN, the youngest son of Jonathan Willis and Malvina Register Martin, was born in Philadelphia on August 14, 1859. His preliminary education was obtained in the public schools of this city and for a short period at Central High School. He attended Swarthmore College four years, ranking first or second in all classes and obtaining Phi Beta Kappa. He graduated in 1878, *magna cum laude*, obtaining the degree of A B. at that time and later (1882) A M., and (1920) D Sc. from this College. He graduated from the medical school of the University of Pennsylvania in 1883 and served as assistant to Dr. D. Hayes Agnew and later to Dr. J. Wm. White. For a few years he practiced medicine and then devoted his time to the lines in which he ultimately specialized—genito-urinary and general surgery. He was a prolific writer, being the author of several authoritative textbooks on surgical subjects, sections for medical systems, editor of the University medical magazine and surgical editor of *The Therapeutic Gazette*, and as well he wrote innumerable papers which were read before various medical societies. He was a true teacher, with the ability so to present his thoughts as to impress them indelibly upon his listeners.

His loyalty and affection to Swarthmore College and the University of Pennsylvania were outstanding—nothing that he could do would ever be enough, in his estimation, to repay these two institutions for what they had done for him. He worked indefatigably for them in every way that he could. His motto was

'The best is yet to come' and with this in view he worked and planned to the last for work in the Edward Martin Biological Laboratory at Swarthmore, which laboratory was really a tribute to the lasting friendship existing between Mr. Fred M. Kirby and Dr. Martin, and made possible by Mr. Kirby's generous million dollar gift for this purpose.

Another permanent memorial to this friendship was the Kirby Fund, founded by Mr. Kirby for the benefit of students who needed financial aid to complete their medical course. It was instituted after Mr. Kirby heard Dr. Martin tell of a student who tried to work his way through medical college and died in the effort. Under this fund students were enabled to borrow such money as they required, paying it back to the fund as soon as they became able to do so. Dr. Martin helped financially and through his influence obtained scholarships for more than one young man—and these men have since achieved success in the medical and other professions, thanks to his effort and encouragement.

Dr. Martin was a pioneer in many lines—prior to the Wright Brothers' achievements, he and Dr. Paul Chamberlin conducted a number of experiments to prove

air flight possible. He also was interested in the Eastman Kodak films from a teaching standpoint and made several trips to the Eastman plant in the making of motion picture films—one of which dealt with appendicitis—to be used in the medical schools. He was a pioneer in the use of the lantern slide and later movie films for student teaching.

He was the first man in the University of Pennsylvania Hospital to use morphia after an abdominal operation and to Dr. Martin we owe the deep breathing exercises to prevent postoperative pulmonary complications, which practice has withstood the test of time and is today used even more commonly than is carbon dioxide. He early practiced the no touch or instrument technique in surgery using white cotton gloves as tell tales on the offender. Gentleness in the handling of tissue was his daily admonition.

In all things Dr. Martin believed in preparedness, and this, with his ideas on loyalty, honesty of purpose, kindliness, tactfulness and consideration in the handling of his patients, constituted his creed. He was honest with himself and others in all his dealings, a strict disciplinarian himself yet most charitable of the failings of others.

Dr. Martin had many allied activities in public enterprises. It was through his efforts that typhoid fever was stamped out during the Spanish American War; he was director of health and charities in Philadelphia under Mayor Weaver from 1903 to 1905; commissioner of health in Pennsylvania from 1918 to 1923 under Governor William Sproul (a classmate of his at Swarthmore); he inaugurated the traveling dental and prenatal clinics, did special work regarding syphilis and gonorrhea, instituted the use of toxin antitoxin for preschool age children and of antitoxin early in diphtheria, was responsible for schools of instruction held 1 week each summer for state inspectors. The Philadelphia Health Council and their good work against tuberculosis is the result of his efforts.

Since 1885 he was a member of the board of managers of Swarthmore College, a member of the board of education since 1911 and president at the time of his death. He was elected clinical professor of surgery of the Women's Medical College of Pennsylvania in 1902, resigning after several years. He was professor of clinical surgery at the University of Pennsylvania, 1903-1910, and John Rhea Barton professor of surgery at the same institution from 1910 to 1918. He also served the University of Pennsylvania as professor of surgical physiology. He was chief surgeon to the University of Pennsylvania and the Howard Hospitals, consulting surgeon to Bryn Mawr Hospital, Norristown State Hospital for the Insane, State Hospital for the Insane at Wernersville and the Philadelphia General Hospital.

He was a Fellow and Regent of the American College of Surgeons and the second president of the Clinical Congress of Surgeons of North America, a member of the American Philosophical Society, American Surgical Association, Society of

Endowed with a keen, quick sense of humor, Dr Martin with his 6 foot 1 inch straight soldierly carriage and dark auburn hair, was much in demand among his friends and professional colleagues, excelling alike as speaker, toastmaster or host—he was never at a loss for the appropriate word or expression in any situation. He was extraordinarily clever as a correspondent and always kindly, sympathetic, and helpful to those who were fortunate enough to come in contact with him. He was quick to sense any possible talent in those in whom he was interested and would do all in his power to bring such talent to perfection. The death of his wife last fall after many years of companionship was a great loss to him.

And so lived a great man—a true servant of the public—whose virtues often escaped the superficial observer as is true of so many of the world's kindest and most helpful members whose sincerity and naturalness leads them to hide their real selves behind a "smoke screen" to escape embarrassing acclaim. Of no one was this more true than of that Hicksite Quaker—Edward Martin.

E. L. ELIASON

.

Clinical Surgery, American Association of Genito Urinary Surgeons, and of several foreign surgical societies, as well as the local state and county organizations Incidentally, he was a member of the Philadelphia County Medical Society for 54 years and received a framed certificate to that effect which he prized very highly In 1935 Temple University conferred on him the degree of Sc D

Dr Martin's war record covered a period of many years, he having been a Reserve Officer for some years and in the O R C several years before the World War His active service in the World War began in Philadelphia on January 1, 1918, although he had been a member of the Medical Section, Council of National Defense from the beginning of the war Dr Martin was lieutenant, major, lieutenant colonel, colonel, reserve officer of the World War—364th Medical Regiment, O R C, U S A, regimental and brigade surgeon Spanish American War, surgeon and major in Third Regiment National Guard of Pennsylvania for twelve years in the early '90s, director of School of Surgery, Fort Oglethorpe, Georgia also chief of surgical section of hospital He was the first director of Base Hospital No 20 of the University of Pennsylvania, however, he was soon called back to Washington, being succeeded by his assistant, Dr J B Carnett who carried it to its fruition Dr Martin was chairman of states committee—School of Surgery University of Pennsylvania, for medical officers of the Army director of professional service and surgical chief Walter Reed Hospital, chairman of states committee, Advisory Board, Medical Section Council of National Defense He was honorably discharged from the service on January 27, 1919

Athletics always aroused his greatest enthusiasm He was on a winning crew of the University of Pennsylvania in the '80s, played tennis fished, and in later years was an ardent golfer At the close of the football season he acted as host to the entire football squad of Swarthmore College, giving a traditional dinner at The Lamb's Tavern with the main feature on the menu a suckling pig with a red apple in its mouth

For a number of years beginning in 1903, Dr and Mrs Martin entertained children from the city slums at Valley Farm a short distance from their Orchard Farm These youngsters were exceptionally well cared for during their stay and were returned to their home after a vacation of a week or two, Girl Scouts have occupied a part of Dr Martin's farm for several years, his cousin presiding as hostess For the past 20 years Dr Martin spent his winters in Florida, his summers at Orchard Farm, Media Pennsylvania, and about a month at his home in Graefenburg Springs in the beautiful South Mountain part of the Blue Ridge chain There were many deer here and he planned to give this estate to the State as a game preserve after the death of Mrs Martin and himself

He was a member of the Jury Rittenhouse Pine Valley Golf, Rolling Green Golf and Seaview Golf Clubs

were successfully treated without amputation and that in any case there was every reason to attempt the salvage of the limb.

The seventh rule calls for amputation when a missile passing through a limb "denudes a large portion of the bone without fracturing it." After stating this condition as an indication it was advised that symptoms should be attentively considered before a decision for amputation is made. Mann says that cases of this character rarely require amputation and that always they should be "consecutive" (secondary) operations.

Larrey's eighth indication for primary amputation is a large opening by a cutting weapon into the larger joints, such as the knee or elbow. He gives as his reason the great liability to fatal infections. Mann considers that expectant treatment is warranted in these cases and cites instances of good recovery from such joint wounds.

In the axioms of Larrey the use of the terms "most prompt," "instantly," "immediately," and "without delay," in relation to battlefield amputations attracts attention. Without criticizing this feature of the great surgeon's dicta, Mann makes the observation, well confirmed by later experience, that a greater mortality followed early amputations than those which were deferred. His whole experience pointed to a conservative attitude in relation to indications for amputation and he was struck with the highly fatal results of such operations performed in haste under unfavorable conditions of weather and shelter. In his discussion of Larrey's indications for "consecutive" amputations, he appears to be in more agreement with that great authority.

Traumatic gangrene, it was agreed, demanded early amputation to forestall absorption of the

"deleterious principle." "Convulsive spasm of a wounded limb" is accepted as an absolute indication for its amputation, though Mann states that he encountered no case of tetanus during the war. An ununited compound fracture with continuing purulent discharge was a problem to be solved only by amputation. Mann reports excellent results in gunshot fractures of the femur from the use of the Desault splint, constructed for extension and counter-extension of the limb, and praised the modification devised by Dr. Philip Physick of Philadelphia.

"Bad state of the stump" is a general term for various conditions demanding reamputation. Mann agrees with Larrey that every means of treatment should be exhausted before reamputation is made.

It should be understood that while Mann was the medical advisor of the army commander he was also at all times in charge of a general hospital at army headquarters and always its chief operating surgeon. He thus had first-hand practical knowledge of the subject of which he writes. He was a contemporary of Baron Larrey, whose war experience and writing antedated Mann's by but a few years. While mainly deferring to Larrey's great authority, his attitude on indications for amputation was decidedly more conservative. In following this conservative bent he arrived by experience at the important conclusions that some delay was advantageous in a majority of cases, that by deferring amputation the operation was often found unnecessary and that amputations so deferred were attended by a lesser mortality.

Had these significant lessons been planted firmly in the mind of every medical officer it would not have been necessary to learn them anew, by bitter experience, in every succeeding war for the remainder of the century.

LANDMARKS IN SURGERY

SURGEON JAMES MANN, U S ARMY, OBSERVATIONS ON BATTLEFIELD AMPUTATIONS

JAMES M PHALEN M D Washington District of Columbia

JAMES MANN was born in Wrentham, Norfolk County Massachusetts, on July 3, 1759. Graduating with an arts degree from Harvard College in 1776 he studied medicine with Dr Samuel Danforth of Boston and on July 1 1779 was appointed surgeon of Colonel William Shepard's 4th Massachusetts Regiment in the Continental army. After the war he practiced medicine and surgery in Wrentham. At the time of Shays' Rebellion in western Massachusetts he was called to duty with the state militia. With the outbreak of the war with Britain in 1812 he was commissioned a surgeon in the regular forces and appointed medical director of the Northern Army under General Henry Dearborn. Until the appointment of James Tilton as Surgeon General in June 1813 Surgeon Mann was the senior medical officer in the service and remained in charge of the medical service in the field until the close of the war. Thereafter he served practically until his death in 1832 at Fort Independence in Boston Harbor. In 1819 he was appointed to the surgical staff of the Massachusetts General Hospital in succession to his old preceptor Dr Danforth. He became an influential and useful member of the state medical society. In 1822 he reported in the *Medical Repository of New York* a successful amputation at the elbow joint performed the previous year with favorable claims for joint amputations.

Following the close of the war Surgeon Mann prepared and published his *Medical Sketches of the Campaigns of 1812-13-14* (Dedham 1816) which constitutes the principal source of information in regard to the medical history of the War of 1812. It covers the operations of the Northern Army in considerable detail with observations upon the topography of the area of combat. Much of the medical section is devoted to the discussion of dysentery pneumonia and the ill identified fevers which plagued the army. It is of interest to note that he advocated the use of ipecac in the treatment of dysentery.

The section devoted to surgery is mainly given over to the pronouncements of Baron Larrey in his *Mémoires de Chirurgie Militaire* (Paris 1812) on the indications for primary and secondary amputations in battle casualties and their evaluation in the light of his experience in the late war. Though in the main in agreement with Larrey's dicta and citing case reports in their support he dissents sharply from certain of the great Frenchman's arbitrary rules and

finds many exceptions in his indications for mandatory amputation.

Taking up Larrey's axioms serially he agrees that "when a limb is carried away by a ball by the bursting of a grenade or a bomb the most prompt amputation is necessary. He agrees also that 'when a body is projected from a cannon and strikes a limb so that the bones are fractured and the soft parts violently contused, extensively torn and broken up amputation should be instantly performed.' Larrey's third proposition that 'when a large portion of the soft parts and the principal vessels of a limb are carried away by a ball and the bone fractured amputation should be immediately performed' also meets with his approval.

The capture of Little York (Toronto) by General Dearborn's army in April 1813 was attended by the explosion of the enemy's powder magazine which produced scores of frightfully mutilating wounds among the American forces. Conditions for treatment of these casualties were highly unfavorable and Mann tells of the disastrous results of amputations too long delayed. On the other hand he speaks of fortunate results attending early amputation in cases of similar character.

Larrey's fourth rule says that 'when a large ball strikes a thick part of a limb breaks the bone cuts and tears the muscles destroys the great nerves and yet leaves the principal artery entire immediate amputation should be resorted to.' Mann dissents from unqualified acceptance of this rule and cites cases in which not only life but fairly useful limbs were saved.

The fifth rule pertains to the effects of a spent missile which without breaking the skin produces more or less damage to the underlying tissues. Bones may be broken muscles shattered and blood vessels cut off. Mann agrees with Larrey's dictum that the necessity for amputation must depend upon a determination of the site and nature of the deep traumatism. It was agreed that an incision was indicated for this purpose and for drainage of any hematoma.

Larrey's sixth indication relates to the injury caused by a missile which has fractured the orbital extremities more particularly those which form the knee or the ankle joint and when the ligaments which surround these articulations have been torn or broken up. Mann dissents strongly from the necessity for amputation in these cases and states that numerous instances of musket ball wounds of joints

THE term "disruptive chemiotaxis" has been coined by Bertwistle in his recent book¹ to express the power of certain hard substances (bone) of attracting and drawing into themselves certain soft, living structures. An example would be the attraction of the earth and its moisture for roots as seen in the study of the germinating seed.

The chapters dealing with the histology and development of bone contain the standard text on bone growth and are concise and clear. The author then lays down the following law: Whenever young fibrous tissue, particularly young blood vessels, is in contact with bone or a calcium deposit, bone will form. The question of periosteal bone generation is discussed. Evidence of each school of thought is presented. The author believes that the periosteum is capable of producing bone according to the law stated. This is illustrated by the fracture in which we have hemorrhage about the bone ends, the cells in the vicinity die leaving a calcified deposit which is invaded by fibrous tissue cells, becoming bone cells. The problem of ectopic bone formation is presented. Original evidence is lacking to either confirm or negate the proposed theories except that disruptive chemiotaxis may account for the invasion of calcified material by young blood vessels. The object of the book is to present this viewpoint.

LEON J. ARIES

IT SHOULD be respectfully noted that with the withdrawal of Sir Robert Muir from active participation, the original authorship of the book, *Muir and Ritchie's Manual of Bacteriology*,² which was first published in 1897, has come to an end. Detailed review of this well known standard English text is quite unnecessary. Suffice to state that the present writers, alert to the recent advances in the subject, have brought the book up to date and maintain the spirit and high character of the previous editions. However, it is again remarked that the small type employed and the narrow inner page margin, together with the tight binding, interfere with ease of perusal.

A. A. DAY

FREIBURG is one of the centers of research in endocrinology. The relatively brief monograph, *Innere Sekretion und Chirurgie*,³ from the Surgical Department there reviews the physiology of the glands of internal secretion, outlines very briefly the diseases of these glands, and mentions the surgical indications for their hormones. The section on each gland is followed by a bibliography of considerable extent. The discussion of such subjects as the pre-operative iodine remission of hyperthyroidism, or the postoperative management of parathyroid tetany is inadequate. Nevertheless, the book

furnishes a starting point and represents much German work and practice in this field.

PAUL STARR.

ALTHOUGH the first edition of Hamilton Bailey's *A Physical Signs in Clinical Surgery*⁴ was published in 1927, we in America have failed to recognize the full import of this splendid book. The present volume, the sixth of its kind, is even more valuable. Short, containing but 284 pages, it reads like a story book. Within these pages are contained 334 photographs, many in color. These colored plates are perhaps the most beautiful it has been my pleasure to find in any medical work.

The story behind Bailey's book can best be given in the author's own words, taken from the preface to previous editions, in which he states.

There is a growing tendency to rely on laboratory and other auxiliary reports for a diagnosis. A former chief was wont to picture the modern graduate of medicine, when summoned to an urgent call, driving up to the patient's house followed by a pantechucon containing a fully equipped X-ray installation, and a laboratory with a staff of assistants. Without these aids the future doctor would be unable to formulate a diagnosis. The history, and physical methods of examination, must always remain the main channels by which a diagnosis is made.

The medical man has put much stress and is very proud of his ability to interpret physical signs, but, unfortunately, the surgeon has been, only too often, considered a mechanic. This book will do much to dispel this idea. It is the elicitation of physical signs in their relationship to clinical surgery which makes this book so valuable. Particular emphasis is placed on the eyes, ears, and hands in arriving at the correct diagnosis. The use of other adjuncts, especially those of the X-ray, chemical, bacteriological, and histological examinations are given their importance, but as confirmatory evidence.

The book is divided into 26 chapters, each dealing with a special section of the body. Each division is critically analyzed, and the more important physical signs, as related to a given disease are presented (mostly by way of pictures). In addition an explanatory note is offered as to why certain signs are obtained.

One of the most valuable chapters is that which deals with the physical signs found in the common acute abdominal conditions. Acute appendicitis, appendiceal abscess, ruptured peptic ulcer, acute cholecystitis, acute intestinal obstruction, intussusception, ectopic gestation and acute retention of urine are discussed.

Although Bailey's book offers nothing startlingly new as to physical signs, it is the way the author has put this book together which makes it valuable. His use of pictures, and especially the colored photographs, adds much to the interest of the book. Every medical man, be he surgeon or not, will find much of benefit in Bailey's *Physical Signs in Clinical Surgery*.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

IN THE field of diseases of the lung one of the striking developments during the past two decades has been the marked increase in the incidence of carcinoma of the bronchus. From being a rare disease it has come to be exceedingly common and has accordingly, attracted a great deal of attention and been the subject of a great number of articles. Numerous points of discussion have arisen concerning the increase in incidence, the pathology and the treatment. *Primary Carcinoma of the Lung* by Simons is a careful review of a very extensive literature and for that reason is exceedingly valuable. This is not the first book on this subject but is the most recent and most complete. For any one working in this field who has not had time to read every thing written it should provide a satisfactory shortcut.

JEROME R. HEAD

IN THIS present day of growing interest and understanding concerning the autonomic nervous system it requires no small amount of courage to undertake the task which Gask and Ross have so well handled in this, the second edition of their successful work first published in 1933, *The Surgery of the Sympathetic Nervous System*.¹ The authors forewarn the reader that they do not intend to compile a complete record of all the conditions which are today being treated by sympathectomy and their discussion covers only surgery of the thoracolumbar portion of the autonomic nervous system. They have deliberately omitted any treatment of the subjects of *retinitis pigmentosa*, *hyperhidrosis*, *hypertension* and *bronchial asthma*.

The section dealing with circulatory disease and particularly with *Raynaud's disease* is an especially enlightening one and the authors apparently have had a wide experience in the surgical treatment of these conditions. They stress the importance of an exhaustive pre-operative study to select cases suitable for surgery and they look with definite favor on such treatment but here as elsewhere in their book they are conservative and restrained from overinterpretation of their experiences and from overenthusiasm for their own results. They take a very definite stand in favor of the *periarterial sympathectomy* operation of *Leriche* properly applied.

The plan of the book is pleasingly simple and direct and it is based entirely on a careful study of the authors' own cases. The section on the anatomy and physiology of the sympathetic nervous system

is clear, concise, and free of theorizing; ambiguous statements yet accuracy is not at all sacrificed. There are sections on (a) sympathectomy for disorders of the circulation, (b) sympathectomy for disorders of the visceral motor mechanism (gastro-intestinal and urinary tracts), and (c) sympathectomy for pain that is visceral pain and *causalgia*. The illustrations, while not profuse, are adequate.

JOSEF MARTIN

THIS monograph² by Mackee and Cipollaro was prepared with the idea of reducing the mortality from accessible cancer. It was written not only for general practitioners but for all physicians interested in the cancer problem.

This type of monograph was badly needed and the publishers are to be congratulated not only for seeing the need of such a work but for their choice of authors. No one is better able to write such a book than Mackee with his long years of clinical experience in dermatology and radiotherapy.

The work is divided into four chapters: (1) a few pages dealing with the morbidity and mortality of cutaneous cancer, (2) the precancerous dermatoses. Twenty different dermatoses of precancerous character are briefly but fully described in this chapter, (3) carcinoma and sarcoma, (4) established therapeutic methods.

The monograph is not long. There are only 222 pages of reading matter but in this short volume is packed a fund of valuable information. Each subject is handled in such a clear, concise manner that it is an extremely easy book to read. As the aim of the work is entirely practical many question and theoretical matters are omitted. On the subject of treatment the authors have not attempted to describe in minute detail therapeutic measures but have simply indicated the recommended form of treatment.

There are 231 splendid illustrations—photographs of cutaneous lesions and photomicrographs.

There is an extensive bibliography at the end of each chapter. The book is printed on good paper in clear legible type.

The authors have attempted to present the symptomatology, diagnosis, etiology, pathology, and treatment of precancer and cancer of the skin and mucosa as concisely and clearly as possible. In that they have succeeded admirably. This book should be added to the library of every practicing physician. It is a splendid work.

CORRESPONDENCE

AMERICAN CONGRESS OF OBSTETRICS AND GYNECOLOGY

SEVERAL meetings have been held by the members and directors of the American Committee on Maternal Welfare Inc. to develop the arrangements for convening the Congress in Cleveland, Ohio during the week of September 11, 1939.

The Congress has been organized to include the interests of medical educators, physicians, nurses, public health workers, hospital administrators and

others interested in the problems of human reproduction.

Morning sessions will be devoted to the presentation of scientific and technical papers. In the afternoons general discussions will be held and the evening sessions will be open to the public.

All inquiries should be directed to the general chairman of the Congress, Dr. Fred L. Adair, whose executive office is at the Annex of the American College of Surgeons, 650 Rush Street, Chicago, Illinois.

AMERICAN COLLEGE OF SURGEONS

GRADUATE TRAINING FOR SURGERY—GENERAL SURGERY AND THE SURGICAL SPECIALTIES

DALLAS B. PHEMISTER, M.D., F.A.C.S., Chicago, Illinois

FOR 25 years the American College of Surgeons has pursued its objective—to advance the science of surgery and to insure the competent practice of its art. During those years the knowledge on which the science of surgery is based has been greatly broadened and the techniques on which the art of surgery depends have steadily become more intricate and varied. In line with progress, the College has concerned itself with the lengthening and strengthening of preparatory study and training for doctors who aspire to a surgical career, in order to assure the patient of service which is commensurate with the latest and best practice.

The advancement of surgery is dependent upon better trained surgeons. A year's internship following graduation from medical school does not provide training sufficient to equip the doctor to perform surgery independent of supervision. His knowledge of theory and his observation of procedures should be supplemented by skill and good judgment acquired firsthand but under experienced eyes. Otherwise the life of the patient is endangered.

The American College of Surgeons, as it begins its second quarter century of service, commits itself to a thorough, systematic, and determined effort to advance graduate training for surgery. Only through such an effort can it continue to fulfill its obligation to the profession and to the public—to protect the patient from incompetent surgery. Graduate training is not merely a classroom or laboratory function and should not be confused with postgraduate study which means the pursuit of an already acquired training in a specialty.

It is important, first, to say that the fault does not lie with many recent graduates who must acquire their experience unguided. Not from them will complaint be heard when extension of the training period becomes the rule rather than the exception. They have proved themselves eager for opportunities to gain thorough training, but

corresponding eagerness has not been shown heretofore in providing such opportunities for them.

The College is taking into consideration the impressive fact that there were in existence in 1937 only 164 hospitals approved by the American Medical Association for residencies in general surgery; 292 hospitals were approved for residencies in the surgical specialties. These hospitals accommodated 580 residents in general surgery and 910 in the surgical specialties. The figures, of course, do not represent the number of residencies available each year, since some of the appointments are for periods of from 15 months to more than 3 years. It is therefore quite generally conceded that if thoroughly trained surgeons are to be supplied in sufficient numbers, more opportunities for graduate training must be provided. Hospitals which offer residencies are deluged with applications. Failing of acceptance in these, the graduate seizes a lesser opportunity where he can, but he is likely to be among the large group who are faced with the discouraging fact that there are for them no supervised training facilities. Sometimes, like his predecessors of an earlier era, the graduate is fortunate enough to become associated with an older and experienced surgeon who will supervise his work. The training of a surgeon, however, should not be left to chance.

The College began its study of graduate training for surgery in 1930. Four years later a committee was formed under the chairmanship of Dr. Samuel C. Harvey of New Haven, Connecticut, who submitted his report at the annual meeting of the College in San Francisco in October, 1935, recommending that "in conjunction with the development of a program for graduate training for surgery a re-study be made of the requirements for admission to fellowship in the College." Since that time the College has been surveying the possibilities for graduate training, and following the particularly broad investigation conducted by its special field representatives in 1937, the results of which are published in the *Bulletin* for January, 1938, it is ready to state authoritatively that it is

upon hospitals not controlled by medical schools that effort must be concentrated. Most medical school hospitals are providing excellent training—but naturally they cannot undertake to train all the surgeons who are needed.

To quote from the report of the College survey:

'Residencies in selected hospitals afford the broadest opportunities for training a larger number of surgeons or rather for the more thorough training of a larger number. Any plan for the extension of residencies into this group of hospitals should take into consideration the fact that graduate training for general surgery and the surgical specialties necessitates a carefully directed and supervised apprenticeship in which the graduate actually participates in practical surgical work. Consideration should also be given to the facilities for further study of the fundamental sciences of anatomy, physiology and pathology as well as for the acquisition of a detailed knowledge of the past and current literature of surgery. This implies more affiliations with medical schools and more co-operative effort in graduate training programs.

The 1937 report of survey by the American College of Surgeons was based on 140 selected hospitals of all types which present facilities for graduate training in general surgery and the surgical specialties. The purpose was to obtain detailed information regarding the duration and quality of training being given in various hospitals. Valuable data were gathered. It was discovered that "there exists no basic standard of uniformity in the methods of graduate training" to quote the language of the report which goes on to say 'This lack of uniformity is not sectional or provincial for even in the same cities there is this heterogeneity of methods and opinion regarding courses of training. It was also found that 'a few of the best planned and best functioning surgical residencies are in non university connected hospitals' which should be encouraging to the hospital that has hesitated to establish residencies because it is not a so-called "teaching hospital."

As the result of an analysis by Dr. Malcolm T. MacEachern and his associates of information gathered by the College, there were formulated "Criteria for Graduate Training for Surgery" supplemented by a "Manual of Graduate Training for Surgery." The manual is the first concrete help that is being offered to the groups upon whom will fall the responsibility for extending more and better opportunities for graduate training.

The magnitude and importance of any program in graduate training for surgery may be judged from the fact that more than 2,500,000 operations are performed in the United States and Canada annually by some 35,000 doctors many doing only the limited surgery of their general practice.

The experience of the College in promoting Hospital Standardization has qualified it for lead-

ership in interesting a greater number of approved hospitals to provide acceptable graduate training. Three competent, long experienced officers of the College are engaged this year in carefully noting and recording the respects in which those hospitals having residents are meeting the criteria and the extent of the adjustments others would have to make to establish graduate training facilities that could be approved under this standard. Three hundred and eighty six hospitals are included in the 1938 survey. The complete, detailed reports are being reviewed by the following Committee on Graduate Training for Surgery, which will determine the hospitals that are now qualified to accept responsibility for graduate training in general surgery and the surgical specialties:

Dallas B. Phemister, Chicago, Chairman
Donald C. Balfour, Rochester, Minnesota
John R. Fraser, Montreal
Albert C. Fuestenberg, Ann Arbor
Harry S. Gradle, Chicago
Everts A. Graham, St. Louis
Howard C. Naffziger, San Francisco
Gilbert J. Thomas, Minneapolis
Allen O. Whipple, New York
Philip D. Wilson, New York

The committee will submit in October a report in which will be listed the hospitals which are meeting the criteria and also those hospitals which with minor adaptations could do so. Periodic surveys will be made to ascertain whether the minimum standard for such training is being adhered to.

Acting on the recommendation of the original Committee on Graduate Training for Surgery, the Board of Regents of the College at a meeting on May 10, 1936, raised the requirements for fellowship as stated in the following extract from the minutes of that date:

BE IT RESOLVED that applicants for fellowship whose qualifying medical degree shall have been obtained after the date of January 1, 1938, shall be required to present evidence of having completed 3 years of hospital service in one or more acceptable hospitals of which 2 years shall have been spent in training in surgery in hospitals approved by the American College of Surgeons. In the case of graduates of medical schools which withhold the medical degree until after a fifth year of hospital internship the date set will be January 1, 1939.

In justice to all who aspire to future fellowship in the College there must be assurance that no qualified man shall lack the opportunity to obtain the graduate training required for there is no desire to set the requirements so high that they cannot be met. As the standard for fellowship goes up so must the standard for the profession itself be raised. This can be accomplished best at the present time by winning hospital support for wider graduate training opportunities.

SUBJECT INDEX TO VOLUME 66
